"On some South African Gulellæ, with Descriptions of Some New Species and Varieties." The genus Gulella was formerly reckoned as a section of the genus Ennea, under which name most of the numerous species were formerly described. The fascinating little group, which externally calls to mind the British 'chrysalis shells,' is remarkable for the armature of the mouth, which in some is so studded with teeth that the occupants must be seriously incommoded when issuing or retreating. Twelve species are dealt with in this instalment, of which four are described as new, and the whole illustrated by the author on a plate of 39 figures.

COPEPODS IN THE BAY OF BISCAY.—In his account of the Copepoda from the collections made by Dr. G. H. Fowler on board H.M.S. *Research* in the Bay of Biscay in 1900, Mr. G. P. Farran (*Journal of the Linnean Society* (*Zoology*), vol. 36, April 1926) not only enumerates the various species but also gives most valuable data concerning their diurnal and nocturnal movements; thus treating the subject in a somewhat similar manner to that employed by Dr. Fowler himself for the Ostracoda in the same collections (1909). The samples were all taken in July, approximately in the centre of the Bay of Biscay, mainly along a diagonal line about 65 miles in length from the N.W. to the S.E. corner. The soundings taken lay between 1219 and 2341 fathoms, and the author divides his material into the epiplankton hauls made chiefly down to 100 fathoms with horizontal non-closing nets which lasted an hour or more, and the deep water hauls, almost all of which were made with closing nets hauled vertically. The former could not be treated quantitatively, but in the latter all the copepods were counted. The copepod population from the surface to 100 fathoms was found to be approximately doubled during the night by an upward migration consisting mainly of *Metridia lucens*, *Pleuromamma robusta* and *P. gracilis*, and from 50 fathoms downwards, *Undeuchaeta minor*, several other species joining in the migration. In the deep water hauls a number of little-known forms are noted whilst the new genus Bathyidia and fourteen new species are described, three of which belong to Calocalanus and five to Scolecithrix. The view that *Aegisthus dubius* is the male of *A. mucronatus* has been rejected by Sars, but the present author seems to have good cause to regard the question as still an open one

FISHERIES AROUND GREENLAND AND ICELAND.—The report of the North-western Area Committee (*Conseil Internat. Expl. Mer*) for the years 1924 and 1925 contains seven papers dealing with the hydrographical and biological researches undertaken in Greenland and Iceland waters. Hydrographical observations in the Faroe-Shetland Channel on May 3-14, 1924, showed that the water at the surface was composed of Atlantic water, while that at the bottom was bottom water from the Norwegian Sea. Between the two there was an intermediate layer formed by the mixing of Atlantic and bottom water with water introduced from the east Icelandic Arctic current. The biological part of the report deals with the five species of fish under the Committee's observation, namely, cod, halibut, herring, haddock, and plaice. It seems now beyond doubt that a particular stock or population of cod exists in Greenland which is indigenous to the waters of western Greenland. In Iceland, however, an almost unparalled density of young cod is experienced off the north and east coasts, in spite of the fact that very few cod-eggs are spawned there. Thus, the stock is recruited by drift, and the quantity must depend on the success of this drift. Faxe Bay, at the south-west part of Iceland, has proved to be a most important nursery-ground for the halibut, and there is little doubt that an enormous destruction of undersized halibut is caused by trawling operations in this area. The herring investigations are said to establish the fact that there are two distinct races of herrings in Icelandic waters, a spring herring and a summer herring, and that, as yet, no characters are known by which the Iceland spring herring can be distinguished from the Norwegian spring herring. Interesting figures from the estimations of age of haddock in Icelandic waters, in material collected over a number of years, show the way in which certain year-classes dominate. Thus, material of 1908–1909 showed an absolute dominance of the 1904 year-class, while that of 1924 indicated the predominance of the 1922 year-group. The study of the growth of haddock reveals the fact that growth is greatest off the south coast. Samples of plaice from Faxe Bay and Skiálfiandi Bay in Iceland were examined as to their age composition, and important conclusions were drawn from the analyses of catches at intraterritorial and extraterritorial trawling stations.

A NOVEL CURRENT METER.—In No. 2 of the *Journal du Conseil International pour l'Exploration de la Mer*, Mr. J. N. Carruthers describes a current measuring instrument which, lowered from an anchored raft or vessel, records the direction and velocity of the current. It is an advance upon the customary form of meter in that it may be left working for several days, when the velocity and direction of the residual current or drift of the water, over and above the tidal oscillations, can be found. The instrument has been put to fairly extensive use and has already provided very interesting information. It will undoubtedly prove of considerable value for purposes of fishery research in relatively shallow areas such as the North Sea and eastern end of the English Channel, where the drift of water carrying the egg and larval stages of fish plays an important rôle.

PROPORTIONS OF KRYPTON AND OF XENON IN THE ATMOSPHERE.—The values obtained in 1898 by Ramsay and Travers, shortly after the discovery of the above gases, and those obtained by Ramsay in 1903, differ greatly from one another. In the *Comptes rendus Acad. Sci.*, Paris, July 19, Messrs. C. Moureu and A. Lepape describe measurements made by the spectrophotometric method previously used by them. The two gases were fractionated from commercial argon by means of coconut charcoal cooled to suitable temperatures. The volumes obtained per unit volume of air were, kypton $1 \cdot 0 \times 10^{-6}$, xenon 9×10^{-8}.

SWEDISH RAINFALL.—The Swedish rainfall statistics for 1925 are already published in fairly considerable detail in Part 7 of *Årsbok* of the Swedish Meteorological and Hydrographical Institute. The greater part of a considerable volume is occupied with the data from 705 rainfall stations. In each case and for every month the figures given are the total, the heaviest fall in twenty-four hours, the number of days with precipitation of various stated amounts, and the days with hail and snow. The depth of the snow and its rainfall equivalent is added for certain stations. For the various departments of Sweden the duration of snow covering on the ground is given in another table. There are small scale rainfall maps for each month and a somewhat larger scale map for the year. The volume is very complete in the data it affords, but contains no discussion of the figures nor comparisons with the mean or any previous year.

CLIMATE OF NEW YORK STATE.—This subject is discussed by Mr. R. A. Mordoff in Bulletin 444 of the Cornell University Agricultural Experimental Station, Ithaca, New York. It is mentioned that the first organisation for local climatic observation in America was that inaugurated in 1825 by the New York Board of Regents. This was continued until 1863, when it was abandoned owing to the Civil War. In 1870 the National Weather Service was organised and five weather-observing stations were established in New York. Later, under the administration of the United States Weather Bureau, the number was increased to nine regular stations. It is said that New York State has a diversity of climate not usually encountered within an equally restricted area. Charts are given for each month showing the average temperature over the State. The temperature is greatly influenced by the proximity of the Lake Ontario and Lake Erie. Charts are also given showing the highest and the lowest temperatures recorded. During the summer months the maximum temperature often reaches 90° F. or above, and in winter temperatures of $-40°$ F. are experienced in exposed localities. Frosts are dealt with and the periods when killing frosts occur. Precipitation over the State is shown by monthly rainfall maps; the heavy summer rains are largely due to thunderstorms. There is a good distribution of rainfall throughout the growing season. A serious drought affecting the State as a whole is of rare occurrence; the two most serious in recent years occurred in 1889 and 1908. Winds, sunshine, and humidity are discussed. Analysing past records, it is asserted that no change of climate can be traced.

THE INHIBITION OF THE GLOW OF PHOSPHORUS.—It is now fairly certain that the propagation of the glow that accompanies the slow oxidation of phosphorus is a process comparable with the passage of flame through a combustible gas mixture. It is therefore possible to determine the rate of propagation by measuring the blast of gas necessary to maintain the glow in a fixed position. H. J. Emeléus describes the application of this method to experiments on the inhibition of the glow of phosphorus by ethylene, in the *Journal of the Chemical Society* for June 1926. Measurements of the effect of temperature on the action of the inhibiting substance at constant volume and constant pressure are included, and the mechanism of inhibition is discussed.

THE ATOMIC WEIGHT OF SILICON.—The apparent variation of the atomic weight of boron with the source of supply, and the discrepancies between the published values of the atomic weight of silicon, have led P. L. Robinson and H. C. Smith to redetermine the atomic weight of silicon in materials from different sources. In order to make the comparison it was decided to determine the densities of silicon tetrachloride with great accuracy. The tetrachloride was prepared by chlorinating ferrosilicon manufactured from silicon from different sources, and was carefully purified by fractionation, shaking with mercury, sodium amalgam, and finally fractional distillation in a vacuum. A full description of the density determinations is contained in the *Journal of the Chemical Society* for June 1926, the measurements involving the use of glass floats, calibrated in a standard liquid (bromobenzene) with properties similar to those of the tetrachloride. It appears from the results that there is no variation in the atomic weight greater than 0·005 of a unit. (See letter by authors in the present issue of NATURE, p. 303.)

ELEMENT 61.—Moseley's work on X-ray spectra showed definitely that an element with an atomic number 61 should exist between neodymium and samarium. Its isolation and X-ray analysis are the subjects of two papers by J. A. Harris and B. S. Hopkins, and by these two authors and L. F. Yntema, published in the *Journal of the American Chemical Society* for June 1926. When suitable rare earth minerals are fractionally crystallised using the double magnesium nitrates, element 61 concentrates between neodymium and samarium, but the ratio of the quantities of the new element and its neighbours is such that X-ray analysis fails to show its presence. Detection by absorption spectra, although more sensitive, fails on account of the width of the neodymium and samarium bands. If, however, the fractionation is carried out with the bromate series, element 61 concentrates with terbium and gadolinium, the former having one absorption band and the latter having none. By continued fractionation of this series the presence of a band was revealed which had always been regarded as due to neodymium. The crystallisation was continued until a fraction was obtained which contained sufficient of the new element for X-ray analysis. The *L*-series was investigated, and lines were obtained corresponding closely to the theoretical values for L_α and L_β of element 61. It is proposed to call the element illinium (Il), in honour of the state of Illinois and of the University (*v.* also NATURE, June 5, p. 792).

COSMICAL CREATION OF MATTER.—The issue No. 15 of the *Sitzungsberichte Acad. Sci.*, Vienna, for 1926 contains a suggestion by Dr. A. Haas as to the possibility of the creation of matter at any point of the universe at which, at a given instant, radiation is excessively concentrated. If at such a point an incandescent gas is present having a mean molecular speed of the order of one-half or one-third of that of light, about a hundredth of the molecules will have speeds equal to that of light, and energies equal to that of a proton and an electron. The observations of the Compton effect show that it is possible that a light quantum impinging on such a fast-moving molecule may have its frequency increased, and a repetition of the impacts may so raise the frequency of the quantum that its energy becomes equal to that of a proton and electron, and it is transformed into these two constituents of matter.

A MUMETAL MAGNETIC SHIELD.—A paper by Prof. A. V. Hill, describing an effective magnetic shield for a moving needle galvanometer, is published in the July number of the *Journal of Scientific Instruments*. The shield is constructed of 'mumetal' strip, wound alternately with copper strip on a copper cylinder. At each end it is closed by two mumetal plates separated by a copper plate. Although only two pounds of actual magnetic material is used in the device, a screening ratio of 1000 to 1 is obtained, which is a great advance on the screens in ordinary use. It seems highly probable, therefore, that moving needle galvanometers, after being neglected for some thirty years, will again come into favour. The sensitivity of these instruments is far higher than that of moving coil instruments, and the coils used can have a much lower resistance as they are not limited by the resistance of the suspension. Their only drawback is their liability to magnetic disturbance, and this has proved most troublesome in the past. It can now be almost wholly prevented by this shield made of a nickel-iron alloy. The editor of the *Journal* makes the useful suggestion that a shield could be employed as the case of a chronometer watch, and doubtless other uses can be found for it. It seems certain that cobalt steel permanent magnets and the use of nickel-iron shields will raise the sensitivity and greatly widen the sphere of usefulness of moving needle instruments.

The Recently Discovered Gibraltar Skull.

At the Oxford meeting of the British Association the first authoritative account of the discovery by Miss D. A. E. Garrod of a human skull associated with Mousterian implements at the Devil's Tower, Gibraltar, was given in a session of the Anthropological Section. The discovery was made on a site which first attracted the attention of the Abbé Breuil in 1917, who observed fragments of bone breccia in a cleft facing an old signal station known as the Devil's Tower. From this he obtained a few Mousterian implements and bones of a variety of animal species, including hyæna and panther, which are now extinct in Spain.

Miss Garrod, who undertook the excavation of the site at the suggestion of the Abbé Breuil, found that the cave contained a succession of seven deposits, which emerge from the mouth of the cave and spread fanwise in a succession of steps. All levels of the deposits contained a large number of animal bones, some broken and burnt by man, some evidently the relics of an animal's lair. As the cave faces north, it was probably occupied by man in summer only and by animals in the intervals of human occupation. The animal bones included deer, wild goat, boar, and rabbit in abundance, and, rarely, horse and ox. Resting on the raised beach which formed the seventh and lowest deposit was a carpal bone of an elephant. Implements of Mousterian type were found at all levels down to the fifth, those of the second level being definitely assignable to the upper Mousterian; but no implements of a later industry and no pottery were found.

The removal by dynamite of a large block of limestone in the hard travertine of the fourth level opened up a number of fissures and led to the discovery of a human frontal bone at a depth of 15 cm. from the surface of the deposit. The left parietal was discovered half a yard away, but, whereas the frontal bone had been loosened from its matrix, the parietal was firmly embedded in the travertine and had to be brought away in a mass of that material for reduction in the laboratory. As explained by Mr. L. H. Dudley Buxton, to whom that task was entrusted, the freeing of the interior from the mass of deposit with which it was filled proved a particularly difficult and tedious operation. Implements of quartzite and flint definitely of Mousterian type, but less well made than those of the overlying levels, were found near the skull. The fact that the skull and the implements were found embedded in the travertine in a manner allowing no possibility of disturbance places the Mousterian age of the skull beyond question.

The anatomical characters of the skull were described by Mr. L. H. Dudley Buxton. Owing to the fact that the greater part of the month which had elapsed since the skull had been brought to England had been taken up by the task of freeing the fragile bone from the travertine in which it had been embedded, it was possible to put forward tentative conclusions only; but an attempt had been made to reconstruct the upper part of the skull. There is no doubt that the two fragments belong to the same skull. From various characters it would appear to be that of a very young person; but the exact age and the sex are difficult to determine. A comparison with the three skulls of Neanderthal man of immature age available—a skull of a child of five from La Ferrassie, the skeleton of a youth found at Le Moustier, and fragments of the skull of a child, perhaps of eight years of age, from La Quina—shows that it agrees with them in the characters in which they differ from those of modern skulls of corresponding age. The measurements, which, however, must at present be regarded as entirely provisional, indicate that the skull is broader in its proportions than would have been expected, nor are the eyebrow ridges and temporal fossæ developed in the manner distinctive of Neanderthal man. The most striking feature in the parietal bone is the fact that the parieto-squamous suture, which is more or less straight in the apes and the human infant and bowed in the adult man, in the Devil's Tower skull is most markedly bowed; but instead of a regular squamous suture, with a bevelled edge, the actual edge of the bone is only recessed very slightly—a condition which is to be attributed to age and not to race. On the provisional measurements which have been made the cranial index works out at 80, a high figure which further consideration may make it necessary to correct.

In view of the very tentative character of the conclusions put forward by Mr. Buxton, it would be premature to offer any comment. Opportunity to appreciate the bearing of the discovery will occur later when the skull has been examined more carefully and the results have been made public at a meeting to be held by the Royal Society. It may be pointed out, however, in the meantime, that its importance is two-fold. It affords some degree of corroboration of the Mousterian date of the Gibraltar skull discovered in 1848 not far from the Devil's Tower site—a corroboration much needed in view of the fact that the collection of implements made at the time of the earlier discovery has disappeared; and secondly, it adds another to the number of skulls of the Neanderthal race, and, what is most important, the specimen is of an age which will add much needed information to our knowledge of the process of growth in that interesting and peculiar variety of early man.

Adhesives and Adhesive Action.[1]

In reviewing the first report of the Adhesive Research Committee, the present writer had occasion to remark on the extreme persistence of the three main types of adhesives, which documentary evidence shows to have been quite familiar to craftsmen of the eleventh century. Believers in proverbial wisdom may incline to the opinion that this familiarity, continued through generations, has indeed bred the contempt with which the subject of adhesion—with or without adhesives—is generally treated in the literature of physics. In this respect the second report breaks entirely new ground in Appendix IV., entitled "Adhesives and Adhesive Action," by Prof. J. W. McBain and Dr. D. G. Hopkins, in which the authors attempt, with a considerable measure of success, to develop rational theories of the mechanism of adhesive action.

The first important conclusion at which they arrive is that there are two fundamentally different types of joints: those between porous surfaces and those between smooth, non-porous ones. In the first type the penetration of the adhesive, while liquid, into the pores of the surfaces to be united is an essential part of the effect. This view is borne out strikingly, apart from much other evidence, by comparison of the strengths of glued joints, made between plain and stained specimens of the same woods; the latter are

[1] Second Report of the Adhesives Research Committee, Department of Scientific and Industrial Research. Pp. iii.+128. (London: H. M. Stationery Office, 1926.) 3s. net.

considerably weaker, as the stain (a spirit varnish) fills the pores and prevents the penetration of the adhesive. It is in complete accord with this explanation that the diminution of strength is less marked with a very porous wood, like deal, than with a closer grained one, like walnut.

For the second kind of joint, that between smooth, non-porous surfaces, the authors postulate some specific action between material and adhesive, and refer to Hardy's views on lubrications. They arrive at the conclusion that any liquid which wets the surfaces and can somehow be transformed into a solid will act as an adhesive for these surfaces. As soon as the statement is put in this form, it would seem to follow quite naturally from considerations of continuity, which does not lessen its novelty or importance. Very remarkable examples of such 'specific' joints are given; *e.g.* shellac joints between metal surfaces with a tensile strength of more than two tons per sq. in. Space does not permit more detailed discussion of the paper, which will be read with profit not only by those interested in adhesives, but also by any one who derives pleasure from seeing a complex problem attacked by the whole armoury of research.

Prof. Schryver briefly describes his attempts to isolate a pure standard gelatin or, incidentally, to decide whether a body of uniform composition answering to this description exists; the results are not conclusive. Dr. J. C. Kernot and Miss N. E. Speer have achieved a result of technical and economic interest by producing from suitably treated fish skins a glue quite free from "an ancient and a fish-like smell," such as in ordinary fish glues is disguised—or, as sensitive people might say, accentuated—by various additions. The same authors in another paper suggest improvements in the manufacture of bone glue. Appendix V. deals with the mechanical tests of adhesives for timber used by the Royal Aircraft Establishment; the general conclusion is reached that the causes of the large variations in the results of timber tests remain obscure, and that "until the degree of these variations has been reduced the present forms of test-piece are unsuitable for experimental or even inspection purposes."

Readers of the report will learn with regret, though without surprise, that important investigations on the manufacture of glue have had to be abandoned owing to lack of financial support from manufacturers—a position which is perhaps explained, though scarcely justified, by the great fall in the price of glue.

E. H.

Herrings along the Baltic Coast of Sweden.

IN *Publications de Circonstance* of the Conseil Permanent International pour l'Exploration de la Mer, No. 89, Chr. Hessle surveys the herring investigations which have been carried on during the past few years along the Baltic coast of Sweden. Nets, both drifting and anchored, land-seines, and big traps are all used for the fishery, but the main part of the total catch is fished by nets. Although the bulk of the fish is landed between July and November, considerable quantities are taken during the winter and early spring. Ice on the water is a severe hindrance to the net fishery during the colder months, and in some places it may put a stop to fishing when, by all evidence, herrings are still present. In the archipelagos nets are sometimes used actually under the ice.

Baltic herrings are characterised by their small size, the low average number of vertebræ, and of the keeled scales behind the ventral fins. In contrast to these, the average number of the first vertebræ with closed hæmal arches is rather high. Both autumn-spawning and spring-spawning herrings occur, the former being of the greater economic value. Catches of autumn-spawners nearly always contain a percentage of spring-spawners, the proportion varying with the season and from year to year. In these catches of mixed fish the spring-spawners are generally smaller in size. This is due partly to the greater percentage of smaller fishes among the spring-spawners, but also to the fact that the rate of growth of the spring-spawners is inferior. In both classes the rate of growth is exceedingly slow after the second or third year. Spawning would seem to occur in the same places for both autumn and spring fish, the former spawning at a temperature of 11°-14°, and the latter at 6°-10°.

In the innermost parts of the archipelagos, and especially in the fjords which penetrate deep into the country of the Middle Baltic, there is a fishery which is based on stationary local races in waters so closed and isolated that sea herring do not enter them. The size and rate of growth of these isolated fjord herrings show a very great variability. Gudingen and Gamlebyviken are two fjords separated only by a narrow strip of land: in Gudingen the rate of growth is quite normal, but in Gamlebyviken sexually ripe fish of only 10 cm. in length have been taken.

Along the coast of the Gulf of Bothnia herrings are caught in traps, fishing commencing as soon as the ice breaks up in the spring, and lasting until midsummer. The bulk of these 'ice herring' are spring-spawners, and a typical feature of the catches is the great number of remarkably large fish which show a peculiar mixture of characters and habits typical of one or another of the races previously dealt with. Altogether Hessle has provided us with a most interesting and instructive paper.

University and Educational Intelligence.

ABERYSTWYTH.—Dr. W. Robinson, senior lecturer in the department of cryptogamic botany in the University of Manchester, has been appointed to the chair in botany in University College, Aberystwyth, in succession to Prof. Lloyd Williams, who retires under the age limit in September.

CAMBRIDGE.—The University Commissioners have published a number of regulations that they have made for bringing into action next term the new statutes governing the General Board and the various faculty Boards. They have also published further regulations which they propose to make—after discussion by the Senate—on the election of members of the Council, degree committees, the Buildings Syndicate, and University finance. The chief point on which discussion is likely to take place is the proposal that members of the Council shall be elected by the method of the single transferable vote. So far as the election of ordinary members of the Regent House is concerned, where four members are elected at a time, this provision is probably suitable, as it will ensure representation on the Council of different groups of electors. It is doubtful, however, whether this method secures the most effective result in the case of the election of the other two groups—(*a*) heads of colleges, and (*b*) professors and readers. Here only two members are elected at a time in each class. So far as University politics is divided into two fairly even parties, this method generally means the election of one candidate from each party—not by any means necessarily the best way of electing an executive body.

Mr. A. Hopkinson, Emmanuel College, has been reappointed demonstrator in anatomy.

THE Air Ministry announces further appointments to short-service commissions in the Royal Air Force to be made in September. Applications are specially welcome from young men who have had some engineering training or have shown a bent towards mechanical matters in their private amusements, as well as from those who are keen sportsmen and have a leaning towards travel and adventure. Short-service officers are taught to fly and at the same time receive instruction in aeronautical engineering, armament, navigation, etc. Service in the R.A.F. counts in part towards the period necessary to become associate members of the Institute of Mechanical Engineers. Applications for regulations should be addressed to the Secretary, Air Ministry, Adastral House, Kingsway, W.C.2. Candidates must be between 18 and 25 years of age, should have received whole-time education at least up to the age of 16 years, and should possess good physique and eyesight.

THE Ramsay Memorial Fellowship Trustees have made the following awards of new fellowships for the session 1926–27:—A British Fellowship of 300*l*., tenable for two years, to Dr. R. F. Hunter, for work at the Imperial College, London; a Glasgow Fellowship of 300*l*., tenable for two years, to Mr. J. D. Fulton, for work at the University of Manchester; a Swedish Fellowship of 307*l*., to Mr. Gunnar Hägg, for work at University College, London; a Swiss Fellowship of 300*l*., tenable for one year, to Dr. Max Brunner, for work at the University of Cambridge. The Trustees have renewed the following Fellowships for a year; Mr. G. A. Elliott (British Fellowship)—at University College, London; Mr. T. Corlett Mitchell (Glasgow Fellowship)—University of Cambridge; Dr. D. McKay Morrison (Canadian Fellowship)—University of Cambridge; Mr. W. G. Burgers (Netherlands Fellowship)—Royal Institution, London; Dr. Ekonomopoulos (Greek Fellowship)—University College, London; Dr. P. Misciattelli (Italian Fellowship)—University of Oxford; Mr. Erik Rudberg (Swedish Fellowship)—King's College, London.

THE League of Nations Committee on Intellectual Co-operation has received from its sub-committee of experts recommendations concerning the instruction of children and young people in the existence and aims of the League. These recommendations raise questions of principle of the highest importance. It is proposed to request Governments to include the subject in their programme of studies and to ensure that the relevant text-books mention it, that education authorities should arrange that in examinations, questions on the League should be set whenever practicable, and that universities should organise special courses of at least six lectures which all students might attend. In addition numerous devices are recommended for propagating knowledge of the League and its gospel, such as the dissemination of books and periodicals, lantern slides, kinematograph films and radio broadcast addresses, special courses for teachers, celebration of League Days at schools, essay competitions, inspirational lectures, and national conferences. The exact place which this instruction will occupy in the curriculum and the time to be allotted to it are, the sub-committee remarks, questions which should be left for the national or local authorities to decide, but it is recommended that it should be correlated with the lessons in "geography, history or civics." Where civics is included in the school curriculum a teacher may fairly be expected to give some instruction about the League of Nations, but where it is not, it is open to question whether such instruction should be smuggled in as "geography" or "history."

Contemporary Birthdays.

August 27, 1865. Prof. James Henry Breasted.
August 28, 1858. Prof. Roland Thaxter.
August 30, 1871. Sir Ernest Rutherford, O.M., P.R.S.
September 1, 1877. Dr. F. W. Aston, F.R.S.
September 1, 1859. Dr. Walter Gardiner, F.R.S.
September 2, 1877. Prof. Frederick Soddy, F.R.S.
September 3, 1882 Dr. William Lawrence Balls, F.R.S.

Prof. J. H. BREASTED, the accomplished American Egyptologist, was born at Rockford, Illinois. His interests early centred in the University of Chicago. Since 1905 he has been professor there in Egyptology and Oriental history. In 1894–95 he was collecting in Egypt for the University, and, later, director of its Egyptian Expedition. In 1920 he was in charge of an archæological survey of Mesopotamia. Prof. Breasted is an honorary fellow of the Society of Antiquaries of London, and D.Litt., Oxford.

Prof. THAXTER, who was born at Newton, Mass., U.S.A., graduated at Harvard Assistant professor of cryptogamic botany there from 1891 until 1901, he later occupied the chair, and he has been, since 1919, emeritus professor. He is the author of many papers on the fungous diseases of insects. Prof. Thaxter is a foreign member of the Linnean Society.

Sir ERNEST RUTHERFORD, president of the Royal Society, Nobel laureate in chemistry, 1908, was born at Nelson, New Zealand. He was educated at the University of New Zealand and Trinity College, Cambridge. After prosecuting research work at the Cavendish Laboratory, he left England in 1898 to occupy the chair of experimental physics in McGill University, returning in 1908. His record of accomplishment in the domain of radioactivity and atomic structure is world known.

Dr. ASTON, Nobel laureate in chemistry, 1922, was born at Harborne, Birmingham, and educated at Malvern College and the University of Birmingham. In 1910 he became one of Sir J. J. Thomson's research assistants at the Cavendish Laboratory, Cambridge. Here it was, under stimulating associations, that Dr. Aston engaged in his classical researches on isotopes. In 1922 the Royal Society awarded him its Hughes medal for his "discovery of isotopes of a large number of the elements by the method of positive rays."

Dr. GARDINER was educated at Bedford, graduating at Clare College, Cambridge. Sometime a science lecturer at Girton, and University lecturer in botany, he received one of the Royal Society's Royal medals in 1898, at the hands of Lord Lister. His researches in vegetable histology established that the protoplasm in the tissues of plants is continuous from cell to cell. Other work of his dealt with the function of tannin, protoplasmic contractility, and the phenomena accompanying stimulation in insectivorous plants.

Prof. SODDY, Nobel laureate in chemistry, 1921, a graduate of Merton, was born at Eastbourne Early, at McGill University, Montreal, he was working under the inspiring guidance of Sir Ernest Rutherford, engaged in researches on radioactivity; afterwards he was with Sir William Ramsay at University College, London, a period when proof was obtained with the spectroscope of the production of helium from radium. Occupant of the chair of chemistry in the University of Aberdeen from 1914 until 1919, he left to become Lees professor of chemistry in the University of Oxford.

Societies and Academies.

CAMBRIDGE.

Philosophical Society, July 26.—P. A. M. **Dirac**: On quantum algebra. In this algebra the commutative law of multiplication no longer holds, but the other axioms of ordinary algebra are still valid. A general definition of a function is proposed, and the differential coefficient is defined without introducing the idea of a limit.—Miss B. **Swirles**: The polarisabilities of atomic cores. The polarisabilities of the cores of several atoms are calculated from the terms of their spectra by means of a formula due to Born and Heisenberg. The values so obtained agree with those given by a modification of the dispersion formula of Kramers and Heisenberg.—J. R. **Oppenheimer**: On the quantum theory of the problem of the two bodies. (Preliminary communication.) In addition to the Balmer terms derived by Pauli, Schrödinger and Dirac, the line intensities are computed; for example, the first Balmer emission line is 12·2 times as intense as the second Lyman line, and the first Balmer absorption line is 5·37 times as intense as the second. The probabilities of transition and capture are derived, and a method of obtaining the deflexion spectrum is sketched. The argument is based throughout on Schrödinger's theory.—G. P. **Thomson**: An optical illusion due to contrast. A blackened strip on a photographic negative sometimes has the appearance of being blacker at the edges than the centre, though the reverse is found to be the case when measurements are made by a photometer. The edges are narrower and clearer the more rapid the transition from light to darkness, but become too narrow to be seen when the transition is made as abrupt as possible. The eye appears to see rapid change of blackness as enhanced blackness. A converse effect appears for a light strip on a blackened ground.—M. H. A. **Newman**: Integral invariants of the affine field.—A. **Young** and H. W. **Turnbull**: The linear invariants of ten quaternary quadrics.—G. S. **Mahajani**: A contribution to the theory of ferromagnetism.—E. B. **Moullin**: On some resistance properties of a certain net-work containing inductances and capacities, and their analogies in a mechanical system. If the net-work is in acceptor resonance at a certain frequency when excited from a particular member, then it will also be in resonance when excited from any other member, but then the resonance may be either acceptor or rejector.—J. C. **Burkill**: On Mellin's inversion formula.—Major P. A. **MacMahon**: The elliptic products of Jacobi and the theory of linear congruences.—R. **Hargreaves**: Geodetic and dynamical principles, a comparison and connexion.—J. R. **Oppenheimer**: On the quantum theory of vibration-rotation bands. The dynamical problem of the diatomic molecule is solved on the new mechanics. The quantum numbers, chosen to give a normal state, are $n = \frac{1}{2}, \frac{3}{2} \ldots$; $m = -\frac{1}{2}, -\frac{3}{2}, -\frac{5}{2} \ldots, \frac{1}{2}, \frac{3}{2}, \frac{5}{2} \ldots$; $r = -m + \frac{1}{2} \ldots, +m - \frac{1}{2}$. The frequencies differ from the classical frequencies for half integral vibrational and rotational quantum numbers in having $m^2 - \frac{1}{4}$ for m^2 in the coupling term. The weights of the m states are $2m$. The intensity of the central line of the band vanishes. The intensities of the lines are worked out to the second order in $\nu_{\text{rot.}}/\nu_{\text{vib.}}$.—P. A. **Taylor**: An approximation to the motion of two rotating electrical doublets in a plane.—D. R. **Hartree**: Some relations between the optical spectra of different atoms of the same electronic structure. (ii.) Aluminium-like and copper-like atoms. For penetrating orbits of the series electron, the quantum defect can be expressed as the sum of contributions from the groups of core orbits of different principal quantum number. Based on this, relations are obtained between the values of the quantum defect for corresponding terms of the spectra of an atom of a given element in different states of ionisation, and of different atoms in such states of ionisation that they have the same electronic structure.—J. P. **Gabbatt**: Note on the extension to higher space of a theorem of Wallace.—J. B. S. **Haldane**: A mathematical theory of natural and artificial selection (Pt. iii.).

ROME.

Pontifical Academy of Sciences (Nuovi Lincei), June.—**Gemelli**: Perception of the position of the body in relation to the sensation of equilibrium of an aeroplane pilot. The importance of muscular, cartilaginous, and tactile sensations, in opposition to those of the semi-circular channels of the ear, is emphasised. Anile, however, reaffirms the importance of such channels with reference to the equilibrium, and states that these studies necessitate consideration of the vast and complex relationships between the vestibular nerve and the nervous centres.—**Luigioni**: A case of trifid antenna in *Demetrias atricapillus*, a small coleopterous insect of the scarab family.—**Teofilato**: Motion of a weight in a medium with viscous resistance.—**Pagnini**: Hypotheses serving as foundation for the undulatory theory.—**Gianfranceschi**: De momento theoriae physicae circa quanta. The bases and the results of the quantum theory are examined and those of real value indicated.—**Scatizzi**: The demonstration of formal generality by means of differential equations of a typical case of the ideal problem.—**Colonnetti**: Experimental investigations on elastic co-actions. Results are given of the study of a rectilinear beam and of a ring subjected to the action of a source of heat which induces in them a state of co-action.—**Giorgi**: Unsolved questions in the fundamental theories of electromagnetism.—Isabella **Biasi**: The extension of Birichbet's theorem to the general typical case of impulsive function.

SYDNEY.

Linnean Society of New South Wales, June 30.—R. J. **Tillyard**: Upper Permian insects of New South Wales (Pt. ii). The orders Mecoptera, Paramecoptera and Neuroptera. These fossils are from Belmont and Warner's Bay and belong to three closely allied holometabolous orders. The Mecoptera are represented by no less than two families, five genera and eighteen species, this being the largest fossil Mecopterous fauna yet discovered, though the Lower Permian of Kansas comes fairly close to it with six genera and fourteen species. This order is also the oldest of the three, as it can be traced back into the Upper Carboniferous. The most abundant genus is Permochorista Till., of which eleven species are described. Fragments of the wings of this genus are the commonest fossils in these beds. The order Paramecoptera is not known outside these beds, and there are only two species; they are interesting as being the early ancestral types from which the orders Diptera, Trichoptera and Lepidoptera have evolved. The Neuroptera are represented by one family, four genera and eight species of the suborder Planipennia.—A. P. **Dodd**: New species of Australian Proctotrypoidea, with revisional notes. One new genus in the family Scelionidæ and ten new species in the families Scelionidæ, Belytidæ and Diapriidæ are described.—G. H. **Hardy**: A new classification of Australian robberflies belonging to the subfamily Dasypogoninæ (Diptera, Asilidæ). Eighteen genera of the Dasypogoninæ are recognised and are divided into three tribes, Brachyrrhopalini (4 genera), Saropogonini (10) and Phellini (4).—May M. **Williams**: Contributions to the cytology and

worker so as to incite him to better work entirely overlooks one important consideration: it is that the manual labourer is a free Englishman, and, like every other freeman he is a merchant. His merchandise is his labour, which it is to his interest to dispose of at the highest price.

It is not a question of the labourer giving less or more according to his mood, but of his fulfilling his bargain. A grocer is not entitled to deliver thirteen or eleven eggs for a dozen according to whether he feels good tempered or bad tempered. In a word 'piece-work' is the one and only remedy for 'ca' canny' and under-production. The real cause for the relatively low wages of the English worker as compared with those of the American is the over-'reproduction' of the former. The wage is the reward for a certain product; the more mouths which have to be fed on this wage the worse off the individual will be.

In countries which have large untapped natural resources, revolutionary experiments may perhaps be indulged in without doing permanent irreparable damage, but in England it is a life-and-death matter to combat them. In a country with such a population that it is unable to feed more than two-fifths of them, our very existence depends on daring private enterprise, just as truly as did that of our Norse forefathers. As Mr. Walter Runcimann, who certainly will not be suspected of Toryism, once put it, "England lives on her business men." It must therefore be our constant endeavour to encourage private enterprise in every possible way, and especially by making its rewards secure, and the very worst manner of doing so would be by limiting the right of bequest.

The dependence of England for its food on foreign trade naturally leads us to the consideration of Sir Daniel Hall's address on the relation between cultivated area and population. Three years ago, at the Liverpool meeting of the British Association, Sir William Beveridge airily disposed of what he termed 'the Malthusian devil' by pointing out what large areas of the world in general and of the British Empire in particular were thinly peopled. His address was exploited by the leading socialist journal under the heading of "Malthusian Moonshine."

Sir Wm. Beveridge's conclusions were severely criticised at the time: and Sir Daniel Hall, speaking not only as a statistician but also as a distinguished biologist, substantially confirms all those criticisms. He points out that the possibility of increase of population is dependent on the increase of food supply, and that between 1850 and 1920 the numbers of the 'white race' increased from 200 to 700 millions. This increase in numbers was rendered possible by the addition of 500,000,000 acres of land to the world's farms: but no further reserves of such lands are to be found on the earth's surface. It is true that the product of those acres might be greatly increased by the adoption of more intensive farming, but intensive farming means greatly increased labour, and even now, despite very much higher wages, the product per man-power is much greater in the lightly farmed lands of Canada and Australia than in heavily farmed England. That the plant-breeder, by the production of better cropping varieties, might increase the yield without necessitating more labour, is conceded, but it will come as a shock to many to read Sir Daniel's opinion as to the narrow limits within which this improvement is to be expected. The main productivity of the plant, he avers, cannot be much increased; all that can be done is to alter the proportions between useful and useless products, such as grain and straw in wheat, sugar and starch in beet, and so on.

The return of the land in food-stuffs per acre is about twenty times greater for wheat than for beef. Further, a considerable portion of our cereal products are employed in producing beer and whisky. If we were all to become prohibitionists and vegetarians we could support a larger population on the same area; but we fully agree with Sir Daniel Hall when he says that the virile and enterprising races, such as have heretofore dominated the world's destinies, would never submit to such a pauperised mode of existence. On the other side of the ledger we have to take account of two grave facts: first, that the fertility of the virgin lands which produced such a great part of our supply is slowly but surely becoming exhausted; and secondly, that everywhere over the world, in Ontario no less than in England, there is the tendency for the rural population to drift into the towns. This tendency Sir Daniel attributes to the poorer rewards offered by agricultural labour as compared with industrial wages in towns. Greatly increased facilities of transportation, wide diffusion of news by wireless and other amenities of civilisation have certainly not diminished the tendency. It will eventually be checked in Sir Daniel Hall's opinion by the better organisation of agricultural workers, who will demand higher prices for the food which they produce. Certainly a cheerful prospect!

It seems to us that the imperative necessity of the limitation of the numbers of the human race in general and of the British Islands in particular is the lesson driven home in sledge-hammer blows by Sir Daniel's able address. If the principle be granted that every human being born in a civilised community may claim the right of full maintenance, whether at work or not, the obvious corollary is that society must be able to control its numbers or become bankrupt.

The Solid Foundation of Organic Evolution.

Evolution. By Prof. J. Graham Kerr. Pp. xii+278+2 plates. (London: Macmillan and Co., Ltd., 1926.) 12*s.* net.

THE object of this book, as set forth in the preface, "is to provide a sketch in outline, approximately correct in its proportions and not overburdened with detail, of the evolutionary science of to-day." The author rightly claims that "a grasp of the main principles of biological science, and amongst these principles Evolution is one of the first, is an essential part of the intellectual equipment of the citizen of the modern state." The necessity was never greater than it is to-day. Although the proceedings in Tennessee last year would have been unthinkable in Great Britain, even amidst the fierce and embittered controversies of the early 'sixties, we often meet with the confident expression of opinions which are all the more injurious because less obviously absurd. Thus in the *Spectator*—on most subjects a sober and well-balanced journal—Mr. C. E. M. Joad wrote in the issue of February 20, 1926, on the causes of evolution: "There were two contemporary explanations in the field; that of Darwin and that of Lamarck. Darwin's was no explanation at all. He said, in effect, that he could not tell why variations occurred; all that he could affirm was that those which were suited to their environment survived." It might with equal force be maintained that the form of a house is not determined by an architect because he did not make the bricks, if I may thus condense an argument employed by Darwin in his correspondence with Asa Gray before the appearance of the "Origin of Species."

Quite apart from this old objection, raised long ago by distinguished controversialists, there is a tendency in these later years to depreciate natural selection, not indeed by contesting its truth but by maintaining that it is self-evident and obvious—a barren guide devoid of inspiration. In Prof. Graham Kerr's book we are provided with admirable and convincing answers to the mistaken opinions of those who maintain that evolution is a delusion, and of those others who admit evolution but deny or depreciate the value of natural selection as its cause. The author's answers are firmly based on a consideration of all the important aspects of the subject—embryology, palæontology, comparative anatomy, geographical distribution, heredity (cytological, statistical, and experimental), natural selection, adaptation, sexual selection, evolution in communities of cells and of individuals, evolution and man, the final chapter containing a summary and the brief discussion of certain general problems of evolution. The book is well and freely illustrated with 53 excellent text-figures and two beautiful coloured plates with well-chosen examples of mimicry in butterflies.

There is something deeply impressive, and to an open mind utterly convincing, in the convergence of so many and such widely different classes of evidence to one inevitable conclusion—the reality of organic evolution. It is not to be expected that the powerful and, in my opinion, irresistible arguments in favour of natural selection as the motive cause of evolution will meet with the same immediate acceptance as those which advocate evolution itself. The latter are driven home by the experience of every biologist; but in estimating the force of the case for natural selection, "the laboratory-trained zoologist lacking in field knowledge often shows a singular incapacity for understanding the importance of evolutionary factors which experience in the field, more especially tropical experience, drives home—such as, for example, the intensity of the struggle for existence or the adaptive significance of animal coloration" (p. 9). There is no doubt about the conclusions to which the author has been led by his own experience in South America. He writes on p. 272: "I adhere to the position of Darwin that the potency of natural selection is in actual fact enormous; I hold that the attempts that have been made to minimise its importance are to a great extent fallacious, invalidated in some cases by their author's want of experience and skill as field naturalists, and in others by the making of unwarrantable assumptions." Prof. Kerr is thus in no doubt about his foundations of belief.

A few slight changes in the excellent Chapter xi., on the "Coloration of Animals," might be advantageously introduced into the second edition, which is sure to be called for at an early date. Mombasa is not one of the localities where the females of *Papilio dardanus* resemble the males (p. 175). If space permitted it would be well to mention the Nairobi district, where ancestral forms of female occur, intermediate between the most primitive of the fully mimetic females and the male-like females of Madagascar and Abyssinia. Different forms of females have not been bred in the same batch of eggs in the Cape district, but in Natal; also in South-East Rhodesia, Southern Nigeria, Uganda, Tanganyika Territory, and of recent years on a very large scale by Dr. V. G. L. van Someren at Nairobi.

The section on "Aromatic Attractions" (p. 186) would be improved by a short account of the advance which has been made along lines originally laid down by Fritz Müller:—Lamborn's observations on male Danaine butterflies brushing the scent-patches on their hind wings and thus charging the anal tufts; Carpenter's, on the actual use of these tufts in courtship; Eltringham, on the minute structure of the scent-producing and

scent-diffusing apparatus of these butterflies and of Phryganidæ.

Returning to Chapter xi., it would be an advantage in such a complicated and difficult subject as butterfly mimicry to adopt a uniform system of illustration, with the models to the left and mimics to the right, and to print "Models" or "Danaine Models," etc., as the case may be, at the head of one column, and "Mimics" at the head of the other. In Plate I. four of the models are to the left, but the fifth butterfly (Fig. 9) would be generally looked upon as a mimic. It appears, however, to be commoner than its model *Heliconius telesiphe* (Fig. 10), but both species are probably distasteful and the mimicry Müllerian. In Plate II. the Danaine models are to right and the mimetic females of *Papilio dardanus* to the left.

The author has been misled, as so many have been, by Bates's use of the word "Heliconidæ" in his classical memoir on butterfly mimicry in the *Transactions of the Linnean Society*. It is extremely difficult, wellnigh impossible, to correct effectually and for all time a mistaken impression conveyed by a great man in his greatest contribution to thought, embodied in a memoir which has been read and re-read unnumbered times and handed on to a widening circle by reprint in hundreds of volumes and journals. It is impossible on the present occasion to discuss this unfortunate result in any detail. It must suffice to explain that the chief models for mimicry among the tropical American butterflies are not the far-famed "Heliconidæ" at all, but a specialised group formerly united with the Danainæ but now placed in a separate sub-family—the Ithomiinæ. These are not only extensively mimicked by other butterflies but also by an important section of the Heliconines. An excellent example is figured by Prof. Graham Kerr on Plate I., Fig. 8, and its Ithomiine model in Fig. 7, but this relationship would scarcely be gathered from the author's words on p. 171, where Fig. 8 is referred to as a "typical example of the . . . Heliconiides." It is by no means typical of these, but only of that large section which mimics the Ithomiines. A far more typical example is represented in Fig. 10 of the same plate. Furthermore, the description of the Heliconiides on p. 171 refers to the Ithomiine and only to those species among the Heliconines which mimic them.

It is scarcely necessary to point out that this criticism, which equally applies to nearly every published account of butterfly mimicry, does not in any way affect the immense strength of the author's argument, and I wish in conclusion to emphasise again the excellence of the work and draw attention to the comfort of its clear type and entire freedom from misprints.

E. B. P.

Sunshine and Health.

Sunshine and Open Air: their Influence on Health, with Special Reference to the Alpine Climate. By Leonard Hill. Second edition. Pp. vii+132+8 plates. (London: Edward Arnold and Co., 1925.) 10*s.* 6*d.* net.

PROF. LEONARD HILL possesses to a marked degree the facility of presenting to his readers a graphic picture of the facts he desires to convey. The first few sentences of his admirable book, "Sunshine and Open Air," vividly and felicitously illustrate this power. "Going out before breakfast at 8 A.M., before the sun has risen over the mountains, one passes into a cold, dry, exhilarating atmosphere, cold enough to make one draw down a cap over one's tingling ears. The snow, crisp with some 10° of frost, crunches beneath the feet. The frosty snowfields glitter with light, and the distant snow peaks of the mountains, catching the sun, blush rosy red; the pines stretch upwards their black boughs drooping heavy with snow." We are transported at once to the scene he so graphically visualises. He writes not only as a scientist but as a poet; and when a few lines further on he says, "So one comes back with a good appetite for breakfast after an hour's climb," we almost feel the healthy hunger that morning walk over the enchanting snow-clad mountains has aroused, and plunge with added zest into a book readable from cover to cover, and replete with information and original observation.

The author considers the characteristics of the Alpine climate and on which of these its curative value is based, contrasting the outdoor English climate on one hand, and the indoor city conditions on the other, with these Alpine conditions. He finds no evidence of differences in atmospheric pressure ionisation of the air, or in chemical purity being of importance. The important factors are:

(1) Freedom of the air from pollution with infectious microbes, dust, and smoke which prevails in indoor city atmospheres.

(2) A high physiological saturation deficit; that is, a large difference between the water vapour in a cubic metre of air at atmospheric temperature and that held in the air when saturated at body temperature. On this depends the evaporation from skin and lung. The evaporation from the lung entails passage of blood and lymph through the respiratory membrane and a secretion which cleanses and immunises against infection. In crowded, warm rooms the physiological saturation deficit is lowered while microbic infection is increased, and with it the natural defensive cleansing

mechanism. The free evaporation from the skin is also of much importance to comfort and health.

(3) High drying power ensures dry clothes, houses, and soil; and these warmed with abundant sunshine prevent uncomfortable loss of body heat by radiation.

(4) Cool dry air stimulates the skin and exhilarates the feelings while keeping up the loss of body heat to an adequate level, maintaining appetite and good digestion.

(5) At night the cool air descending from the mountains prevents stuffy, warm conditions in the summer and gives an exhilarating change to the warm sunny day conditions. In winter the frosty cold air, with absence of wind, affords exhilarating conditions for sleeping in open-air balconies, the very antithesis of the stuffy, warm, stagnant, moist air of crowded city rooms which lowers the rate of cooling of the body and with this the respiratory metabolism. The absence of high wind prevents excessive cooling in the Alps.

(6) The sunshine, with its plentiful supply of ultra-violet light, acts beneficially on the skin and so on the general health.

The author discusses in detail the evaporative power of the air exerted on the body, the biological action of light, the cooling power of the air and its marked effect on the resting metabolism and heat production of the body.

In a volume so valuable and informative it is difficult to select special sections particularly deserving of mention, but in the concluding chapter is a section devoted to clothing which is of great practical interest. The author protests against excessive clothing, by which the natural vigour of the body is weakened. "It does no harm to go out and feel cold until warmed by exercise; the impulsion to vigorous exercise does good. It is only the old and feeble who require very warm clothing, those whose fire of life cannot be fanned up by vigorous exercise and exposure." Prof. Hill practises on himself his own preaching. He concludes his book by confessing: "The writer finds a light cellular shirt and pants and a woollen tweed suit ample for winter, and rarely wearing an overcoat, keeps himself warm and in good condition by walking on every possible occasion, covering to and fro from his place of work and in a walk before breakfast some five miles a day, and at week-ends having, whenever weather allows, a sunbath."

In a short appendix artificial light treatment is very briefly discussed.

"Sunshine and Open Air" is well worthy of careful study. The information it conveys cannot be too widely known and applied. Acquaintance with the facts described would do much to teach essential principles of sound hygiene and sensible care of the body. There is a lucidity and charm in this volume which adds greatly to its value. After perusal one cannot but wish that the author should be persuaded to issue an abridged edition suitable for the widest possible circulation amongst medical men, nurses, teachers, parents, and indeed all those who are concerned with and influence the management and upbringing of youth. Prof. Hill has rendered valuable service in producing a volume which may be commended in the highest terms as of great scientific and utilitarian merit.

Vacuum Practice.

Vacuum Practice. By L. Dunoyer. Translated by J. H. Smith. (International Text-Books of Exact Science.) Pp. x+228. (London: G. Bell and Sons, Ltd., 1926.) *12s. 6d.* net.

It must be very difficult to write a book on this subject, for it has to cover such a wide and varied range. There are two distinct aspects of the matter, theoretical and practical, both important and interesting. A complete exposition of the theories involved would require almost an entire text-book on physics, new and old; and most of them are still attended by considerable uncertainty. The practical side is no easier to treat: for practice is best taught by example and not by precept; and yet perhaps it is the more important. The principles—at least, of the theories—lie on the high road of academic physics and form a normal part of the training of every serious student; but the practice has developed in the factory rather than in the laboratory, and its literature consists of patent specifications rather than formal papers. In most of the university laboratories of Great Britain, the best designed and best executed piece of vacuum apparatus that they contain is the incandescent vacuum lamps (already almost obsolete) by which they are lit; and many a skilled experimenter with years of pure research behind him would be quite unable to produce such a common domestic article as a 'dull-emitter' valve. The reason lies partly in the lack of equipment from which all British universities suffer, but far more in the gulf between the followers of pure and applied science, which is only slowly being bridged.

No apology would therefore be needed (nor is any offered) for the appearance in English of a third book covering the same ground as those of Dushman and Newman, even if it possesses no merit that they lack. Actually in one respect M. Dunoyer's book is greatly superior to either. It is critical. Dushman dealt mainly with work in which he was so closely concerned

that he is not in a position to criticise; Newman aimed chiefly at being encyclopædic. M. Dunoyer has passed all the work through his own mind, and offers his opinion freely. His presentment is therefore better, and his book more readable; he has been greatly assisted by a translator of complete competence and sufficient wisdom to risk slang, if only he may avoid Gallicisms.

If fault has to be found with M. Dunoyer—and how else can a reviewer display his omniscience?—it must be sought in his selection of material. He tells us that his principal object is the study of technique. But then would it not have been well to sacrifice some part of the theory of monomolecular absorption to a recipe for making 'activated' charcoal (for which every investigator has his pet method) or even to advice in constructing ovens for baking during absorption? Would not a few details of the commercial process of 'gettering' be worth as much as the somewhat nebulous theories that have been advanced to explain it? Why should Knudsen's theory of gas-flow at low pressure be carried beyond the point at which it has any practical application, while Gaede's theory of diffusion is left before it has indicated the effect of dimensions and temperature on the performance of the pump, or even the relation between speed and the nature of the gas pumped? Lastly, the simple theory of metal to glass constructions is quite as interesting and much more practical than many others for which space has been found.

We would not leave the impression, however, that M. Dunoyer has not lived up to his professions. He is most admirable when he is most practical. He is really helpful in the sordid matter of leaks; he knows all about waxes and cements, but realises their limitations; and, though he writes before the recent startling developments in this direction, is aware that metal to glass joints are not so difficult as the amateur believes. But even in these matters his outlook is not perhaps quite that of the professional expert. It is possible, and indeed easy, to be too ingenious in leak-hunting; in most circumstances a leak which cannot be found by simple means in a few minutes is best eliminated by reconstruction. The disadvantage of waxes is not their vapour-pressure, but their low melting-point; apparatus which involves them cannot be baked. If so much is said of the physical properties of these makeshifts, surely some attention should have been paid to the physical properties of the essential material, glass. In Great Britain, nearly all laboratory workers continue to handicap themselves by the employment of treacherous and generally unsuitable soda glass; they seem never to have heard of the lead and borosilicate glasses; a table of comparative thermal and electrical properties would do much to enlighten their ignorance.

There is only one matter, other than a choice of material, in which we differ seriously from M. Dunoyer. In his discussion of gauges, the account of the characteristics and limitations of the various types is excellent; but when he sums up in favour of a form of Knudsen gauge against the ionisation gauge, he misconceives the problem and might mislead a novice. A gauge is often used merely to indicate that a certain rough limit of pressure has been reached; for this purpose all that is needed is sensitivity, simplicity, and ease of attachment; in all these the ionisation gauge is vastly superior to the Knudsen. Sometimes only relative accuracy is required in the comparison of different quantities of the same gas; here again the dependence of the calibration of the ionisation gauge on the nature of the gas in immaterial. The Knudsen gauge is superior only if an absolute measure is required of mechanical pressure or of number of molecules per unit volume; the requirement is so rare and arises only in such elaborate researches that it should not be taken into account in offering a general recommendation

NORMAN R. CAMPBELL.

Geography and Geology of Makalla.

Ministry of Finance, Egypt: Survey of Egypt, Geological Survey. The Geography and Geology of Makalla (South Arabia). By O. H. Little. With Two Appendices: (i.) Description of Fossils from South Arabia and British Somaliland, by Prof. G. Stefanini; (ii.) Note on some Terrestrial Mollusca from the Hinterland of Makalla, by P. Pallary. Pp. xi + 250 + 36 plates. (Cairo: Government Publications Office, 1925.) 50 P.T.

THIS volume is the outcome of two expeditions led to Makalla at the request of the late enlightened ruler Sir Ghalib bin Awad bin Omer el-Kaitai, K.C.I.E., Sultan of Shehr and Makalla. Makalla is located on that little frequented coast-line of Arabia between Aden and Muscat. Under the impression that minerals of economic value existed in the territory he ruled, the Sultan requested the British Government to undertake an examination. A reconnaissance survey was made in May 1918, but so great are the difficulties of travel, and so lawless the tribes outside the immediate control of Makalla, that even under the protection of the Sultan's troops geological work is greatly hampered and every excursion is, in fact, an adventure.

The later and more detailed survey of Mr. Little confirmed the view that there were no minerals of economic value in the country even if the difficulties of access were surmountable. Exaggerated importance is attached

by the Bedouins to any unusual rock or mineral, and the slightest attention from a European is sufficient to convince them that something of enormous value exists.

Every tribe claims the right of imposing tribute on travellers passing their territory, even if permission is granted, and camels must be hired in the country being traversed. Any departure from recognised custom invites trouble, and the country is very convenient for ambushes. A virulent form of malaria prevails in the swampy regions along some of the nullahs and near the sea, and many of the expedition were incapacitated for long periods. The heat is very trying from May onwards, and even at night the air breathed resembles furnace gases at times. The tribes do not trust each other, and any unusual sound at night usually results in an outburst of wild firing from any strange party encamped in hostile country. One member of Mr. Little's party was, indeed, murdered shortly after he had left the main body.

The physiography of the region is extremely fascinating, as the interior is reached by traversing deep wadis which narrow down at times to cañons with precipitous sides, 1000 to 1500 ft. high. Men and animals trapped by a sudden flow of water due to rains in the interior can find no escape. At intervals these cañons are broken by steep falls, which make it necessary to climb out of the gorge by a zigzag track to reach a higher stretch. Immense boulders strew the path in these gorges and at times exceed 1000 cubic metres in size. Water disappears and appears in some at intervals where the valley floor is pervious or impervious.

Some of the roads, which traverse narrow spurs and ridges leading into the mountains of the interior, are so steep and so polished by the constant treading of the bare feet of men and camels that passage is exceedingly dangerous, and both animals and men occasionally lose their lives through falls of many hundreds of feet.

Sufficient fossils were found to distinguish the age of the sedimentary rocks. Beds of Pleistocene, Pliocene, Miocene, Oligocene, Eocene, Cretaceous, and Jurassic age were recognised. The Pliocene conglomerates appear to correlate with the Bakhtiari series of the Persian Gulf and the great calcareous conglomerates of Somaliland.

The Miocene beds are not well developed and are gypseous in character; they are thought to correspond with the Fars series of the Persian Gulf, and they resemble the Miocene gypsum series of Egypt. It is, however, the Eocene and Cretaceous beds which cause the most striking topography of the country. Imposing vertical scarps 1500 feet and more in height often border the side of the wadis and the edges of valleys. The middle Eocene semi-crystalline limestones reach sometimes a thickness of nearly 1000 ft., and they overlie a series of massive variegated sandstones of Cretaceous age approximating another 1000 ft. in thickness. Where the Jurassic is absent these Cretaceous beds directly overlie the igneous basement rocks. Apart from occasional granites the igneous rocks are basic in character. Lignites are found in the Cretaceous sandstone series, while oil shales occur in the Jurassic rocks.

The only mineral deposits of any likely value are the lignites and oil shales, but neither are in sufficient bulk to warrant development to-day.

Two appendices with excellent illustrations describe the fossils of Southern Arabia and Somaliland; consequently the volume will prove valuable to all those studying the geology of that part of the world. The country and the customs of the inhabitants are admirably described, and many useful hints may be obtained by would-be travellers in these wild regions.

Our Bookshelf.

Commission Internationale de l'Éclairage en succession à la Commission Internationale de Photométrie. Sixième session, Genève, Juillet 1924. Recueil des travaux et compte rendu des séances. Publié sous la direction du Bureau Central de la Commission, the National Physical Laboratory, Teddington, Angleterre. Pp. 432+19 planches. (Cambridge: At the University Press, 1926.) 15s. net.

THE initial portion of this comprehensive volume contains a list of the members of the International Illumination Commission, an account of the proceedings at the various meetings, and a summary of the chief decisions taken. The Commission recommends the initiation of researches on the incandescent black body as a primary standard of light, and adopts a series of values for the relative visibility factor for light of different wave-lengths. A series of terms and definitions for international adoption (in French) is also presented. In an appendix, recommendations on the lighting of schools and factories, presented by Mr. L. B. Marks, the chairman of the committee devoted to this subject, are reproduced. Values of illumination range from 0·2 to 50 lux (approximately 5 foot-candles) according to the purpose served by the light.

The remainder of the volume is devoted to papers read. These fall into several well-defined groups. Amongst those of a more purely scientific character may be mentioned researches on the primary standard of light, characteristics of tungsten lamps, notes on symbols and nomenclature, and heterochromatic photometry. A new feature is the inclusion of several papers dealing with educational propaganda in favour of good lighting, and illustrating methods of cooperation between supply undertakings, manufacturers, and the public in the United States. There are several papers dealing with the public lighting of Paris and with motor-headlight problems. Finally there is a

group of papers by representatives of different countries dealing with industrial lighting. The various papers presented thus cover a wide ground, and it is evident that the work of the Commission is extending. The interchange of views between experts in different countries is helping towards the formulation of common principles of illumination, and it is to be noted that international committees are now engaged on a variety of problems.

The Historical Geography of Early Ireland. By Walter Fitzgerald. (*The Geographical Teacher* Supplement No. 1.) Pp. vii + 100. (London: George Philip and Son, Ltd.; Liverpool: Philip, Son and Nephew, Ltd., 1926.) 5*s*. net (to Members of the Geographical Association, 4*s*. net).

THIS work is worthy of a better exterior. A closely printed pamphlet is apt to repel a reader, who would peruse with delight the same matter in an attractive book. Having said this, and having added a word of censure on the poor scratchy drawings of gold ornaments (p. 70), we proceed to the pleasant task of commendation. Mr. Fitzgerald has undertaken, and has done well, a work long overdue; although the way was prepared by the late Prof. Cole's short but notable "Ireland the Outpost." In the past the history and antiquities of Ireland on one hand, and her geology and geography on the other, have received attention; Mr. Fitzgerald shows the inter-relation of the two sets of facts. The first half of the book is occupied with geography, and is illustrated with many valuable maps; the second half is archæological and historical, and is likewise illustrated with maps of the distribution of types of implements, roadways, colonisation-areas, the routes of early Irish enterprise on the Continent, etc.

We sincerely hope that the author will expand his work into a 'full-dress' book, and we venture in anticipation to offer a friendly hint or two. 'Gacillon' (p. 63) should be *Gaileoin*: 'Ushnagh' should be *Uisneach*. The Cat-stone is not on this hill, but on the slope of the hill next to it; and it is not a dolmen, but a large erratic boulder (the author has been misled by Borlase's imposing but unsatisfactory "Dolmens of Ireland," which should be used with discretion). And let him be cautious about taking literally the legends of the Tuatha Dé Danann; the complex stratification of these strange tales must be worked out much more critically than has yet been done, before they can be safely utilised in a study such as this.

R. A. S. MACALISTER.

Coal: Ways to Reconstruction. Being a Sequel to "The Coal Crisis and the Future." By Members of Leplay House. Pp. vi + 58. (London: Leplay House Press, 1926.) 2*s*.

THIS volume consists of a number of articles by various contributors, and, as is stated in the preface, the studies are both complementary and divergent. The main thesis, however, is that reconstruction in the coal industry is to be effected by means of regional planning. The application of the surveys is to be based on the co-ordination of the recommendations of the several experts, while the corresponding theory of the "transition from the confused empiricism of current business and politics to an ordered advance" is to be supplied by the sociologist. Prof. Geddes contributes an interesting summary of the methods of regional planning, and advocates regional surveys of the coal districts as a preliminary to the solution of the problem. Then follow articles by Prof. Desch and Prof. Hay, who both emphasise the importance of better methods of coal utilisation. The former deplores the present wasteful methods, while the latter holds that there is more hope for the industry in improved systems of coal consumption than in reorganisation of the mines.

Prof. Hay's thoughtful survey, which can be commended to those interested in the problem, stresses the importance of a greater production per man-shift, the development of markets, and the stabilisation of prices. At the same time he pleads for more understanding among the various parties, consumer, owner, and miner. An abstract of a previous volume is given by Mr. Sandeman, while Mr. Victor Branford contributes a theoretical exposition illustrating the application of sociological principles.

Superpower: its Genesis and Future. By William Spencer Murray. Pp. ix + 237. (New York: McGraw-Hill Book Co. Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 15*s*. net.

THE term 'superpower' is used to indicate a "greater unity of effort and broader co-ordination in (electrical) power production and utilisation." The author was chairman of a committee authorised by Congress to study the possibilities of superpower in the Boston-Washington zone. This committee began its activities in July 1920 and twelve months later presented its report (*Professional Paper* 123, U.S. Geological Survey).

The present book is to some extent an amplification of that report. It contains many interesting reflections and personal touches which will make it good leisure-time reading to those who have read the original report. A wide survey of the problem is made and a considerable portion of the book is devoted to finance, but the difficulties involved in standardisation of frequency and the stereotyping of generation and distribution methods in an age of rapid progress do not appear to have been dwelt upon sufficiently.

W. T. D.

A Bibliography of Indian Geology. Part IV. Palæontological Index. Compiled by T. H. D. LaTouche. Pp. iv + vii + 414. (Calcutta: Government of India Central Publication Branch, 1926.) 7.4 rupees; 11*s*. 6*d*.

SINCE his retirement from the Geological Survey of India, Mr. T. H. D. LaTouche has devoted his leisure time to the great task of compiling a bibliography of Indian geology. Part I. A gives a list of authors' names in alphabetical order with the titles of their papers arranged chronologically; Part I. B is an index of minerals; Part II. an index of localities; Part III. an index of subjects. Part IV., which has just been issued, gives an alphabetical list of the species of Indian fossils, followed by references to the works in which each species is described. This index will be indispensable to palæontologists whether they are dealing with the fossils of India or of other countries.

Letters to the Editor.

The Recurrence of Magnetic Storms.

IN recent communications to the French Academy of Sciences Prof. H. Deslandres (see NATURE, vol. 118, p. 71), the distinguished director of the Meudon Observatory, has described a tendency in magnetic storms to follow one another at intervals $iT/6$, where i is integral, T being the rotation period shown by sunspots. It is now, I think, generally agreed that there is a tendency to a repetition in magnetic conditions, whether disturbed or quiet, in what is described for brevity as the 27-day interval. Investigations (*Phil. Trans.* A, vol. 212, p. 75, and A, vol. 213, p. 245) which I made in 1912 and 1913 showed a tendency to recurrence in intervals which were multiples of T, but in none shorter. Supposing in accordance with modern ideas, as seems to have been first suggested by Kr. Birkeland, that magnetic storms are due to the discharge of ions from the sun, if such discharge, whether from sunspots or other approximately fixed limited areas, went on for a long time, a repetition of disturbance according to the solar rotation period is exactly what we should expect. But repetition at intervals submultiples of T would suggest a different explanation, namely, that the sun as a whole acts somewhat like an intermittent geyser. The subject seemed so important both to magneticians and astronomers that I have further considered it.

Some things fairly patent to magneticians may be less so to others. A magnetic storm is not definable with the same precision as a solar eclipse. It is true that an eclipse commences at different times at different parts of the earth, whereas the S.C. (sudden commencement) of a magnetic storm may, for all we know, be absolutely simultaneous all over the earth. But many storms have no S.C.'s, and, when S.C.'s occur, highly disturbed conditions may not follow for some hours. Thus, in general, the time when a storm begins at a particular station, and still more the time when it ends, cannot be specified exactly. Again, there seems to be at all stations a marked diurnal variation in disturbance, and this renders it extremely difficult to estimate to the fraction of a day the interval between successive storms.

The accompanying table gives some of the results which I have obtained. The results all ultimately depend on daily character figures assigned on the international scheme 0 (quiet), 1 (moderately disturbed), and 2 (highly disturbed), and they further depend on the selection of five highly disturbed days a month. Take, for example, the 11-year data distinguished by the letter A. The entry in column n is the mean character figure from the $5 \times 12 \times 11$, or 660, selected disturbed days, the entry in column $n+1$ the mean character figure from the 660 days immediately following these selected days, and so on. In the case of A and B, the 5 days selected for each month were the days of largest horizontal force range at Kew. A includes the whole eleven years 1890 to 1900, while B represents only three of these years, 1891, 1895, and 1896, selected for a special reason. In the case of A and B the daily character figures depended entirely on the estimate of disturbance at Kew. In the case of C and D the selected days were the days of largest international character figure, and use was made of the daily international character figures which range from 0·0 to 2·0. C includes six years, 1906 to 1911, and D five years, 1920 to 1924.

If, to take a round figure, we suppose 27·0 days to be the solar rotation period, M. Deslandres' conclusions would suggest maxima answering to days $n+4·5$, $n+9$, $n+13·5$, $n+18$, $n+22·5$, $n+27$, and $n+31·5$. As disturbance is seldom limited to a few hours, we should expect to find maxima in the table in columns $n+9$, $n+18$, and $n+27$, and to perhaps a minor extent in columns $n+4$, $n+5$, $n+13$, $n+14$, $n+22$, $n+23$, $n+31$, and $n+32$. High disturbance is seldom confined to single (Greenwich) days. It is not unusual for it to extend to 3 or 4 consecutive days, and sometimes even to 6 or 7. This explains

why outstandingly high mean values are not confined to column n, but extend to at least columns $n-2$ and $n+2$. The existence of high mean values for the five columns $n-2$ to $n+2$ entails values somewhat below the all-day means (given in the first column) in the majority of the other columns. Individual years give usually somewhat irregular results, and minor irregularities appear even in 11-year data. But it will probably be admitted that in addition to the primary disturbance pulse extending from column $n-2$ to columns $n+3$ or $n+4$, A shows clearly only one secondary pulse, extending from column $n+25$ to column $n+30$, or possibly $n+31$. The maximum appears in column $n+27$, with column $n+28$ not far behind. The three years included in B are given separately because they rather suggest a minor peak value in column $n+14$. But as the B results form a part of the A results, this is presumably purely accidental. Again, the D results may suggest a small secondary peak centring about column $n+17$, but there is no suggestion of this in the C results. The full 27-day interval is shown particularly clearly in D, which includes the latest international data available. No entry from column $n+3$ to column $n+24$ exceeds 0·58, the all-day mean, while the entry in column $n+27$ exceeds this by 0·25. Magnetic disturbance is the rule rather than the exception, and in the absence of any exact definition of a magnetic storm it is specially necessary to study the phenomena with an unprejudiced mind. The method employed here ensures impartiality. The table does not seem to me to suggest any real recurrence interval

shorter than 27 days, but any one can judge for himself.

Obviously, if two or more solar areas are highly active simultaneously, for a time which includes several rotation periods, we may have several pairs of (unconnected) storms separated by approximately constant time intervals, which might happen to be approximately sub-multiples of 27 days.

C. CHREE.

75 Church Road, Richmond, Surrey,
July 29

Prof. Labbé's Production of 'Allomorphs' by the Action of increased Hydrogen Ion Concentration.

PROF. LABBÉ, in a series of recent papers (*C.R. Acad. Sci.*, Paris, 1924, t. 178, p. 132, 594; t. 179, p. 928; 1924, *Arch. Zool. Exp.*, t. 62, p. 401), has communicated the results of observations made on the Salines of Croisic, and the conclusions he draws therefrom as to the nature and stability of species would, if substantiated, seriously shake the foundations of systematic zoology. For example, he asserts that, from the eggs of a parent form *Canthocamptus minutus* O.F.M. exposed in the ovisac to the influence of a high P_H, he has obtained a mixed progeny consisting of:

(*a*) *C. minutus* (typical).
(*b*) 'Allomorph' *Mesochra* (*Wolterstorffia*) *blanchardi* Rich.
(*c*) 'Allomorph' *Canthocamptus lucidulus* Rehb.
(*d*) 'Allomorph' *Mesochra salina* n. sp.

From these and other results Labbé draws very far-reaching conclusions which will, no doubt, receive serious consideration from all concerned with biochemical investigations; and it is possible that many will accept the premisses on which the conclusions rest without the close critical study which is the province of the systematist. For this reason the following remarks may be justified. I will take only the example given above of *C. minutus* and its 'Allomorphs.'

(1) 'Allomorph' *C. lucidulus* Rehb. In the first place one may observe that *C. lucidulus* is a common *fresh*-water species; secondly, the descriptions and figures given (*Arch. Zool. Exp.*, 62) are sufficient to show that the specimens described did not remotely resemble *C. lucidulus*. The antenna figured (Fig. 17) is unlike that of any Harpacticid of which I can find a description, since in all 8-jointed antennæ[1] the æsthete or "organ of Leydig" is borne by the fourth joint, which is followed by four more small joints; whereas in Labbé's figure it is borne on the fifth, and followed by two joints only. The fifth legs of both male and female (Figs. 28 and 29) are not only totally unlike those of *C. lucidulus* but have no parallel among Harpacticids. I can only call to mind two examples of a fifth leg having a two-jointed exopod—*Misophria pallida* and the male of *Microthalestris forficula*. It is conceivable that Labbé's figures are inaccurate drawings of swimming legs of immature individuals; but they are quite certainly not those of the fifth leg of *C. lucidulus*. Lastly, the operculum of his allomorph is, as he admits himself, quite different from that of *C. lucidulus*.

(2) 'Allomorph' *Mesochra blanchardi* Rich. Fig. 31 of the fifth foot bears some resemblance to that of *M. blanchardi*, but those of the antennæ, the furca and the first leg do not. The antennæ, if correctly drawn, can only be interpreted as monstrosities.

[1] Labbé's figure shows seven joints only, though all species of the genus have eight. The legend of the figure is "Canthocamptus minutus O.F.M. ♀ Antenne antérieure gauche de l' 'allomorphe' " and presumably is intended to represent that of "Allomorphe Canthocamptus lucidulus Rehb."

(3) 'Allomorph' *M. salina* n. sp. Here there is no question of alleged identity with a known species, but Labbé states that it differs from *M. blanchardi* only in the structure of the fifth legs. Curiously enough Fig. 32, which is said to represent the fifth leg, is so nearly like the *first* leg of *M. blanchardi* that (apart from a discrepancy in the proportional length of the joints) it might represent that limb, while Fig. 26 of the first leg represents an appendage described in the text as the fifth, but quite unparalleled among known Harpacticids.

Similar criticisms might be directed upon the 'Allomorphs' *Eurytemora affinis* and *E. lacustris*, while the remarks concerning *Artemia salina* are open to serious objection.

The experimental methods are so briefly described that any one acquainted with the difficulties of breeding Copepods without accidental introduction of the Nauplii of other species cannot fail to be sceptical of the results. Prof. Labbé's statement that the parents died on being placed in the new medium, but that their eggs were successfully hatched, leads one to doubt very much if the larvæ observed actually came from those eggs. In the brackish water such as fills the Salines at Croisic in winter, a number of Harpacticids may be expected to occur—*e.g.* species of Amphiascus and Nitocra—and it seems quite probable that the unsuspected presence of such species may have vitiated the results.

Having regard to the importance of the questions at issue it is essential that the foundation of fact should be impregnably secure, and it is to be hoped that, before Prof. Labbé's conclusions are accepted, he will be required to produce not only a detailed account of his experiments, but also accurate figures of his 'Allomorphs.'

I do not find anything at present in his writings which "fera malheureusement le désespoir des morphologistes classificateurs."

ROBERT GURNEY.

Stalham,
Norwich.

Scattering of Electrons in Helium.

THE energetic relations in collisions between electrons and gas molecules have been made the study of a very large group of workers, all of whose results show the essentially unmechanical nature of the processes involved. Our picture of the nature of such a collision must remain incomplete, however, until the angular relationships of the electron and molecular paths are also known.

Such information as we already possess of the scattering of electrons is in the highest degree unexpected. The work of Ramsauer has shown that slow electrons in the rare gases possess free paths much longer than would be anticipated on the kinetic theory, while that of Davisson and Kunsman (*Physical Review*, **22**, 242, 1923), on the scattering in metal films is also of revolutionary character. Quite recently Langmuir (*Physical Review*, **27**, 806, 1926) has shown that inelastic collisions in several gases lead to very small angles of scattering. Elsasser (*Die Naturwissenschaften*, **13**, 711, 1925) has put forward an explanation of these results on the basis of the theory of de Broglie, in which a moving particle is associated with a 'phase wave,' the interference of which governs the scattering.

In the course of an investigation of the energy distribution of electrons after a collision with a gas molecule, it was found possible to study at the same time the angular distribution of scattering.

Electrons from a tungsten filament were restricted by two slits to a narrow beam and traversed the gas under investigation, which was helium at a pressure of 0·03 mm. A beam of scattered electrons could be selected by two slits and afterwards bent in a magnetic field to determine the velocity distribution. Fast pumps maintained a low pressure in this region. The filament and first two slits could be rotated, so that the scattering angle could be varied from 0° to 90°.

The results for the scattering of electrons, which have suffered inelastic encounters and have lost 20 volts energy, are shown for two initial velocities, $V_i = 100$ and $V_i = 400$ volts, in Figs. 1 and 2. For $V_i = 100$, there are two maxima, the principal one at 5° agreeing with the observation of Langmuir, and another, much broader, at about 60°. For $V_i = 50$, the principal maximum broadens and moves to 20°. At higher initial velocities this maximum moves to smaller angles and for $V_i = 200$, is at less than 2·5°,

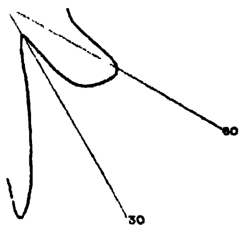

FIG. 1.—Scattering of electrons losing 20 volts energy; initial velocity, $V_i = 100$.

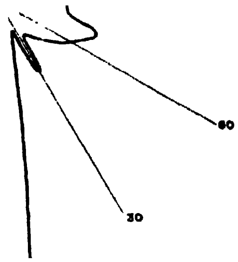

FIG. 2.—Scattering of electrons losing 20 volts energy, initial velocity, $V_i = 400$.

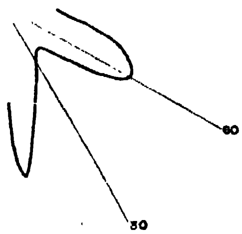

FIG. 3.—Scattering of electrons losing no energy; initial velocity, $V_i = 400$.

the smallest angle at which measurements could be made. At the higher velocities a very remarkable third maximum appears at 30°, which is much sharper than the other two. It is found first at 200 volts and increases in importance to 400 volts, which was the highest point at which measurements could be taken. The position of this peak was found to be independent of the velocity. This type of scattering is limited to the inelastic collisions, as is shown in Fig. 3, which shows the distribution of 400 volt electrons which have lost no energy, and is very similar to that of 100 volt electrons that have lost 20 volts energy (Fig. 1).

The occurrence of these maxima is strongly suggestive of an interference pattern, as suggested by Elsasser, but the fact that the position of the sharp maximum at 30° is independent of the velocity does not agree with his explanation.

It is hoped to extend this work to higher velocities and to the case where collision leads to ionisation and not excitation of the atom.

Intensity and Polarisation of Skylight at Sunrise and Sunset.

IT is now well-established that the illumination of the clear day-sky at high-level stations is almost entirely due to molecular scattering by the atmosphere. The remarkable changes in the character of sky-illumination which take place when the sun approaches and gets below the horizon have been the subjects of study of a number of investigators and in recent years, particularly of Profs. Dorno[1] and Gruner.[2] Some of the phenomena, as for example, the changes of colour and polarisation of skylight and the appearance of the earth-shadow, occur in the clearest of weathers and at such high-level stations that their origin cannot be attributed to anything other than molecular scattering. Gruner has, indeed, shown that the observed changes of colour of skylight when the sun is near the horizon can be explained by scattering by a pure atmosphere.

The writer has recently calculated the intensities of sky illumination due to molecular scattering when the sun is on the horizon at a place 2 km. above sea-level for the wave-lengths 0·45 μ, 0·55 μ, and 0·65 μ by a method somewhat different from that of Gruner, and as some of the results obtained are new, they may be of general interest. The light from the sky when the sun is on the horizon has a much smaller proportion of the shorter waves than the normal daylight sky. In the zenith, where the relative proportion of the short waves is the largest, the ratio of blue (0·45 μ) to red is only 1·3 while, according to the inverse fourth-power law, it would be 4·3. As we move from the zenith to the horizon, the proportion of blue decreases still more, the ratio becoming 0·48 at a zenith distance of 80° in a direction perpendicular to the sun's rays, and 0·45 at the same zenith distance on the side opposite to the sun. The calculated absolute values of intensity are also of the same order of quantities as the values observed by Dorno at Davos (1·6 km. above sea-level), but there is a tendency for the observed values to be larger in the quadrant of the sky containing the sun.

The way in which different layers of the atmosphere contribute to the illumination is also interesting. The proportions of the total light of wave-lengths 0·45 μ and 0·65 μ coming from different layers of the zenith sky are as follow:

Height.	Wave-length.	
	0·45 μ.	0·65 μ.
2-10 km.	8 per cent	38 per cent.
10-20 ,,	47 ,,	44 ,,
20-30 ,,	33 ,,	15 ,,
30-50 ,,	12 ,,	4 ,,

The single kilometre layers from which the maximum percentages come are 17 to 18 km. for the shorter wave and 9·5 to 10·5 km. for the longer.

In the calculations mentioned above, only primary scattering has been taken into account. But observation shows that complete neglect of self-illumination is not justifiable. For example, even in the clearest weather during the winter months at Simla (1·9 km. above sea-level), when the light from the zenith sky is analysed by a double-image prism and nicol, the weaker component is found to be richer in blue than the stronger, due, no doubt, to the self-illumination being greater for the shorter waves.

The effect of self-illumination may be expected to be a minimum, if confining our attention to the longer

[1] C. Dorno, "Himmelshelligkeit, Himmelspolarisation und Sonnenintensität in Davos, 1911 bis 1918," *Veröffent. des Preussischen Meteor. Instituts, Abhandlungen*, Bd. 6, 1919.

[2] P. Gruner, "Beiträge zur Physik der freien Atmosphäre," Bd. 8, pp. 1 and 120 (1919).

waves, we observe in a direction perpendicular to the sun's rays but at a zenith distance of 70° to 80°, where the absolute intensity of the primarily scattered longer waves is greater and the greater part of the radiation comes from a comparatively thinner layer nearer the surface of the earth. Observations at Simla show that the polarisation for the red in these directions often reaches values so high as 30 per cent., which may be compared with 91·6 per cent., the value of the polarisation of the light transversely scattered by pure air. K. R. RAMANATHAN.

Colaba, Bombay, June 25.

Medical Entomology and the Tropical Field Worker.

WITH a wider enlightenment on matters of public health among all communities, east and west in the tropics and sub-tropics, nowadays the medical officer of health finds a more insistent demand on his attention to problems connected with medical entomology.

Before proceeding to his tropical or sub-tropical appointment the medical officer of health has doubtless had a training in medical entomology, and often has acquired an active interest in this important subject; so much so, that if his destination is to some locality, let us say, where malaria is rife, he takes up his appointment with an enthusiastic intention of improving conditions. To those of us who have seen the arrival of many a medical officer of health in the tropics that is but the beginning of the story. The remainder is less satisfactory, and sadly uniform in most instances: on arrival he can give a fairly excellent account of the systematic divisions of the Anophelini, and a poorer—often a decidedly bad account—of the Culicini, and can readily distinguish an anopheline from a culicine larva (when it is in the laboratory, or microscopically mounted). So he arms himself with a few tubes, and then usually wonders where on earth he can find the species of his locality. At the back of his mind is the recollection that 'old tin-cans, broken bottles, gutters, and water-tanks' have been mentioned as being dangerous mosquito-breeding places, and a search is therefore diligently made in these situations. His efforts are rewarded, maybe, by the capture of what ninety-nine times out of a hundred are culicine larvæ—which he distinguishes by the presence of the siphon. Ere long the capture of 'Culexes' becomes less exciting, and he possibly seeks in the foulest pond in the district for the more interesting anopheline larvæ. By great good luck he may find one or two, and with a feeling of just pride orders the abolition of that breeding-place; while some clearer, but, in reality, more pestilential pond in which he found no larvæ, yet where there are actually thousands, continues to breed its pests.

In the end, supported only by a meagre knowledge of the systematic divisions of the Culicidæ, upon the capture of a few larvæ which all look horribly alike and cannot be identified as anything particular, and perplexed by the unaccountable numbers of mosquitoes which continue to swarm, enthusiasm speedily dies with the feeling that "this mosquito business is a subject only for the expert."

The reason for all this is obvious: we might as well expect to produce competent surgeons by a training devoted to descriptions and the examination of excised pathological exhibits. At present, astonishing as it is, instruction in medical entomology follows an absurdly parallel course: academic teaching and laboratory exhibitions (decidedly essential as they are) are almost the sum total of what instruction in medical entomology constitutes. The bionomics, the remarkable habits of some species, the practical methods of demonstrating the breeding-places in Nature, the varied methods of collection, the practical application of control measures in the field; all these matters of paramount importance in the training and successful work of the sanitarian receive no more attention than can be given in lectures. Consequently, once the sanitarian finds himself in the field, he discovers immediately that for all he has learnt he has no idea how to proceed.

I have merely taken the case of mosquitoes as an example. The same thing is true of the 'field' aspects of all other insect-enemies, and it is indeed time that the essential importance of proper field instruction should be taken into account so as to ensure that the men whom we send out from our schools are not so completely stranded when they meet the problems as Nature herself presents them. To avoid misapprehension, I should perhaps add that the Wellcome Field Laboratory is *not* a teaching centre where such practical instruction as that referred to can be obtained. MALCOLM E. MACGREGOR.

Accurate Square Roots.

IN NATURE for June 19, Mr. John Wishart directs attention to certain inaccuracies of one unit in the last printed place in Barlow's Tables of the square roots of numbers. Such errors are very common in these tables, applying to approximately ten per cent. of all the square roots; and they also apply, apparently even more frequently, to the cube roots. The reciprocals in the same tables are much more accurate, but even these are occasionally in error by a unit of the last printed place.

Mr. Wishart says that "there are some who have need of all the figures that existing tables give them, who sometimes wish, indeed, that more were available." I gather from this and from other hints in his letter that he may not be acquainted with the very useful collection: Hülsse's edition of Vega's Tables, published by Weidmann at Leipzig, 1840. On pages 476 to 575 are there given the square roots of all integers up to 10,000. They therefore have the same extent as Barlow's Tables but they give the roots to twelve decimals, five more than Barlow. The same table gives cube roots to seven decimals just as Barlow does, but they are carefully rounded off to the correct digit.

The best table of reciprocals is that by Oakes (published by Layton, London), which gives them to seven significant figures for all integers up to 100,000; care was taken to make the last printed digit correct. Hülsse's and Oakes' tables together should replace Barlow's where great accuracy is needed. But Barlow's tables, as Mr. Wishart intimates, are very convenient indeed whenever an error of one part in 100,000,000 is not important, and this is almost always the case.

The following method for deriving or testing square roots to many places may be of interest. Let N be the number the root of which we wish to extract, and let a and b be two nearly equal numbers such that

$$ab = N.$$

We have then

$$\sqrt{N} = \sqrt{ab} = \frac{1}{2}\sqrt{(a+b)^2 - (a-b)^2}$$
$$= \frac{a+b}{2} - \frac{(a-b)^2}{4(a+b)} + \dots$$

If, therefore, b differs from a by one part in 10^7 say, $\frac{1}{2}(a+b)$ will differ from $\sqrt{N}$ by only about one part

in 10^{15}. With an eight-bank computing machine we can readily find values for a and b that do not differ by more than one part in 10^7 and will usually differ by much less than this. Their arithmetical mean will therefore be the square root of N with an error of, at most, one part in 10^{15}. If still more digits are required, eight additional ones can be obtained in a few minutes by computing the term in $(a-b)^2$ above.

The same method can be used to extract square roots to three significant figures by mere inspection, and this degree of accuracy is sufficient in many computations, including solutions by least-squares. Thus, for example, the square root of 8·46 is seen to be not far from 3; dividing by 3 we get 2·82; the mean between this and 3 is 2·91, which differs from the square root of 8·46 by only 0·0014.

The Polishing of Surfaces.

THE manner in which an optical polish is produced on glass and metal surfaces has been considered by the late Lord Rayleigh (" Polish," Collected Papers, vol. 4, p. 542, " Interference Bands," vol. 4, p. 54). The amorphous layer theory of the late Sir George Beilby is well known. The article by Dr. J. W. French on " The Working of Optical Parts " (" Dictionary of Applied Physics," vol. 4) summarises and extends these considerations. Reference may also be made to a paper by M. M. Fichter, a notice of which appeared in NATURE, August 2, 1924, p. 173.

The object of this present note is to suggest that, in the process of polishing, surface layers are really melted by the communication of heat vibrations to them Consider a single surface layer of glass molecules of area 1 sq. cm. If glass consisted wholly of silica there would be approximately 9×10^{14} molecules per unit area, each of mass 9×10^{-23} gram. Taking the specific heat of glass as 0·16, initial temperature 20° C., melting-point 1100° C., and assuming a latent heat of fusion 100 calories per gram, the heat required to melt a single layer of molecules of 1 sq. cm. area would be 900 ergs.

Now Beilby gives a pressure of 4 lb. per sq. inch (280 grams per sq. cm.) as sufficient to produce surface flow with rouge polishing. Taking a coefficient of 0·3, the work done against friction when this force is overcome through 1 cm. is 83,000 ergs.

As one stroke of a polisher will polish only a small proportion of the 1 sq. cm. area considered, there will be available in the ordinary polishing procedure frictional energy of amount many hundreds of times that required to melt one layer of glass molecules.

At first sight it might be thought that any great rise in the temperature of the surface molecules would be prevented by the loss of heat due to conduction, etc. But this is to suppose that conduction would take place across plane interfaces. Is it not more reasonable to consider the heat as being produced at *points* of contact? If these were mathematical points, then no matter how small the rate of production of heat at a point, the temperature at the point would be infinite (the expression for the steady temperature v at distance r from a point in an infinite solid where heat is being supplied at the rate of q calories per sec., is $v=q/4\pi rk$, where k is the thermal conductivity of the material).

That the temperature attained by a surface depends essentially on the manner in which the heat is applied, is illustrated by the fact that a bunsen flame (of high temperature) may be played on a block tin surface without melting it, while a small globule of molten lead (only 100° C. above the melting-point of tin), if dropped on to a tin surface, will melt the tin below.

As an analogy to the manner in which high temperature vibrations may be set up locally, in polishing a surface, reference may be made to the setting of a Kundt's tube into vibration by slowly stroking it by hand, or a violin string by the slow stroke of the bow.

The Planetismal Hypothesis.

As there is a rising tide adverse to the planetismal hypothesis, may I record the following observation in its favour? Looking at the moon with a 9½-inch reflector, I saw details of the structure of the great south wall of the crater Hommel; the circular fault is perfectly fresh, and the rock exposed is a giant conglomerate, the boulders several hundred yards in diameter, with cavernous spaces between. In moments of perfect pellucidity, my instrument is quite capable of defining objects half a mile in diameter. My observation confirms Pickering's at Arequipa, when he was looking at the fault-scarp of the Sinus Iridium, in the opposite quadrant.

On the earth, iron is being taken from the surface rocks by weathering; it is washed down in solution into the rivers, but does not reach the sea. It goes downwards, and where there is a precipitant, it replaces limestone, forming deposits of iron-ore; where there is nothing to stop it, it must proceed towards the centre of the earth. Reversing the process, it follows that this iron would have made the crust of the earth an ultra-basic material in the early history of our planet, or in other words, it would have been similar to what we now find on the moon, where there has been no water to obscure matters. The lower specific gravity of the moon would be accounted for by the boulders making an arch and girder formation, with spaces between.

Zoological Nomenclature: Suspension of *Sarcoptes*, type *passerinus*, in favour of *Sarcoptes*, type *scabiei*.

THE secretary of the International Commission on Zoological Nomenclature has the honour to invite attention of the zoological profession to the fact that application has been made to the Commission to suspend the rules in the case of *Sarcoptes* Latr., 1804, tsd. (Latr., 1810) *passerinus*, and to place *Sarcoptes*, 1804, in the Official List of Generic Names with *S. scabiei* as type.

The argument states that the application of the rules to this 'transfer' case will result in greater confusion than uniformity, involving generic, subfamily, and family names, and designations of diseases in human and comparative medicine. The suspension requested will result in validating internationally accepted (though erroneous) nomenclature in consistent use for more than a century in zoology, and in human and comparative medicine.

The secretary is familiar with the premises, and in his report to the Commission will state that he considers this a typical case in which suspension is justified. He will, however, delay announcement of final vote until about October 1, 1927, in order to give ample opportunity to interested persons to express their views for or against the suspension.

C. W. STILES,
Secretary to Commission.

Hygienic Laboratory, Washington, D.C.,

The Optical Works of Sir Howard Grubb, Parsons and Company.

A FEW years ago it was very difficult to obtain a large object glass for an astronomical telescope. The optician would only promise a glass conditionally on his being able to procure suitable discs. For example, the director of the Johannesburg Observatory placed a contract for a 26-inch refractor in 1909, and four years later, in 1913, he reported that "it is hoped that glass discs will be obtained shortly." Large discs of optical glass are required only rarely, and their manufacture is a delicate operation requiring special plant; consequently very few people make them.

FIG. 1.—Erecting bay showing sliding roof partly open.

British astronomers were greatly pleased when the manufacture of large discs of optical glass was taken up by Sir Charles Parsons, who acquired the business of the Derby Crown Glass Works from Messrs. Wood Brothers, in 1921. Sir Charles Parsons has an hereditary interest in astronomy and the manufacture of large astronomical telescopes, as his father, the Earl of Rosse, built the famous six-foot reflecting telescope at Birr Castle, Parsonstown, King's County, Ireland. This early interest doubtless influenced him in taking up the manufacture of astronomical instruments from beginning to end—the manufacture of glass, the grinding and figuring of lenses and mirrors and the mechanical parts of telescopes. Near the beginning of 1925 he acquired the old-established business of Sir Howard Grubb. This famous firm was founded by Thomas Grubb a hundred years ago, and developed by the optical and mechanical skill of Sir Howard Grubb, under whose direction many fine telescopes, refractors, and reflectors have been produced. In 1918 the works were moved from Dublin to St. Albans in connexion with the manufacture of periscopes for the Navy, instruments which have been a standard product of the firm since the date of the first British submarine.

New works were set up in 1926 at Walker Gate, Newcastle, in close proximity to the well-known works of Messrs. C. A. Parsons and Co., Ltd., makers of steam turbines, electrical machinery, and searchlight mirrors. Close association with large engineering works is a great asset for makers of astronomical instruments. For small telescopes comparatively small plant is required, but for large ones the resources of engineering works with machines of the necessary size and accuracy are essential. In such accessories as large domes and rising floors, which are necessary with big instruments, large machinery is also required. For all heavy machine work the large machine shops of the Heaton works of Messrs. C. A. Parsons and Co. will be used. Nor must the great advantage be overlooked of the interchange of ideas among the staff, made possible by close association with the larger world of engineering.

An internal view of the principal bay of the new optical works is shown in Fig. 1. An important feature of this building is the provision for sliding off a large portion of the glass roof by carrying it on a supporting gantry moved by electrically operated motors. The shop possesses a five-ton electric travelling crane; one end of the bay is fitted up as a machine and fitting shop, and the other is used for the erection of instruments. Means of testing large instruments in course of construction by actual observation of

FIG. 2.—Insulated tunnel for the horizontal testing of mirrors and objectives.

stars are thus provided. Generally this is a matter of difficulty at optical works, but however well the laboratory tests may be satisfied, the purchaser of a telescope, as well as the maker, wishes to see how the instrument performs the end for which it is intended, before it is taken away from the works and erected in a possibly distant observatory.

In the transfer of the optical works from St. Albans to Newcastle the essential personnel as regards both staff and workmen was retained. One establishment is in complete continuity with the other, and it may well be that some of the improvements in the fitting up have been suggested by the previous long experience of the firm of Sir Howard Grubb. The means for testing large mirrors and objectives in the course of construction have been carefully planned. While in position on the polishing machine they can be conveyed by an electrical lift to the bottom of a shaft belonging to the optical testing room. Much labour and time is thus saved in the course of polishing a large mirror or objective which will be tested many times. Fig. 2 shows the horizontal testing tunnel. This is 100 feet in length, and gives the means of testing mirrors and objectives in a room of constant temperatures and free from disturbing effects of air currents. The rough polishing shop is shown in Fig. 3.

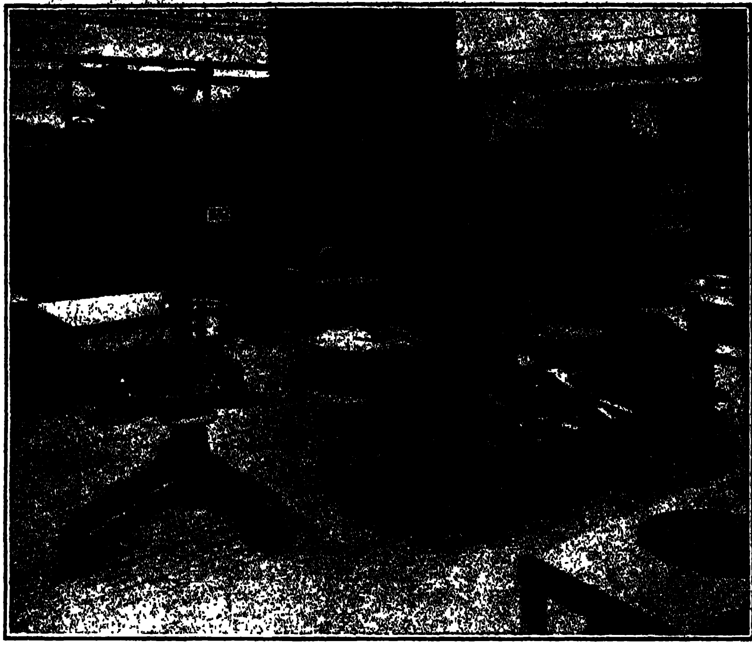

FIG. 3.—Optical roughing shop.

Among the instruments already constructed by the firm are a seven-metre solar spectrograph for the Pulkovo Observatory and a 40-inch reflecting telescope for the Observatory of Simeis in Southern Russia. In the annual report of the Observatory, published in the *Vierteljahrschrift*, and quoted in NATURE of July 17, p. 97, an account is given of the mounting and testing of the mirror. The departure of the mirror from paraboloidal state is found to be of the order of one-tenth of a wave-length, showing the mirror to be of very perfect figure. A description of the telescope, and of its mounting and control, was given in NATURE of April 12, 1924.

FIG. 4.—Optical discs for 41-in. objective.
These discs were manufactured by The Parsons Optical Glass Company at Derby.

At the present time, Sir Howard Grubb, Parsons and Co. are engaged on the ambitious task of constructing a refracting telescope with an object glass of 41 inches diameter. When completed, this telescope, which is also intended for the Simeis Observatory, will have a slightly larger aperture than that of the Yerkes Observatory. The focal length will, however, not be so long, as the instrument is designed for photographic rather than visual work. The discs have already been made at the Crown Derby works, and Fig. 4 shows them in the optical testing shop in Newcastle. Some time ago it was reported by a news agency that the discs had failed to satisfy the optical tests specified, but, as was announced in NATURE of June 19, p. 868, the statement was entirely erroneous. The progress of this large telescope will be watched with great interest and in confidence that a very fine instrument will be

The Mechanics of the Electric Field.[1]

By Sir J. J. THOMSON, O.M., F.R.S.

THE subject which I have selected for the Kelvin Lecture is one that from the very beginning of his scientific career was never long absent from Lord Kelvin's thoughts. It is one, too, which researches only dawning towards the close of his life have put into quite a new aspect. These researches have given us very definite information as to the structure of the atom; they have taught us that the atom is made up of electrons and positively electrified particles of known masses; they have told us the number of electrons and positive particles present in each atom; they have, in fact, given us a definite specification of the electrical state of the atom. With this in our possession it would seem as if we ought to be able to deduce the properties of the atom, by calculating by means of the laws of electromagnetism the behaviour of this definite electrical system. We find, however, if we do this, that the properties of our mathematical atom are in some respects in contradiction to those of the real atom. It is of course a gigantic extrapolation to pass from any system which we can test by direct experiment, and for which the laws of electromagnetism have been verified, to systems like the atoms, where the times and distances involved are of an entirely different order of magnitude. The extrapolation fails, but the point is that if the usual interpretation of these laws is the right one it ought not to fail.

I propose to discuss the question whether the equations of classical electrodynamics or, for the matter of that, classical dynamics are as fundamental as they have been thought to be; whether, instead of giving us a complete representation of the field of force, they do no more than give us the relations between the average value of the quantities used to define the field. That, in fact, they express statistical and not particle dynamics.

Let us consider some of the consequences of supposing that electric force consists of separate impulses separated by finite times. I must point out that this conception involves the existence in the universe of a structure beyond that represented by electrons and positive particles; if there were no structure of this kind, we could not account for the intervals which elapse between the impulses. This structure must be far finer in texture than the electrons; thus, on this view, the electron does not represent the last word in minuteness and there are still smaller entities awaiting discovery by the physicists.

For heuristic purposes, *i.e.* for the purpose of making our meaning clear, and without committing ourselves to the reality of this particular structure, we may liken it to a sub-atomic and sub-electronic gas the particles of which are much finer than the electrons. It is in these particles that the energy and momentum of the electric field are stored. We may regard these particles as concentrated round the electric charges, each charge carrying with it an atmosphere of these particles. The particles are crowded together near the centre of the charge, but get more and more widely separated as the distance from the centre increases. To distinguish between the positive and negative charges, we may suppose that the particles rotate round the charges and that the rotation as viewed from the centre of the charge is in one direction for the positive and in the opposite direction for the negative charge.

The particles bombard intermittently the charges round which they are congregated. If there were only one charge in the field the particles would be symmetrically distributed around it and the bombardment would not, on the average, make it move in one direction rather than in another; but when two or more charges are near together the symmetry of the distribution of the particles is disturbed and the bombardment results in the charges acquiring momentum.

Let us now consider in some detail the way in which the effects produced by intermittent forces differ from those due to continuous ones. We may represent the intermittent force analytically by saying that the chance of a body on which this force is acting receiving in time δt an increment of momentum is $\delta t/D$, where T is the average time between two increments and is a measure of the fineness of the time structure of the electric field. Let I be the increment of momentum given at each impact; then the expectation of the increase in momentum in time δt is $(I/T)\delta t$. If the force had been continuous and equal to F, the increase in momentum would have been equal to $F\delta t$ and have had a definite value. On the intermittent view, instead of a certainty we have an expectation: sometimes the results will exceed expectations, sometimes they will fall below them; but on the average, when there are a great many increments, *i.e.* when δt is large compared with T, they will differ but little from the expectation, so that the increase of momentum will be $(I/T)\delta t$, or the same as the body would receive from a continuous force $F = I/T$. Thus for effects lasting for times long compared with T, the results will be very nearly the same whether the forces are continuous or discontinuous; but for shorter times they will be very different.

We may illustrate the difference between a continuous and an intermittent force by considering a simple case. Take that of an electron projected horizontally and exposed to the influence of a vertical force for a time t. Whether the force be continuous or intermittent the horizontal velocity will remain constant and the horizontal distance travelled is not affected by the intermittence of the force. When the force is continuous and constant there is only one orbit, the parabola. If the force is intermittent there will be an infinite numb of possible orbits. In fact any polygon is a possible orbit, provided the rth side makes an angle with the horizontal such that tan $\theta r = kr$, where k is a constant. Thus a horizontal straight line is a possible orbit, because there is just a chance that the electron may escape a collision for the time t.

There is an infinite number of two-sided orbits where the electron makes one collision in the time t. At the end of these orbits all the electrons have the same kinetic energy, but they will not all have suffered the same vertical fall, *i.e.* they will not all have the same potential energy; this is an illustration that the

[1] From the Seventeenth Kelvin Lecture, delivered before the Institution of Electrical Engineers on April 22.

conservation of energy in the ordinary sense does not hold for these intermittent forces. To get the same increase in kinetic energy as they would under the action of a continuous force, some of the electrons under the intermittent force would have lost less, others more, "potential energy" than they would under the continuous force.

Again, there is an infinite number of 3-, 4-, 5-sided orbits; there is no limit to the number of sides, and the greater the number of sides the greater the kinetic nergy acquired by the electron describing the orbit. ll these are possible orbits, but some of them are very probable. We can calculate the probability of any of orbit. We have already seen that the most bable number of sides for the orbit is t/T; this m kes the final momentum have the same value and dir tion as it would under the continuous force. But the number of sides is given, the individual side y have very different lengths. We can show that most probable orbits are those where the impad are equally spaced over the journey. Again, the m probable orbit is the one that approximates most ly to that described under a continuous force. is, however, only when t/T is a very large number that the chance of orbits departing widely from this becomes inconsiderable.

I have already pointed out that the principle of the conservation of energy in its usual form does not apply when the forces are discontinuous. This is because the energy is stored in the particles which constitute the electric field, and the distribution of these particles and their energy may change, even though the electrons and positive particles do not move: an electron may take energy from these particles or give up energy to them without suffering any change in its potential energy.

Take, for example, the case of an electron starting from an infinite distance from a positive particle, falling close to the particle and then receding from it until it is again at an infinite distance away. The potential energy is the same at the beginning and end, so that if the principle of the conservation of energy holds, the kinetic energy at the end must also be the same as at the beginning. If we suppose that the mass of the positive particle is infinite compared with that of the electron, so that it absorbs no kinetic energy, the velocity of the electron at the end of the journey must be the same as that at the beginning.

This need not, however, be the case if the force is discontinuous, for when the electron is falling from aphelion to perihelion the increase in its kinetic energy depends upon the number of increments of momentum it receives during its journey from aphelion, and when it goes away from perihelion to aphelion its loss of energy depends upon the number of increments of momentum it receives on the return journey. Now, according to the intermittent theory of the force, these numbers are not fixed but are a matter of chance, so that there is a finite probability that the electron on its journey from aphelion to perihelion may receive more than a normal number of increments, whilst on the return journey it would receive less. If this were so, the electron would receive more energy in its approach than it would lose on its return, so that it would have gained by the journey kinetic energy without losing potential.

The chance of losing more energy on its return than it gained on the approach is just as great as in the case we have considered, so that some electrons may lose kinetic energy by the journey without gaining potential energy. The fact that it is possible for an electron to gain energy in this way has, I think, an important application to the question of the spontaneous dissociation of atomic systems.

Let us take the case of an electron describing an elongated orbit about a positive centre, and suppose that in going from aphelion to perihelion it receives more than the normal number of increments of momentum; when it gets to perihelion it will have more than the normal amount of kinetic energy. Suppose that the increments in the return journey are not more than normal, then on reaching aphelion again the electron will have more kinetic energy than when it started. If this increase in energy exceeds a certain amount, *i.e.* if it is so great that when the electron approaches the place from which it started it has sufficient energy to carry it against the attraction of the positive centre from this place to an infinite distance, the electron will break away and separate from the positive centre.

In this way the discontinuous character of the force may give rise to a spontaneous dissociation of the system—spontaneous in the sense that it is a consequence of the character of the forces acting between the members of the system, and does not depend upon collisions with other molecules or electrons or on the influence of radiation.

An example of this spontaneous dissociation is afforded by the negative ions in gases; these have two phases, one being the electron, the other a complex of the electron and one or more molecules. The first phase is continually passing into the second by the combination of electrons with molecules, and the second into the first by the dissociation of the complex. The rate of this dissociation is independent of the pressure of the gas, and there is no evidence that it is affected by radiation. Similar considerations show that when the force is intermittent an electron moving past a positively electrified particle may acquire or lose energy by the collision, even though the mass of the particle is infinitely greater than that of an electron, when if the force were continuous there would be no transference of energy to or from the electron. Thus it might be possible for an electron projected with less than the energy required to ionise a gas to acquire by collisions with positive particles enough energy for this purpose.

Let us now consider more in detail other characteristics due to the intermittence of the electric force; these will naturally occur only when the phenomena involve times short enough to be comparable with the time interval of the electric field. This time interval, we may say in passing, is not constant but varies with the strength of the electric field, diminishing as the strength of the field increases. Now suppose the electric field acts on an element of volume which contains a very large number of systems, be they electrons, atoms, or anything else which can be effected by electric force; and suppose the time t the force acts is small compared with T the time interval of the force. We can easily show that the momentum received by

the whole system will be the same as if the force had been continuous and equal to I/T. This will be true whatever the time may be during which the force acts. The distribution of momentum will, however, be very different in the two cases, when the time of action is small compared with T.

The difference between the continuous and the intermittent force is accentuated when the forces are reversed after short intervals. If the field is intermittent and t is small compared with T, only a small fraction of the systems will have received any energy. When the field is reversed, the chance that any of the few systems previously excited will receive negative momentum and so lose energy is exceedingly small, and the great majority of systems which receive energy in the second interval will not have received any in the first. Thus the systems absorb practically as much energy from the electric field in the second interval as they did in the first. Under the continuous field, instead of absorbing energy, in the second period they gave up all they had got in the first.

Thus the intermittence of the field may lead to a great increase in the absorption of energy from alternating fields by systems exposed to the action of the field. The question of the transmission of waves of electric force when the period of the wave is shorter than the time interval of the electric force, is therefore one that introduces considerations quite different from those of electrical waves of longer period, and requires special treatment.

In the first place, the equations of the electric field do not, if we take the view of the intermittence of force, represent relations between physical quantities which have an existence at any particular time; they have respect rather to the relations between certain statistical quantities, averages taken over a time which is long compared with the time interval of the electric field; for these equations represent relations between electric and magnetic forces. From the point of view of the intermittent theory, electric and magnetic forces do not represent anything that is happening at any particular instant, but an average taken over a time which is long compared with the time interval of the electric field. Thus these equations are meaningless when the times available are not long enough to allow this average to have a definite value. They would not apply, for example, to the case of electrical waves if the period of the waves were less than the time interval of the electric field.

The consideration of what would happen to electrical oscillations the period of which is shorter than the time interval of the electric field, is a matter of great interest and importance. The time interval T of the electric force is connected with F, the intensity of the force by the relation $F=I/T$, where I is the momentum communicated at each impulse, so that as the intensity of the electric field diminishes I/T diminishes also. Now, whatever view we may take of the origin of the impulses which produce the force, whether, for example, we regard them as due to collisions with a swarm of very minute particles or in any other way, we should expect the interval between the collisions to increase as the field gets weaker. The time interval would be a function of the intensity of the field and would be longer for weak fields than for strong. Now consider an electron oscillating with a definite period T_0. Close to the electrons the electric field may be very intense, and its time interval may be short compared with T_0, the period of the oscillations. In such a region as this the classical theory would apply and electrical waves would travel through it, starting from the source of the oscillations. But as the distance from the source increases, the electrical field gets weaker and the time interval continually increases until when a certain distance is reached the time interval becomes comparable with T_0. When this region is reached it seems clear that the waves must stop, as Maxwell's equations from which the wave motion is deduced do not hold.

We have seen too that when T_0, the interval between the reversals of the electric force, is small enough to be comparable with the time interval, the absorption of the energy of the electric field is far greater than when T_0 is long compared with the time interval. We should not therefore expect these waves to travel farther away from the source than the place where the time interval of the electric field is equal to the period of the oscillations. For oscillations of very long period the critical place would be one where the time interval is long, *i.e.* where the field is very weak, and thus may be at a very great distance from the source; whilst for oscillations of very short period the critical place would be one where the time interval is short, *i.e.* where the force is very intense, and thus, *ceteris paribus*, much closer to the source of oscillations than for the slow vibrations.

As an illustration we may take one often used by Lord Kelvin. This is the case of a tightly stretched long string loaded at equal intervals with equal masses. This system has many periods. If P is the fastest of these, $P=\pi\sqrt{(lm/T)}$, where T is the tension in the string, m the mass of one of the particles loading the string, and l the distance between two adjacent particles. If one end of the string is agitated harmonically with a period p, waves will travel freely along the stretched string as long as P is less than p. If, however, the string is made more sluggish by increasing the mass of the particles or otherwise, so that p becomes less than P, the string will no longer transmit the waves, and the energy, instead of travelling along the string, will be localised close to the extremity which is agitated. The model would resemble the electrical case more closely if, instead of spacing the particles at equal intervals, the distance between two adjacent particles increased with the distance from one end A of the string; the value of P would increase with the distance from this end. If the end A were agitated harmonically with a period greater than the value of P close to A, but less than the value of P at some distance from A, the waves would travel along the string until they reached the place where P was equal to the period of agitation. Here they would be reflected back and the farther parts of the string would be free from agitation.

To return to the case of the vibrating electron; we see that though it may send out electrical waves, these waves, after travelling through a distance which depends on the period of the vibrations and also upon their amplitude, will reach a region through which they cannot penetrate, and will be reflected back. Thus the energy emitted by the radiator will not travel out

into space but will be reflected back and again absorbed by the radiator, and thus there will be no escape of energy.

If the oscillations were due to an electron describing a circular orbit, the reflected waves when they struck the electron and gave up their energy to it would, in general, deflect it and cause it to describe a different orbit. Thus the motion of the electron would not be steady. There may, however, be some orbits where the distance of the boundary at which the reflection takes place from the orbit is such that the reflected waves are in such a phase when they reach the electron that they just compensate for the changes in the motion of the electron produced by the emission of the radiation. For such orbits the uniform circular motion might be a steady state. It is evident that certain conditions have to be fulfilled for this to happen, so that it is only orbits with particular periods which possess this property. Since the application of a strong electric force would diminish the time-constant of the field, these orbits would be displaced by electric force. We may illustrate this point by the case of a piston vibrating at one end of an organ pipe which is closed at the other. In general, the waves reflected from the closed end will influence the motion of the piston, but they will not do so if the period of the piston is such that a loop of the vibrations of the pipe coincides with the position of the piston.

Let us apply similar considerations to light waves. Assuming that light is an electrical effect, we see at once that there can be no unlimited propagation of spherical electrical waves diverging from a source such as is contemplated in the usual conception of the electromagnetic theory of light; for on this view energy in the light is distributed continuously through space, and the energy per unit volume diminishes indefinitely as the light travels farther and farther away from the source. Now we have seen that the condition for the propagation of a periodic disturbance is that the period of the disturbance should be greater than the time interval of the electric field; this interval increases, however, as the energy in the light diminishes, so that when the energy falls below a certain value, which is small for long-period vibrations and large for short-period ones, any further propagation is impossible. Thus the intermittence of electrical force demands a corpuscular theory of light, *i.e.* a theory where the energy is done up in bundles which do not alter in size as they travel through space. The bundle may consist of a periodic distribution of electric force, like a piece cut out of what on the classical theory represents a beam of light. This piece is prevented from spreading because the energy density at its boundary has the critical value, and this boundary acts, on our view, like a reflecting surface and sends back any disturbance which tries to get outside it.

I picture these units as consisting of two parts: a central core in the form of an anchor ring, the plane of the ring being at right angles to the direction in which the unit is travelling. This ring is the seat of an intense electric field, and the circumference of the ring is equal to the wave-length of the light. This ring corresponds to the quantum of the light. This ring vibrates and emits electrical waves which, after travelling to a certain distance from the centre, get to the limit where the time interval of their electric field is equal to the period of the light. This forms the boundary of the unit, and the space occupied by the waves and the energy in them remain unaltered as the unit travels through space. On this view, light has a dual structure consisting of electrical waves with a quantum as the core. The electrical waves give rise to interference effects, the quanta to the photo-electric ones.

On the view that the force is intermittent the electric field must have a structure, and as electrons and positive particles are the centres of intense electric fields, they are probably much more complex than the usual conception of them, and must be regarded as centres of complex systems associated with an electron or a positive particle. If we compare the atom with its electrons to a solar system, we may compare an electron or a positive particle to the centre of a nebula and regard the electron as surrounded by an atmosphere of small particles.

This atmosphere can be distorted by the presence in its neighbourhood of other electrons or positive particles with their atmospheres, and will assume a shape appropriate to its surroundings. Thus the atmosphere round an electron far from other charges would be symmetrical and, if it were distorted, would vibrate about the symmetrical shape. Thus we could have vibrations associated with single electrons or single positively charged particles, even though the electron or particle were itself at rest; for example, without becoming neutralised by the absorption of an electron, a positively electrified hydrogen atom might be able to give out radiation. The possibility of vibrations of an electric field apart from any movement of the charges in the field has not, I think, been sufficiently realised.

These considerations suggest that just as matter is made up of molecules, and molecules are made up of electrons and positive particles, this is not the end of the story; there are still other worlds to conquer, the worlds which build up the electrons and positive particles.

Coal Ash and Clean Coal.[1]

IT is the normal view that the incombustible par of coal is not only a useless but even objectionabl diluent. At times in the past, chemists, familiar wit the theory of contact catalysis of gas reactions, hav speculated that the ash constituents might well pla an active rôle in the processes of carbonisation an combustion. None have been more prominent thai Dr. Lessing, but his opinions met with no great support The reactions in question seemed too complex, and n experimental confirmation had been adduced. Evei Dr. Lessing himself waited until 1924 before disclosin evidence that inorganic substances altered the cours of carbonisation. Since then, however, the subjec has aroused greater interest. It is possible now fo

[1] Cantor Lectures by Dr. R. Lessing before the Royal Society of Art Nov. 23, 30, and Dec. 7, 1925.

Dr. Lessing's ideas to receive independent support. Processes have even been patented for modifying the results of coal carbonisation by means of control of the ash constituents.

In the Fuel Department of the University of Leeds, where the process of gasification of coal has been under experimental study for some years, it was soon observed that the inorganic constituents could not be ignored. They might be incombustible but were not necessarily inert. It was the availability in the West Yorkshire area of seams of coal almost free from ash which made it possible, by the controlled addition of inorganic matter, to investigate the influence of individual compounds on carbonisation. The results exceeded expectations, and it was shown by C. B. Marson and J. W. Cobb that the character of the coke produced was beneficially and extensively modified by the addition of certain substances, especially oxide of iron and sodium carbonate. Certain other oxides examined were apparently inert. Since the publication last year of this paper, further experience has only strengthened their conclusions. There is good ground for hope that a valuable control over the carbonisation process may be secured by means of the ash constituents. Indeed, it is no exaggeration to say that there is to-day no prospect in the distillation of coal more alluring than that offered by this method. Obviously, then, the subject is of great practical interest, especially in connexion with the production of smokeless fuel. It may well be that too much attention has been paid to the possibilities of varying temperatures of carbonisation, and too little to the variation of the character and quantity of the incombustible constituents. This oversight is, however, in the way of being remedied.

It is, however, a condition precedent to the most effective use of this new method of control, that the raw material, coal, shall be adequately clean to begin with. Any coke or smokeless fuel product will have to compete for popular favour with good household coal, which may in the best cases be even so low in ash as 2 per cent. It is, unfortunately for those who set out to provide smokeless fuel, only too true that the housewife is apt to think more of dirt on the hearth than of smoke leaving the chimney-pot. If the carbonised product is to contain added inorganic matter, as well as the ash originally present, it is obviously essential that the raw coal must be very clean, for the ash content of the coke produced from it will necessarily be higher. Nothing is more important to the popularisation of smokeless fuel than the supply of clean coal. The stigma which rests on coke as a fuel is largely due to a reputation for 'dirtiness,' and the smokeless fuel problem can never be regarded as solved until a product is obtained which will find favour in the drawing-room of the most fastidious householder.

It is, however, essentially a problem for the mining industry, and its solution would give a powerful fillip to the popularisation of carbonised fuel for domestic purposes. The problem implies the identification of seams of coal which lends itself to cleaning, the improvement of cleaning technique, and the installation of plant necessary to turn out a fuel of the desired standard. The consumer would have to pay more for the product, but it would be necessary and possible to demonstrate that he was not a loser. Time, study, and capital would be required to carry these ideas into effect. It is then the more depressing to see the mining industry dissipating energy and resources of all kinds in a barren struggle instead of wrestling with its own more fruitful problems.

Dr. Lessing believes that these objects will be attained, that the carbonising industries "will feel constrained to insist for their raw material on coal containing only a fraction of the proportion of mineral matter which is customary to-day," and "that the provision of such a commodity will be technically possible and commercially profitable, and that it will be of economic advantage both to supplier and user."

The three lectures are, however, not confined to the importance of ash to coal carbonisation. They also traverse the chemistry of coal ash and its origin, the technique of coal cleaning, the economic aspects, and present a valuable survey of the whole subject.

H. J. HODSMAN.

Obituary.

DR. C. W. ELIOT.

AT a luncheon recently given by King's College, London, for the delegates to the Congress of the Universities of the Empire, Principal Barker introduced President Lowell as "the most distinguished permanent academic officer in the English-speaking world." The phrase was happily taken, and its substantive truth dates from Charles William Eliot, whose death on August 22, fuller of honours even than of years, removes the last survivor of the three captains who bridged the incredible gap between the primal 'college' and the contemporary university; the others were Angell (Michigan) and Gilman (Johns Hopkins). They mediated a change wherein sober fact nigh outruns imaginative fiction. Eliot, the most conspicuous, foresaw the unbelievable, and it came true.

Circumstances must conspire with men to produce significant results. Accordingly, Eliot was fortunately born (1834) from the soundest New England stock, and educated at the best New England institutions. After graduation at Harvard in 1853 he taught mathematics and chemistry in the College and the Medical School for a decade; resided two years in Europe (1863–65), observing the universities shrewdly; returned to occupy the chair of chemistry in the Massachusetts Institute of Technology, where he pioneered for four years. In 1869, after keen opposition, still the subject of piquant legend, he was elected president of Harvard, and launched upon a unique incumbency of forty years. He found the College (1636) with Medical (1782), Divinity (1816), and Law (1817) Schools of a narrow type; he left the foremost American university with a transformed College and a score of other departments.

As the Harvard inscription bears, the New England College was founded "to advance learning and perpetuate it to posterity, dreading to leave an illiterate ministry to the churches"; or, as the Yale charter runs, "fitting youth for public employment, both in church and civil society." In other words, vocation, and one vocation mainly, took precedence over the

advancement of knowledge. Moreover, although Agassiz used a Charles River shed for a laboratory so early as 1848, acquaintance with the natural sciences was usually confined to little physics and less astronomy. Further, the human sciences, as now understood, enjoyed no independent recognition. While striking persons were to be found on the staffs, they were seldom specialists—Mark Hopkins (Williams) taught all subjects to all undergraduates in their final year! Modifying the clerical and bellelettrist tradition, Eliot, though but thirty-five years of age, set himself to create a new order; in addition, he proceeded to reform the meagre curricula and otiose methods of the professional schools. He agreed with his brilliant colleague Barrett Wendell that "the use of heresy is to vitalise creed." Inevitably, he drew much fire; a rare combination of courage, candour, penetration, patience, above all, aplomb, enabled him to make very rough places plain. Under his leadership Harvard rose to unchallenged primacy in twenty-five years, and the example of her chief began to affect academic policies from coast to coast. Blunders were perpetrated in his name and, being human, he added his personal quota. But in sum and substance he won universal recognition as a national asset.

Eliot's remarkable dignity of address and statement came to him by right of heritage. Democratic puritanism, bred of self-understanding, flowered in a peculiar aristocracy, secure in appeal to sense of duty. Eliot was its most conspicuous example. For, elevated far above sordid affairs, his qualities were means to spiritual ends; thus he could confront the American people as a vocal public conscience. He said his say with none to gainsay on grounds of petty interest. He blandly exposed illusions and dangerous symptoms, protesting against the mediocrity of efficient technique as a peril incident to universal education; telling his countrymen that, after all, they must apply for guidance to the select minority who know; insisting upon the equality of every subject open to sober investigation.

Hence, although the United States had passed to another phase during the period of his retirement, he could still speak forthright to the very end. He contributed to science in particular by affording ample facility and genial stimulus to inquiry. His was an exceptional life, because he rose greatly to a great opportunity. Attempting to sum it in a phrase, one might perhaps venture to say that he furnished a striking illustration of that peculiarity of American culture which most baffles other nations—"the parts are greater than the whole." R. M. WENLEY.

MR. W. FAWCETT.

WILLIAM FAWCETT, who died suddenly at his residence at Blackheath on August 14, in his seventy-sixth year, was originally a schoolmaster and graduated B.Sc. at the University of London. In 1880 he was appointed assistant in the Botanical Department of the British Museum, shortly before the collections were transferred to South Kensington. In 1881 he became a fellow of the Linnean Society, from which he withdrew in 1915, but rejoined in 1923.

On December 29, 1886, Mr. Fawcett sailed to take up his appointment as director of Public Gardens and Plantations, Jamaica, a post he retained after the amalgamation in 1903 of the Botanical Department with the Department of Agriculture until his retirement in March 1908. He edited the *Bulletin of the Botanical Department*, Jamaica, from April 1887 until 1902, and the *Bulletin of the Department of Agriculture* from 1903 until his departure in March 1908, when a new series of the latter was commenced by the Hon. H. H. Cousins, the present director. A note on this department was published in the *Kew Bulletin*, 1906, p. 68. In addition to notes in these journals, he published in 1893 "A Provisional List of the Indigenous and Naturalised Flowering Plants of Jamaica," and in the same year "An Index to Economic Products of the Vegetable Kingdom in Jamaica." He also delivered lectures, one of which, an "Introduction to the Classification of Plants," was published at Kingston in 1889. "Historical Notes on Economic Plants in Jamaica" appeared in vol. 6 of the *Bulletin of the Department of Agriculture*, and dealt largely with cigar and tobacco production. After returning to England he commenced, in collaboration with Dr. A. B. Rendle, a flora of Jamaica, the first volume of which, on Orchidaceæ, including text-figures, was published in 1910, and vol. 5 in July 1926; vol. 2 has yet to appear. Most of the work for this was done at the British Museum, but Mr. Fawcett frequently visited Kew to consult the collections there, his last visit being so recent as July 29 last.

As the titles of some of the above-mentioned papers show, Mr. Fawcett was keen on developing the applied side of botany, and in 1913 published a book entitled "The Banana: Its Cultivation, Distribution and Commercial Uses." During his residence in Jamaica he rendered valuable service in developing the vegetable resources of the island, in association with Sir Daniel Morris, the commissioner of the Imperial Agricultural Department of the British West Indies, after the threatened failure of the sugar crop. To Mr. Fawcett was also due the inception of the Imperial Exhibition in Jamaica in 1891. C. H. W.

WE regret to announce the following deaths:

Dr. J. George Adami, F.R.S., Vice-Chancellor of the University of Liverpool, on August 29, at sixty-four years of age.

Dr. R. D. Carman, president of the American Roentgen Ray Society and chief of the section of radiology of the Mayo Clinic, known for his work on the radiology of the digestive tract, on June 17, aged fifty-one years.

Mr. Charles A. Coffin, founder and former president of the General Electric Company, who was responsible for the organisation of the research laboratory at Schenectady, on July 14, aged eighty-one years.

Dr. Willis T. Lee, sometime professor of geology and biology in the University of Denver, and geologist since 1902 of the United States Geological Survey, who studied the stratigraphy of the south-western States with particular reference to ground water and coal investigations, on June 17, aged sixty-one years.

Mr. Frank M. Woodruff, for many years curator of the Academy of Sciences and Museum of Natural History in Lincoln Park, Chicago, and secretary of the ornithological section of the Chicago Academy of Sciences, on July 21, aged fifty-nine years.

News and Views.

THE German Dye Trust, the actual title of which is the Interessengemeinschaft Farbenindustrie Aktiengesellschaft, has long been in the limelight as the largest and most powerful combination of its kind. Only last year its constituent companies entered into a form of union that is indistinguishable from an amalgamation, and their combined capital was increased to 646 million marks (say, 32,300,000*l.*); now it is announced that the capital is to be raised to the enormous figure of 1100 million marks (55,000,000*l.*). It is well known in chemical circles that dyestuff-manufacture now represents only a very small part of the activities of the I.G. Before 1914, Germany supplied 75-80 per cent. of the world's requirements in dyes; to-day its export trade is relatively very small, and except for a marked revival in exports of zinc oxide and 'lithopone,' it is continually diminishing, whilst importations are steadily increasing. In the opinion of many German industrialists, the practical monopoly enjoyed before the War is unlikely ever to be regained. Manufacture of dyestuffs and pharmaceutical products has now become of inferior importance to that of fertilisers, such as synthetic ammonium compounds and urea, and these materials are responsible for most of the profits made. Nothing is more astonishing than the development of the nitrogen-fixation industry, and the long-threatened competition between it and the Chilean nitrate industry has materialised, to the great discomfiture of the latter. The most fundamental factor in the nitrogen-fixation industry is the cost of hydrogen, and every effort is being made to reduce this cost by extending its uses. This accounts for the interest which the I.G. is taking in the hydrogenation of coal and peat, and in the artificial production of light motor-fuels.

THE ramifications of the German Dye Trust are too intricate and deep-seated to be divined by those outside the inner ring; and they are probably very numerous, if one may take a line from the activities of some of our own large chemical undertakings, the interests of which are known to extend far beyond the sphere of industrial chemistry. A letter from the Frankfurt correspondent of the *Times*, printed in its issue for August 27, throws a little light upon the ever-extending interests of the I.G. and upon the uses to which the new capital may conceivably be put. It may be taken as fairly certain that a good proportion of it is earmarked for developing and extending the nitrogen plants and for financing the rapidly increasing trade in nitrogenous products. The fact that compound fertilisers are in chief demand to-day in Germany, necessitates abundant supplies of phosphates and potash, and it is confidently asserted that the I.G. is contemplating some arrangement with the powerful Potash Syndicate. By absorbing the important Köln-Rottweil explosives company, the Dye Trust has obtained a dominant position in the German artificial-silk industry. That industry has already come to terms with certain foreign producers—including, it is stated, Messrs. Courtaulds—and rumour now says that an understanding with French and Italian manufacturers is in prospect. The Dye Trust, through one of its subsidiaries, is the largest producer of raw films in Europe; co-operation or fusion with its two chief competitors, the Eastman Kodak Co. and Pathé Frères, is said to be maturing. Rumour is also busy with the industrial exploitation of the Bergius process, although its commercial success is by no means assured. The board of the I.G. has officially announced its intention to erect a large plant "for the liquefaction of coal," but it has not stated which process is to be adopted. In many quarters it is believed that the statement refers to the manufacture of light motor-fuel by a process other than the Bergius, and that it is this other process which is the subject of negotiations with British, Dutch, and American petroleum companies.

ALL who are interested in bibliography and in scientific organisations, particularly from the international point of view, will welcome the appearance of the first issue of the *Bulletin for Scientific Relations*, dated July 1926, which has just been published by the International Institute of Intellectual Co-operation of the League of Nations (price per annum, 24 francs, France; 2 dollars for other countries). Written mainly in French, partly in English, the journal deals with many phases of scientific activity, including the results of inquiries initiated by the Institute itself. In the first section, which is devoted to bibliography, general and special, and to libraries and research centres, nothing strikes one more than the interest which Russia is showing in these matters. Soviet Russia is stated to possess 28 libraries containing 50,000 volumes or more, and in these are located more than 16 million volumes, the public library in Leningrad alone containing 4,134,000—the largest library in the world. Moscow has 140 scientific libraries, about 100 of which have been established since 1917, and in May 1925 a bibliographical library containing more than 10,000 volumes was opened to the public. The library of the University of Amsterdam has been enriched by a gift of 10,000 French scientific books. Berlin possesses an information bureau for books and monographs that informs scientific workers where any desired book may be found, as well as a Government central office for scientific information, which co-ordinates bibliographies relating to natural science and procures either original or photostatic copies of the publications mentioned therein. Athens can now boast of a new library, housed in a fine building presented by the Carnegie Institute, and named "Bibliothèque gennadienne," after Gennadios, a former Greek minister in London, whose gift of books to the Greek Government is located in the library.

UNDER the heading "International Scientific Organization," the *Bulletin for Scientific Relations* records that in answer to a *questionnaire* sent out by the International Union of Academies concerning an international language, nine academies replied that they would prefer a living language to an artificial one; Italy asked for Latin, and Japan for Esperanto. This section contains a long report from the International Bureau of Meteorology, also references to the

establishment of microbiological institutes at Moscow and Buenos Ayres, and to the projected opening of a branch of the Pasteur Institute at Montreal. Under "National Scientific Organizations" mention is made of the proposal to remove the anthropological, prehistoric, and ethnographic collections from the Museum of History at Vienna, and to use them for the nucleus of a new "Kulturhistorisches Museum." A Kaiser-Wilhelm Institute for silicate chemistry has recently been founded in Berlin, with Prof. W. Eitel as director. In France a Petroleum Institute has been opened at Strasbourg. In Greece the Academy of Athens has been founded and inaugurated in a building which was intended for this purpose forty years ago. The Academy has three classes of members: pure and applied sciences, literature and fine arts, and moral and political sciences, the number of members in them being restricted to 25, 20, and 15 respectively. In Germany an institute for Chinese students studying in the University of Frankfort was opened at the end of last year.

MR. ERNEST MACKAY'S summary of the results of the Oxford University and Field Museum Expedition to Kish during the past season, in the *Times* of August 25, affords striking evidence of the importance of this site for the early history of civilisation in Mesopotamia. No less than three considerable buildings have been brought to light this year. Of these, one, a temple of Nebuchadnezzar, with walls standing 18 feet high, which is one of the best preserved in Mesopotamia, has another large building of the period of Hammurabi (2100 B.C.) beneath it, and possibly earlier buildings at a still lower level. A ziggurat of Sargonic date (2752 B.C.) is of unusually large proportions, while another building adjoining the Nebuchadnezzar temple is constructed of mud bricks of a size which points to the age of Dungi (2250 B.C.). The discovery of the greatest significance, if the interpretation offered be correct, comes from Jemdet Nasr, a mound on which were discovered fragments of painted pottery, both monochrome and polychrome, and the inscribed signs emerging from the pictographic state to which attention was directed at the time of their discovery in their relation to the evolution of writing from pictographic signs to the later cuneiform writing. The excavation of this mound showed that it belonged entirely to one period (*circ.* 4000–3500 B.C.), but a building discovered there proved to be built, not of the characteristic plano-convex bricks hitherto thought to be the earliest in date in Babylonia, but of a well-made rectangular brick, differing in size and shape from the later rectangular brick which ousted the plano-convex brick. It is thought, therefore, that the latter—an obviously inferior type—must have been introduced by a race of invaders and have entirely superseded the earlier form in Northern and Southern Sumeria, as there is no evidence that the two types were ever in use at the same time.

THE August number of the *Review* issued by the British Brown-Boveri Co. gives an excellent illustration of the trend of electrical development. We learn that Messrs. Brown-Boveri, the famous Swiss firm, is constructing for the New York Edison Co. a turbo-alternator set of 160,000 kilowatt capacity suitable for continuous running. As only a few stations in Great Britain have an output so large as this, it will be seen that it is a bold undertaking. The high steam pressure part, 265 lb. per sq. in., is to drive an alternator of 75,000 kilowatts at 1800 revolutions per minute, whilst the low pressure part drives an alternator of 85,000 kilowatts at 1200 revolutions per minute. This will be the world's largest turbine.

ANOTHER direction in which the Brown-Boveri Co. is specialising is in the manufacture of automatically controlled sub-stations. The importance of these stations in railway work has been long recognised. They are more expensive to build than hand-controlled stations, but the great saving in wages almost invariably makes their adoption advisable. There is no need to consider problems relating to the housing of the staff, and so the most economical site can be chosen. In a recently constructed sub-station for a Swiss railway they have installed a 300-kilowatt rectifier set which converts 8000 volts alternating pressure into 800 volts direct pressure. There is in addition a 300-kilowatt rotary converter for performing the same function. A time switch in the morning sets the rectifier into operation. If a long period of overload occurs a thermal relay operates and the rotary converter operates in parallel with the rectifier. If for any reason the converter failed to act and the rectifier was excessively overloaded, safety devices would act and an alarum would be sounded. In the event of a sudden serious disturbance, the relay tests whether the cause is permanent or not. It operates three times at intervals of ten seconds, and if the disturbance persists it shuts down the whole set. Even when the load is only one-third of the full load, the efficiency of the conversion at the sub-station is 92·5 per cent.

WE have received from Mr. Arthur MacDonald of Washington, D.C., a statement of proposals which he has put before the United States Senate advocating the extension of anthropological studies in certain directions. Among other matters he stresses the importance of the study of man after death, especially in the case of those who have been prominent in the political and scientific world. It is interesting to note that since the beginning of the last century the brains of quite a large number of prominent Americans, including Abraham Lincoln, Lewis Aggasiz, and Walt Whitman, have been studied after death. Mr. Macdonald has also opened up a new line of inquiry in studying the political activities of American senators. In the sixty-second Congress, which lasted over three sessions, he found that the attendance was better in the first and third sessions than in the second, while Progressive Republicans showed a higher percentage of voting than Conservative Republicans. Business men attended quorum calls more and "yea and nay" calls less than professional men, but professional men averaged higher than business men in their frequency of remarks on the

Senate floor. Curiously enough, success in both public and private legislation varied inversely with education; that is, the better educated the senator, the less his success in legislative activity. Mr. MacDonald maintains that continuous study on these lines and a comparison with similar studies of legislatures in other countries should prove valuable, and probably lead to modifications of legislative procedure. It must be confessed that the utility of these studies is not immediately apparent. Abstract studies on statistical lines of political activities, such as frequency of voting in division, introduction of legislation, public and private, and the like, can have little scientific value when considered *in vacuo* and apart from attendant conditions which, from the nature of the case, it is almost impossible to ascertain.

PROF. A. F. C. POLLARD has prepared a Subject Index to volumes 1-25 of the *Transactions of the Optical Society* on the lines set out in his manual on the Decimal Bibliographical Classification of the Brussels Institut International de Bibliographie recently published by the Optical Society. It is printed on one side of the paper only, so as to be suitable for gumming to the ordinary 5 in. × 3 in. catalogue cards. A paper appears under each subject with which it deals, and to each subject is assigned a number, as in the original Dewey decimal system of 1876. This number appears at the right-hand top corner. At the left on the line below is the name of the author. Next below is the date in the order 1923.05.24 and the descriptive title. On the next line the reference in the order-title of publication, volume, year, pages. The manual explains the system of notation, which from 535 = Light gives 535·5 = Polarisation, 535·54 = Chromatic Polarisation, and 535·543 = Colours of thin Plates, and with (02) for Treatises gives 535(02) = Treatises on Light. The system was adopted at Brussels in 1899, but was not used in the International Catalogue of Scientific Literature, where Light had the range 2990–4470 assigned to it. As a system it appears both concise and comprehensive, but it has not yet been accepted as international, although it has been in existence more than a quarter of a century.

PROF. POLLARD'S Subject Index introduces an innovation into the method of indexing individual scientific journals, and it will be interesting to see with what favour the scheme is received and how far the movement will extend to other learned societies and journals and lead to some uniform and standard method of indexing. For, although the Dewey system has been adopted extensively in the libraries of Great Britain for their book classification, the Brussels scheme for indexing periodicals has not so far found much practical application. A few, notably French journals, habitually arrange their monthly abstracts of current literature in this order, and some, including certainly one English, even label the original articles in each issue with the appropriate Brussels notation, but none as yet, we believe, has extended the system to annual or consolidated indexes.

IN the June issue of *Medical Life* (vol. 33, p. 261), Prof. Tenney L. Davis has a short note on Boerhaave's attitude toward alchemy. A remarkable feature of the "Elementa chemiae," a book which did much to establish its author's reputation, is that it does not discuss the phlogiston doctrine of Stahl, and Prof. Davis interprets this silence to mean that Boerhaave thought the doctrine unimportant. Boerhaave, in short, was interested in facts, and was always ready to weigh and consider. This trait made him extremely tolerant and sympathetic in his treatment of the alchemists, whose habits of wide experimentation and careful observation did not, however, prevent him from doubting "whether these skilful persons, after they had discovered so many extraordinary things by naked observations, might not by a too great quickness of apprehension anticipate, and relate things for facts, which they conclude might be done; or even must of necessity have been done, if they had persisted in the pursuit. . . . Credulity is hurtful, so is incredulity: the business, therefore, of a wise man is to try all things, hold fast what is approv'd, never limit the power of God, nor assign bounds to nature."

SOME American museums are accustomed to publish reports of the explorations and travels on which members of the staff have been engaged, while reserving the scientific results for more weighty publications. This has the advantage of encouraging the traveller to observe and note facts subsidiary to his main object, and of preserving a record of details interesting in themselves but not important enough to warrant a formal paper. Thus the Yearbook of the Academy of Natural Sciences of Philadelphia for 1925 contains well-written and well-illustrated accounts of such journeys. Francis W. Pennell describes "Botanical Travel in Peru and Chile," his main objective being the Scrophulariaceæ of the central and southern Andes. Witmer Stone writes on "Past and Present Bird Life of the Southern New Jersey Coast," and publishes some good photographs of terns and skimmers. Samuel G. Gordon reports on a mineralogical expedition to Bolivia and Chile, but manages to introduce photographs of glaciers and mountain lakes.

ANOTHER such volume is "Explorations and Field-work of the Smithsonian Institution in 1925." This contains an account of Dr. Hrdlička's seven months' journey to some of the chief palæo-anthropological sites in the world. The photographs of the locality from which the Pithecanthropus remains were obtained, of the finder of the Rhodesian skull, and of the quarry that yielded Australopithecus, are of particular interest. Dr. C. D. Walcott's geological explorations in the Canadian Rockies, Dr. Bassler's field-work in Tennessee geology, and Mr. C. W. Gilmore's collecting fossil foot-prints in Arizona are among the numerous articles that show the value to the museum of detailing members of the staff for field-work. There are twenty-six such reports in this volume, ranging from field-work in astrophysics

by Dr. C. G. Abbot, to experimental breeding of the mollusc Cerion at the Tortugas, by Dr. Paul Bartsch.

THE thirty-eighth Congress and Health Exhibition of the Royal Sanitary Institute will, at the invitation of the Town Council, be held at Hastings on July 11-16, 1927. The Right Hon. Sir William Joynson-Hicks, Bart., Home Secretary, has consented to act as president of the Congress.

THE eighth International Congress of Psychology will be held at Groningen, Holland, on September 6-11. Sections will be formed for the discussion of eidetic imagery, psychogalvanic reflex, higher psychic processes, animal psychology, psychopathology, and applied psychology. Papers will be read by the following British psychologists: Mr. F. C. Bartlett (Cambridge), Dr. Wynn Jones (Leeds), Dr. Thouless (Manchester), Dr. Aveling, Dr. Ernest Jones, Dr. C. S. Myers, and Prof. Spearman (London). Altogether nearly a hundred papers will be read.

THE issue of *The Fight against Disease*, the journal of the Research Defence Society, for July, contains an obituary notice with an excellent plate of the late Mr. Stephen Paget, who died in May. He was the founder of the Society and of its journal. Dr. J. A. Murray's address at the annual meeting of the Society on "The Experimental Attack on Cancer" is also printed; it gives a good summary of the subject, and tells just how far we have advanced in the knowledge of cancer by experimental methods.

THE Department of Glass Technology of the University of Sheffield has recently published vol. 8, 1925, of its experimental researches and reports, consisting of papers collected from the *Journal of the Society of Glass Technology*, the *Journal of the Royal Society of Arts*, and the handbook to the annual meeting of the Society of Chemical Industry, Leeds, May 1925. Most of the papers describe the work which has been carried out by Prof. W. E. S. Turner, Dr. S. English, and Mr. A. Cousen on the physical properties and the chemical constitution of various glasses. In addition, the publication contains articles on the glass industry and the modern production of sheet glass.

MESSRS. Isenthal and Co., Ltd., inform us that their address now is Ducon Works, Victoria Road, North Acton, W.3, where all communications and inquiries should be sent. The change of address has been necessitated by the expansion of the business, chiefly in connexion with the manufacture of overhead high-tension switchgear, protection apparatus, automatic voltage regulators, etc., all of which now demand more spacious premises than it has hitherto been found possible to devote to them. The manufacture of resistances and the development of some important new lines will also benefit by the greater facilities now at Messrs. Isenthal's disposal.

UNDER the direction of Prof. Doello-Jurado, the Museo Nacional de Historia Natural of Buenos Aires has resumed its custom of distributing a fairly comprehensive "Memòria Anual." That for 1924 (dated 1925) has just been received. It records the celebration of the centenary of the Museum on December 31, 1923, gives an account of the activities of the staff and of the chief accessions, illustrated by 44 half-tone plates, and discusses the proposed new building. Among numerous expeditions, the most noteworthy was that to South Georgia to obtain examples of cetaceans, pinnipedes, and birds. Chief stress, however, is laid on the renewal of collections in vertebrate palæontology. Rich though the museum is in this department, the older material is not always furnished with those precise details of horizon and locality now esteemed indispensable. Among the fossils collected are crania of Scelidodon, bones of Promacrauchenia and Protohydrochœrus from Monte Hermoso, skull and bones of Lestodon and other mammals from the later deposits of Playa de Barco. Apparently the enforcement of the law forbidding the export of palæontological, archæological, and anthropological material before it has been passed by a commission, has proved a difficult and laborious task. It resulted, however, in the retention for the Museum of a fine mandibular ramus of Pyrotherium and a few other desiderata from the collection made by Dr. Elmer S. Riggs for the Field Museum, Chicago.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A European science master at the Agricultural School at Moor Plantation, Ibadan, Nigeria—qualified to teach mathematics, chemistry, physics, and botany to about Junior Local standard—The Secretary, C.A. (N.), Board of Education, Whitehall, S.W.1. Scottish candidates should apply to the Secretary, Scottish Education Department, S E.D. (N.), Whitehall, S.W.1 (September 27). A professor of economics in the University of New Zealand—The High Commissioner for New Zealand, 415 Strand, W.C.2 (September 30). A head of the Department of Chemistry of the Witwatersrand Technical Institute—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (September 30). A museum assistant at the Royal Botanic Gardens, Kew—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (October 4). A whole-time research worker at the Calcutta School of Tropical Medicine for the investigation of hookworm disease from the point of view of its effect on the health on labour forces—The Director, School of Tropical Médicine and Hygiene, Calcutta (November 30). A laboratory assistant for the Veterinary Research Division of the Agricultural Department of the Government of Kenya—The Crown Agents for the Colonies, 4 Millbank, Westminster, S.W.1 (quoting M/14661). A visiting lecturer on engineering quantities and estimates at the Borough Polytechnic Institute—The Principal of the Institute, Borough Road, S.E.1. A director of the National Institute of Poultry Husbandry—The Principal, Harper Adams Agricultural College, Newport, Shropshire.

Research Items.

Pre-hispanic Jewelry in Colombia.—Among the contributions to the session at The Hague of the thirty-first International Congress of Americanists which have recently been published is a description by Dr. Paul Rivet of two collections of pre-hispanic jewelry in gold and gold and copper—one of Chibcha manufacture, the other Antioquian. Although they represent two entirely distinct industries, they have a common technique which is identical on general lines and is also related to the technique of the gold ware of Chiriqui, Panama. The Colombian gold industry was carried by the Chibcha far beyond the bounds of Colombia, and the whole of Ecuador and the Peruvian coastal areas appear to have come under its influence. In the same region an entirely different industry, originating on the Peruvian-Bolivian plateau, has been superimposed. Unlike the Chibcha industry, which is confined to gold and gold-copper, this superimposed industry works in copper, gold, tin, silver, exceptionally lead, and the alloys of these metals. The Chibcha industry, notwithstanding its high development, is probably not indigenous. It may be derived from the industry in an alloy of copper and gold, which the Spaniards found on their arrival among the inhabitants of the Antilles and the area north of the Amazon-Venezuela and the Guianas. This alloy is identical with that of Colombia, and the industry may have been introduced into that area by a Carib invasion. The centre of its origin lay possibly in the hinterland of the Guianas, the legendary site of El Dorado, and may have given rise to that tradition. The antiquity of the Carib invasion must be considerable, as the Chibcha technique appears on the Peruvian coast so early as the proto-Chimu period of Uhle.

Vital Statistics of Southern India.—A study of the vital statistics of southern India, by Major A. J. H. Russell, which appears in the *Scientific Monthly* for July, brings out some interesting points bearing upon the question of the conservation and promotion of the population. Of a population of 41,002,696 (1921), the Hindus form 89·48 per cent., Mohammedans 6·95 per cent., and native Christians 3·2 per cent.; other classes 0·04 per cent. A study of the population curve since the census was initiated in 1871, shows that southern India has very nearly reached an asymptotic population under present conditions. Indeed it has been necessary to import food stuffs during the last few years and, in spite of serious famine years and epidemics, the population is still too large for the methods of cultivation employed. The registered birth rate is 30·0 per 1000, but there is reason to believe that the birth-rate is really so high as 42·5 per 1000. In Madras City, where registration is more accurate, in 1922 it was so high as 41·2, and of 215 towns, 13 registered a rate of 40 to 50. The registered death-rate for the same period was only 21 per 1000, but actually it was probably 33 to 36 per 1000. In Madras City it was 43·1 per 1000. Infantile mortality was very high, although there has been a distinct downward tendency. In several of the largest towns this was so high as 311·6 to 352·8 per 1000, as against the English rate of 80 per 1000. Nearly 50 per cent. occur within the first month. This is attributed largely to the Hindu employment of 'barber' midwives, and it is significant that in the towns, 13·7 mothers die for 1000 births, the rate for the whole presidency probably being much higher.

Roger Bacon and Gunpowder.—In a recent issue of *Archivio di storia della scienza* (vol. 7, 1926, p. 34), Adolf Clément of Copenhagen offers a new and convincing solution of the famous cipher in Bacon's "Epistola de secretis operibus artis et naturae et de nullitate magiae." The passage in question, which it is only right to say has been regarded as of doubtful authenticity, reads: "Item pondus totum 30. Sed tamen salis petrae LURU VOPO VIR CAN UTRIET sulphuris; et sic facies tonitruum et coruscationem, si scias artificium." Lieut.-Colonel H. W. L. Hime interpreted the words in cipher by omitting *et* and rearranging the remaining letters into R. VII. PART. V. NOV. CORUL. V., which he translated "take seven parts (of saltpetre), 5 of young hazelwood (charcoal) and 5 (of sulphur)." Hime's solution (for a detailed account of which see "Roger Bacon Memorial Essays," Oxford, 1914, chap. xii.) has, however, been severely criticised by Lynn Thorndike, and is far less convincing than Clément's. Clément points out that the letters of the words in cipher can be rearranged into "pulveri carvonu tritov," the letters *s*, *m*, and a syllable *rum* at the end of *tritov* instead of *v*, apparently being lacking. It must, however, be remembered, he says, that the cipher was written at an epoch when abbreviations were in common use, and the three final letters of the words as rearranged are really signs of abbreviation, namely, *i* for *ĩ*, *i.e. is*; *v* for *ũ*, signifying *um*; and *v*, in *tritov* for ꝝ, *i.e. rum*. The sentence would then read: Sed tamen salis petrae, pulveris carvonum tritorum, sulphuris, etc.

Arabic Astronomy.—In a recent number of the *Sitzungsberichte der physikalisch-medizinischen Sozietät zu Erlangen* (Band 58, 1926, pp. 33-88) O. Schirmer continues the Erlangen tradition of the study of Islamic science. Inspired by Prof. Wiedemann, Schirmer has investigated some problems of Arabic astronomy, the most interesting being concerned with Arabic determinations of the inclination of the ecliptic. Two pages of figures of these determinations are given, chiefly, as might be expected, for Bagdad, Damascus, etc., though one was made at Toledo by Al-Zarqali. Al-Chugendi's description of his determination at Ray (near Teheran) in 994, for which he obtained the figures 23° 32′ 21″, is very clear. Prof. Wiedemann provides an appendix in which he translates the introduction of an astronomical work by Al-Nasawi; this contains a good deal of noteworthy historical information referring, *inter alia*, to the Aristotle of Islam, Avicenna.

Tabula Smaragdina.—Prof Julius Ruska, of Heidelberg, whose work on the history of chemistry in Islam is well known, has recently published an exhaustive study of the "Emerald Table" of Hermes "Tabula Smaragdina," Carl Winter's Universitätsbuchhandlung, 1926). He deals first with the ancient Hermetic literature, and discusses the conception of the god Thoth among the Egyptians. Passing in review Scott's "Hermetica," he rightly remarks that in sweeping aside all the alchemical books ascribed to Hermes as masses of rubbish, Scott was acting in a high-handed fashion, since "weder der Inhalt noch die Geschichte des ganzen Literaturkomplexes, der unter des Hermes Trismegistos Namen geht, gibt uns ein Recht auf solche grundsätzliche Scheidung und ungleiche Bewertung." A detailed study follows of Hermes and Hermetic literature among the Syrians, Arabs, and Persians, and Prof. Ruska shows that the attribution of the "Tabula" to Greek sources is probably not justified. He gives the Arabic text as found in a work of Jâbir ibn Ḥayyân, and also as it occurs in a collectaneous

MS. in a private library in Germany. He does not give credence to Jâbir's statement that he found the text of the "Table" in a work of Apollonius of Tyana, remarking that all we can be sure of is that by Jâbir's time (eighth century A.D.) a magical, astrological, and alchemical literature ascribed to Apollonius had grown up, but how much of it was genuine, or even from Greek sources at all, it is impossible to say. Prof. Ruska then deals with the "Emerald Table" in its Latin dress, exhibiting a wide and deep knowledge of medieval alchemical literature, but remaining interesting in spite of erudition—or perhaps because of it. The commentary of that enigmatical person Hortulanus is considered, and references to the "Tabula" and other Hermetic writings in Albertus Magnus, Arnold de Villanova, Trithemius, Paracelsus, and others are described. With one or two exceptions, such as the omission of any mention of the work on the "Table" published by Steele and Fulton, the book is extraordinarily complete, and contains everything that is of importance on the subject with which it deals.

HERRING AND PLANKTON.—The correlation of abundant plankton food with large catches of herring, if it can be successfully proved, should point to a means of great value for enabling fishermen to shoot their nets in areas most likely to be profitable, when the herring are actively feeding. In this connexion, Mr. R. E. Savage ("The Plankton of a Herring Ground." Min. Agric. Fish. Fishery Invest. Series 2, Vol. 9, No. 1, 1926) records the results of a cruise of the fisheries research vessel to study the plankton in the North Sea, in July 1922, off the mouth of the Tyne, where the herring fishery was very poor at the time. The catches of plankton on the fishing grounds, which consisted mainly of copepods, chiefly *Temora longicornis*, are stated to have been poor; while the region in which the plankton was most abundant did not coincide with the centre of the area in which the herring boats were fishing, but was some 20 miles south-east of it. Interesting observations are given on the vertical distribution of the different plankton organisms, together with a comparison of the distributions shown by day and by night collecting. It was found, by a series of hauls at each 5 fathom depth, that the deeper layers were generally richer in plankton animals as a whole in the daytime, and that the poverty of the surface layers extended to a depth of at least 10 fathoms.

VERTEBRATE DEVELOPMENT.—Volume 17 of the Carnegie Institution's Contributions to Embryology contains a paper on the origin of the rete ovarii and rete testis by Dr. K. M. Wilson, a description of the vessels of the sow's ovary by Miss D. H. Anderson, a physiological study of cortical motor areas in kittens and adult cats by Messrs. L. H. Weed and O. R. Langworthy, and a paper on the relations between the onset of decerebrate rigidity and the time of myelinisation of tracts in the brain and spinal cord of young animals by Dr. Langworthy. Dr. Wilson's most important conclusion is that the rete cords arise from deeply lying undifferentiated cells in the early sex gland and so indirectly from the cœlomic epithelium; thus they do not have a Wolffian origin. Miss Anderson's paper deals with the cyclic changes in the blood-vessels and lymphatics of the ovaries, and shows that both of these form double wreaths around the follicle, the capillaries growing inwards at ovulation and the lymphatics following two days later when the corpus luteum is becoming organised. Messrs. Weed and Langworthy determined the responses to electrical stimulation of the cerebral cortex in cats of all ages from birth, and found that in the newly-born ones movements of the contralateral fore-leg only were obtained, but in older ones not only these but also movements of the hind leg and of the facial-masticatory muscles were observed. The areas made out for the young kitten corresponded topographically to the same areas in the adult. In the paper by Dr. Langworthy, strong experimental evidence is presented of a correlation between the myelinization of the rubro-spinal tract and the occurrence of decerebrate rigidity. All the memoirs are illustrated by plates.

A DINOCEPHALIAN FROM SOUTH AFRICA.—Prof. W. K. Gregory has published in the *Bulletin of the American Museum of Natural History* (Vol. 61, article 3) a very detailed account, illustrated by 21 plates and 29 text figures, of *Moschops capensis*, a dinocephalian reptile. This study is based on very complete material, some seven or eight skeletons being represented, and, as a result, Prof. Gregory is able not only to describe the osteology but also to discuss the relations of this animal, its probable food and habits, and to make a restoration of it as it appeared when alive. Moschops, a semi-aquatic animal, had advanced from the primitive reptilian condition in that its body was raised well off the ground. In the author's opinion it was derived from some Pelycosaurian ancestor.

JAPANESE EXTINCT MAMMALS.—Prof. Matsumoto describes in *Science Reports of the Tôhoku Imperial University*, Vol. 10, No. 1, various extinct mammals discovered in Japan, many of them being described for the first time. The paper is in three sections, the first dealing with Proboscidea. The chief interest of this account is the description of a new species of the genus Hemimastodon. This genus was first described by Dr. Pilgrim from Baluchistan from rather scanty material, and its existence was doubted by some authorities. Matsumoto's further evidence goes to support Pilgrim's determination of the genus as being a connecting link between the genus Phiomia (Palaeomastodon in part) and the later mastodons. Altogether fourteen species of Proboscidea are listed as occurring in Japan. The second section describes two pinnipeds, one an extinct form *Eumetopias watasei*, the other a specimen of *Odobaenus obesus*, the walrus, possibly of Pleistocene age. The third section deals with four new species of fossil cetaceans.

HYDROGRAPHY OF THE IRISH SEA.—An account of hydrographic observations made in the Irish Sea between Holyhead and Dublin, by Mr. R. J. Daniel in 1925, is published in the annual report of the Lancashire Sea-Fisheries Laboratory (Liverpool University Press). In this area the water is of practically the same temperature and salinity from surface to bottom, which greatly facilitates the survey of these two physical conditions which are being carried out regularly every month. A slow drift of ocean water passing north through the Irish Channel, strongest in some months and weakest in others, has been known for some time, our knowledge being based on inferences drawn from changes in salinity of the water. Mr. Daniel's observations at regular intervals of one month may be expected to give a record of the fluctuations in this drift of water from year to year. A point of interest, recorded in this report, is the considerable differences in surface salinity readings at near-by stations which occur sometimes, and the small differences, at each station, between the surface and deeper samples.

Bottom Currents in the North Sea.—Under the title "The Water Movements in the Southern North Sea, Part 2, The Bottom Currents," Mr. J. N. Carruthers publishes an account of an extensive experiment conducted by the Ministry of Agriculture and Fisheries, by means of 'bottom trailers,' of which some ten thousand were set free from a number of selected positions throughout a year (Fishery Investigations Series 2, Vol. 9, No. 3, London: H.M. Stationery Office, 1926). This ingenious method of observing the drift of the water close to the bottom, by means of bottles so weighted that they remain lightly poised upon their tails of wire, which are about two feet long, was devised by Dr. G. P. Bidder more than twenty years ago, and has been used successfully in several areas of the sea around the coast of Britain. The bottles trip along lightly with any horizontal movement of the water and escape the danger of becoming arrested by mud and rough ground to a much greater extent than any body resting directly on the bottom, until such time as they are caught in the trawl of a fishing vessel or go ashore on the coast. The number of days each has been out and the distance travelled gives an indication of the currents experienced in the course of its wanderings. An idea of the intensity of the trawl fishing in the southern part of the North Sea is given by the fact that 24 per cent of the trailers put out were recaptured by trawlers. Besides these a number were found on the coast, particularly in the case of those liberated from the Sandettie, Galloper and Outer Dowsing Light vessels, from the positions of which there is an onshore set of the deep water. The results of this extensive experiment show that current of bottom water flows in to the North Sea from the English Channel, spreads out fan-wise towards the East Anglia and Dutch shores and proceeds north-easterly. A current also flows south-east off the coast of Scotland and north-east England until it reaches the latitude of Flamborough Head, when it turns easterly and finally north-easterly, forming a counter clockwise swirl system in the vicinity of the South Dogger Light vessel. Water from the two currents mingle and proceed north towards the Danish coast. The speed of the residual drift or current at each of the chosen positions approximates to a mile a day.

A Current Meter for Deep Water.—Much ingenuity has been exercised in the design of meters for measuring currents in the sea during recent years, and considerable headway has been made with a difficult practical problem. The apparatus devised by Prof. V. W. Ekman more than twenty years ago has been used extensively and is probably the best known type. In *Publication de Circonstance* No. 91 (June 1926) of the Conseil International pour l'Exploration de la Mer, he describes "a new repeating current meter" which is a development of the original model for use in deep water. The aim has been to provide an instrument to be used in several hundred fathoms from a vessel riding to a single anchor, which does not provide a fixed point of suspension for the meter owing to the veering of the ship. With this instrument a number of 'messenger weights' are slid down the wire to which the meter is attached, one after another at noted times, and the meter registers the direction of the current at the moment when each 'messenger' hits it, together with the distance the current has travelled between successive hits.

The Compressibility of Rocks.—To test the rival hypotheses that beneath the earth's outer shell the material consists of peridotite or basaltic glass, L. H. Adams and R. E. Gibson, of the Geophysical Laboratory of Washington, have made direct measurements of the compressibilities of dunite and tachylyte (*Proc. Nat. Acad. Sci.*, May 1926). The results show that at a pressure of 17,000 megabars, corresponding to a depth of 60 km., the velocity of longitudinal earthquake waves in dunite would be 8·4 km. per sec. In basaltic glass the corresponding velocity would be 6·45 km. per sec., and in gabbro from 6·9 km. to 7·3 km. per sec. The actual velocity of such waves at a depth of 60 km. is about 8 km. per sec. It is concluded that this gives a very definite indication "that at depths greater than 60 km. we have a material more basic than gabbro and approaching dunite in composition." The new measurements show quite conclusively that Daly's conception of a substratum of basaltic glass meets with no support, but neither can the author's deduction be completely justified. Eclogite would probably satisfy the evidence equally as well as peridotite. It is to be hoped that similar work on this high-pressure facies of basalt may soon be carried out.

Radiation without Quanta.—The Montreal *Mercury* has issued as a pamphlet of 28 pages the two addresses given in April by Prof. L. V. King to the Physical Society of McGill University on the properties of a rotating electron in translatory motion. If the shortening of the axis of the electron in the direction of translation is taken into account, the equations of motion of the electron are shown to give a precessional motion of frequency ν which is connected with the translational velocity v by an equation of the form $h\nu = \frac{1}{2}mv^2$, where m is the mass of the electron when at rest and h is a constant for all electrons. Thus the quantity h of the quantum theory is introduced by classical dynamics as a property of the rotating electron. The extension of the idea to spinning protons and to atoms leads to the series formulæ for the hydrogen and helium spectra and to the *S*, *P*, *D*, and *F* series for other elements with the correct value for the Rydberg constant. The fine structure of lines, the Zeeman and Stark effects are explained as due to perturbations of orbits brought about by external fields. The radiation formula in terms of temperature and wave-length follow from a Maxwellian distribution of electron velocities.

Coal Carbonisation Tests.—The Department of Scientific and Industrial Research has issued a Fuel Research Technical Paper, No. 15, on the Carbonisation of Durham 'Holmside' Coal in Continuous Vertical Retorts (London, H.M. Stationery Office, 1926). The continuous vertical retort has gained its popularity largely because it lends itself to the production of the lower-grade gas which is usually distributed to-day. The tests recorded were made at the Fuel Research Station, Greenwich, at the request of the South Metropolitan Gas Company, which distributes a coal gas of calorific value somewhat greater than is customary in England, and it is of considerable interest to ascertain how far the continuous vertical retort can be applied to the production, from a typical Durham coal, of gas of the quality used in South London. It was found that the settings required certain modifications both in construction and operation, after which it was possible to produce the carbonisation results desired. The tests were extended to study the effect of steaming the charge, so as to obtain results comparable with those previously obtained on other coals.

Phytopathology and Private Enterprise.

IN most of the European countries, as is the case in England, the insect pests and fungus diseases of agricultural plants are dealt with by one phytopathological service, and in spite of the opposition to such a practice in America this union has been found to work satisfactorily, for if at times one branch may seem to be profiting at the expense of the other, the two have so much in common that it is probably the most logical system to adopt. As we in Great Britain are more or less interested in what is happening in the corresponding service on the continent, it may perhaps be opportune to give an account of the National French Phytopathological Congress held at Lyons on June 28-30, which we had the pleasure of attending through the kindness of the promoters, the P.L.M. Railway.

The meetings, on account of the heavy programme, began at the somewhat early hour—for an Englishman—of 8.30 A.M. and continued until after 6 P.M. M. Mangin, the director of the Natural History Museum, Paris, acted as president, and M. Boret, the ex-Minister of Agriculture, and several other deputies honoured the Congress with their presence. Some five hundred persons accepted invitations, and most of the surrounding countries were represented. The subjects discussed comprised papers on various entomological and mycological problems, the disinfection of the soil, the value of colloids in spraying, the relation of birds and field-mice to agriculture, and proposals for the establishment of regional committees to assist in the war against what may be termed shortly the enemies of plants. In view of the large quantities of certain chemicals employed in this fight—on an average 50,000 tons of copper sulphate are used, for example, in a year, and about one-third of that is imported—and the consequent increase in price which such a demand creates, the need for finding fresh insecticides and fungicides was also discussed, while motions were passed dealing with the necessity of obtaining nicotine plentifully and readily and the need for some sort of guarantee of purity in those chemical preparations used by the grower. The latter question, it may be said in passing, has been receiving of late some consideration in this country. The exhibits of the various research stations—Paris, St. Genis-Laval, Montargis, Mentone, etc.—and of various firms, notably those of Vermorel and Truffaut, were very fine, while a practical demonstration of spraying apparatus at Ampuis completed the work of the Congress.

Hitherto it has been left to a government to maintain a phytopathological service, either directly or indirectly, though there are notable examples of the enterprise of private associations in establishing and running laboratories for the study of diseases of the particular crops in which they are interested. Amongst these the Hawaiian Sugar Planters' Association, the Colonial Sugar Refining Company, the Assam Tea Planters' Association, and the recently founded Ceylon Tea Planters' Research Institute may be mentioned, while on a smaller scale we have seen the establishment of works' laboratories by several private firms in Great Britain for the study of certain problems affecting their businesses, but this is a side of which people are in the main ignorant, and indeed there is little reason why they should be enlightened. The fostering of the agricultural industry by the P.L.M. Railway in the area covered by their system dates fairly far back. It has to be remembered that in northern France the carrying trade of the railways consists largely of coal, wheat, and beet, but in mid and southern France the railway derives most of its revenue from flowers, fruit, and vegetables. In 1877, when Phylloxera threatened to wipe out the wine industry, the P.L.M. Railway recognised that its revenue was closely bound up in the prosperity of the vineyards and did its utmost to assist in the stamping out of this dread disease. The service instituted then served as a nucleus out of which has grown the present magnificent organisation, which as it exists to-day is almost entirely of post-war origin. It is quite distinct from the service maintained by the state, but in actual practice it works in conjunction with and is really supplementary to it.

That disease may seriously affect the returns of an industry we all know, though it is difficult to obtain definite figures. M. Raybaud, the chief inspector to the company, estimates the injury caused by insects and fungi throughout the globe at 10 milliards of francs per annum, of which one milliard's worth is done in France. That the former figure is probably a very fair estimate the following data collected haphazardly from literature and reduced to a par value will show; the estimates are for limited areas in most cases and for prices prevailing before or during the War. The Hessian Fly is said to cost the U.S.A. 20,000,000*l.* every year; in the State of Washington the Codling Moth injures apples to the tune of 800,000*l.*, and in another State 400,000*l.*; *Conotrachelus nenuphar*, one of the British "scheduled" pests, injures peaches worth 400,000*l.* in Georgia; leaf injury by insects to tobacco in Sumatra on 80 estates amounts to 750,000*l.*; Helopeltis causes about 200,000*l.* loss every year in the Dutch East Indies; *Phytalus smithi* 33,400*l.* to sugar-cane in Barbados, and figures are not available for the loss it causes in Mauritius, where it is a much more serious pest; *Bruchus pisorum* causes damage of more than 200,000*l.* in one province of Canada alone; *Thrips tabaci*, to those crops it attacks in the U.S.A., 600,000*l.*; Frit-fly in Britain in 1912 damaged 12,126,198 bushels of wheat which, if we allow 1*l.* per quarter, is equivalent to more than 1,515,000*l.*; the Brown and Gold Tail Moths have cost Pennsylvania and the neighbouring States 6,000,000*l.* loss annually; *Prosagrotis orthogonia* caused injury valued at 600,000*l.* in Montana in 1920; *Cylas formicarius*, where it is established in the U.S.A., causes a loss of about 1,500,000*l.*; *Sitotroga cerealella* in Pennsylvania alone 200,000*l.*; one scale insect (*Saissetia oleae*) takes an annual toll of 400,000*l.* from the Californian Citrus industry; and if we include grain pests, Ohio loses 200,000*l.*, Alabama from 800,000*l.* to 2,000,000*l.*, while *Calandra oryzae* alone caused a loss of about 2,000,000*l.* in the U.S.A. in 1918, but this was a particularly bad year. Damage on the grand scale is seen in the case of the Cotton Boll Weevil, which costs the cotton growers of the U.S.A. 35,000,000*l.* in lint and 5,000,000*l.* in seed, and the Pink Boll Worm, which is said to cause a loss of 10,000,000*l.* in Egypt. Then we have the more general estimates of 20,000,000*l.* for the injury to the forest and shade trees of the U.S.A., 1,000,000*l.* to the agricultural products of British Guiana, 1,350,000*l.* to the maize industry in South Africa, 25,000,000*l.* annual loss to the field crops in Canada, and a similar amount in Germany. A mycologist would probably be able to supply as astounding figures for the losses caused by fungi.

Satisfied as to the need, therefore, of keeping a watchful eye on the diseases of plants, the P.L.M. Railway maintains a central agricultural service bureau which carries on a progressive educative policy amongst the growers in the region covered by

its lines, providing them with the latest literature on every subject which may be of interest to them, arranges conferences and demonstrations at convenient centres to which large attendances are assured through free travelling facilities, visits to other countries to study the conditions prevailing there, and also provides free carriage on their system for chemicals and spraying apparatus. The conferences are not confined to university professors and researchers in phytopathology, but the chemist and physicist, the manufacturer and the engineer take their place beside the practical man. Lively discussions result from such a gathering of experts, and not unusually the grower is able to hold his own. We were particularly struck by the keenness of the grower in everything pertaining to spraying, and whatever may be the opinion prevailing in Great Britain as to its value, there can be no doubt that the French agriculturalist is a firm adherent to the practice.

The phytopathological is but one side of the work carried out by the P.L.M. Railway. Since 1912 it has founded 138 experimental nurseries for the training of the peasants, and also many school gardens, subsidised largely the research station at St. Genis-Laval and the Insectary at Mentone, experimented with many varieties of strawberries, established a nursery for growing cypress for hedging, and distributed hundreds of thousands of plants free, fruit trees, vines, black currants, asparagus, artichokes, tomatoes, and osiers being the chief, but potatoes and winter vegetables have also received their share of attention. In addition pisciculture, viticulture, and sericulture owe much to the liberality and the encouragement of the Company. A huge organisation and a well-filled purse have always been behind these movements. What is the result to the Company? In 1910 it carried 190,000 tons of fruit and vegetables, in 1925 this had grown to 488,850 tons, so that the results of its labours are reflected in the balance-sheet at the end of the year in such a way as to encourage the Company to continue in the work which they are doing with such conspicuous success. L.

A British Expedition to the Sepik River, New Guinea.

An expedition has been planned and is now being organised by Mr. V. A. C. Findlay, the object of which is to penetrate to the central mountain chain of New Guinea and locate the head-waters of the Sepik River. There is at present a theory that a large lake lies between the Victor Emmanuel Range to the north and the Muller Range to the south, which feeds both the Sepik and the Fly Rivers. In 1891 Sir William MacGregor reached a point on the Fly River in the territory of Papua at lat. 8° 11′ S., long. 141° 54′ E., and of recent years a number of explorations of the head-waters of the Fly River have been carried out by officers in the Papuan service. In 1913–14 Dr. Behrman's expedition proceeded up the Sepik River in what is now mandated territory and the advance party reached lat. 8° 11′ S., long. 141° 36′ E. in the Victor Emmanuel Range, but failed to attain the objective of the expedition, the source of the river. A survey was made up to the point reached by the advance party.

The object of the present expedition will be not only to locate the source of the Sepik, but also to cross and survey the country lying between the head-waters of this river and those of the Fly. Geological, anthropological, zoological, and botanical observations will be made on the way, and if the objective is attained, should lead to results of great importance, as the higher and hitherto unexplored parts of the central mountain chain should produce much new and valuable material in each of these branches of science.

The expedition will proceed by launch to the highest possible point on the Sepik, where a base will be formed. From this the main party will proceed into the hills. Should they succeed in reaching the Fly, they will return down this river, the base party returning down the Sepik independently. The base party will be in communication with the authorities at Rabal by radio, and the main party will keep in touch with the base by means of a small transmitting set. A kinematograph outfit will also be carried.

The personnel of the expedition so far as arranged at present consists of Mr. V. A. C. Findlay, leader and agricultural and topographical surveyor; Mrs. Findlay, engineer, radio operator and photographer; Mr. A. J. Hill, engineer and radio operator; Mr. K. H. Henderson, zoological and botanical collector; Mr. W. S. Malcolm, anthropologist; and Mr. C. T. Teychenné, geological surveyor.

The expedition has received the approval of the Royal Geographical Society, the Royal Anthropological Institute, and the Committee for Anthropology of the University of Oxford. The expedition is being organised under the direction of a council of which Lord St. John of Bletso is president, and Mr. Henry Balfour, The Hon. Mr. H. A. Casson, and Dr. A. F. R. Wollaston, are members. At the recent meeting of the British Association at Oxford a committee was appointed to co-operate in the work of organisation. The estimated cost of the expedition is 6000*l*., and contingently on that amount being raised, the expedition will leave England in the autumn of 1927.

The Pelagic Young of the Cod.[1]

Mr. Michael Graham and Mr. J. N. Carruthers have attempted to correlate the known distribution of the pelagic young of the cod with the theoretical distribution deduced from three factors—market statistics, wind records, and experiments with drift-bottles. The theoretical part is undertaken by Mr. Carruthers, the practical part, dealing with the actual catches of the young fishes, by Mr. Graham. In addition Mr. H. H. Goodchild investigated the food of the fry from the same samples. Three questions are involved in the present paper: First, to what extent the drift affects the pelagic fry in the North Sea; secondly, what is the distribution of the fry; and thirdly, what is the food of the young in the pelagic stage? To answer these questions the market statistics were used to ascertain the spawning-grounds and times, the methods being justified by previous work of one of the authors in 1924. A system of cruises was undertaken to fish for the larvæ and post-larvæ from these spawning-grounds outwards; experiments with drift-bottles were made and wind statistics consulted. The ascertained distribution was then compared with the theoretical distribution, and the results were found to be so much in agreement that the authors seem to be justified in their con-

[1] "The Distribution of Pelagic Stages of the Cod in the North Sea in 1924 in Relation to the System of Currents," by Michael Graham and J. N. Carruthers. With a section on "The Food of Pelagic Young Cod" by H. H. Goodchild, Fisheries Laboratory, Lowestoft. Ministry of Agriculture and Fisheries. Fishery Investigations, Series 2, vol. 8, No. 6, 1925. London: H.M.S.O.

clusion that the pelagic young of the cod are to a large extent carried by currents.

The method of fishing was by taking oblique hauls with Petersen's young fish-trawl, at first as close to the bottom as possible for ten minutes; then to shorten the warp to half the length used in fishing near the bottom, and tow for a further ten minutes; finally, to tow for ten minutes at the surface. It was not intended to investigate the distribution by depth but to obtain representative hauls from near the bottom to the surface. Thus the fishes from all three depths were mixed together in the sample. In the drift-bottle experiments those at the surface only were taken into account. Information as to the vertical distribution of the pelagic young and the vertical extent of the drift would be extremely interesting.

More than a thousand of these pelagic stages were investigated for food; the result, as was entirely to be expected, showing that from the time when it begins to feed the young cod's main food is copepods. Copepods are pre-eminently the food of the larva and post-larva at least up to the time of its settling down to demersal life. Mr. Goodchild finds that diatoms are practically of no importance as food, which also is not surprising, judging from our knowledge of the food of other baby gadoids. The presence of the few specimens he mentions is in all probability accidental.

The Haslemere Educational Museum.

NEW buildings for the Haslemere Educational Museum, founded a generation ago by the late Sir Jonathan Hutchinson, were inaugurated and opened to the public on August 27. He was an original and powerful influence in many ways; in his hobby of making and directing a museum he became a popular benefactor to the beautiful Surrey district where he had his home, and in the development of which into one of the best known areas for scenery, residence and holiday in the radius of fifty miles from London. The Museum, which was formed and arranged with the educational aim predominant of making every exhibit tell its tale to the average person who came to look at it, has until recently been the property of the Hutchinson family. They have now handed it over to a trust under a scheme by which the collection is placed in new buildings, a maintenance endowment fund is being formed, and the committee becomes representative of local and other institutions, which ensure it being widely popular and therefore educational to many.

The scheme owes much in inception and carrying out to the chairman, Dr. Arnold Lyndon, who presided at the ceremony on August 27, when Earl Midleton formally opened the buildings, and Dr. F. A. Bather, keeper of the Department of Geology in the British Museum, unveiled a memorial tablet to the late Sir Jonathan Hutchinson. A large and distinguished company assembled in the beautiful grounds behind the roomy old mansion in the High Street, which with large additions has been most happily transformed into an admirable Museum. These grounds, with the spacious verandah and lecture hall, make the Museum well suited for education gatherings, whether for instruction of classes or by special demonstrations, etc., or (what may be well looked for) to visits from scientific societies, field clubs, and perhaps summer schools and conferences.

An additional interest is added by the fine collection of so-called Peant Arts, the property for some years of the Peasant Arts Guild, having been donated to the Museum and arranged in a special section. From an anthropological and ethnographical point of view, as well as from that of art and handicraft, this collection is important; there is no other in Great Britain made and arranged on the lines familiar to those who have visited Scandinavia and various continental cities where there are folk-museums. This Peasant Arts Section is entirely sympathetic to the aims and ideas of the late Sir Jonathan Hutchinson; a number of objects which he had collected have come into fitting spaces in this new phase. A great deal is due to Mr. E. W. Swanton, whom Sir Jonathan many years ago appointed as the curator of his Museum, and who, with the aid of Mrs. Swanton, has become a real educational influence in Surrey. This is recognised by the annual grant of the County Council (as Education Authority) to the Museum. Mr. Swanton is a many-sided man, as was the original founder of the Museum, and he may be trusted to carry the Museum on in the fine tradition which it has established.

University and Educational Intelligence.

A USEFUL guide-book to the universities of Germany has been published by the Akademische Auskunftsamt an der Universität Berlin. This has been compiled by Prof. Karl Remme, Director of the Central Office for Foreign Students in Prussia. It is an attractive volume of 290 pages, profusely illustrated and well arranged, and will be most useful to students proposing to visit Germany. It comprises an historical introduction, a general description of the higher educational system, statistical summaries, and chapters devoted to facilities available for foreign students, the distribution of subjects of study as between the different institutions, conditions for obtaining degrees and diplomas, and very readable descriptions of the university towns

RESEARCH in progress at the University of Minnesota, July 1924–July 1925, is described in a three-hundred-page pamphlet issued by the University's Graduate School. It contains the titles of about a thousand papers published or in the press and short abstracts of a large proportion of them. In addition it contains brief notes on the subjects and purposes of researches, the methods and materials used, and the results so far as available, in cases in which publication of papers has not been decided on. The index is not very satisfactory, names of researchers and classification headings of subjects of research being mixed in one series. If universities would co-operate in the production of annual lists of titles of subjects of research in progress, such lists could scarcely fail to be of considerable utility.

THE National University of Ireland's Calendar for 1926 exemplifies the tendency of such annuals to become unwieldy It contains more than 900 pages, chiefly lists of graduates and university honours. A list of published works and theses submitted for doctorate degrees from 1911 onwards contains about 200 titles and is followed by a footnote requesting professors, lecturers, and graduates to forward to the registrar "full details of publications and research work carried out by them." Of the six travelling studentships, each 200*l.* per annum for two years, announced for competition in 1925, only one was awarded, namely, in pathology. The subjects notified for travelling fellowships to be offered for competition in 1927 are: mathematical science, Irish together with English or French or German, philosophy, one of the three sciences, botany, zoology and geology, and anatomy.

Contemporary Birthdays.

September 4, 1845. Sir Thomas Barlow, Bart., K.C.V.O., F.R.S.
September 6, 1870. Prof. Frederick G. Donnan, C.B.E., F.R.S.
September 6, 1876. Prof. J. J. R. MacLeod, F.R.S.
September 7, 1877. Sir John Cadman, K.C.M.G.
September 9, 1867. Mr. Robert Ludwig Mond.
September 10, 1859. Prof. J. Norman Collie, F.R.S.
September 11, 1877. Dr. J. H. Jeans, Sec. R.S.

Sir THOMAS BARLOW, to whom congratulations are due on the anniversary of his eighty-first birthday, is Physician Extraordinary to H.M. the King. President of the Royal College of Physicians, 1910–15, he was also president of the International Medical Congress of 1913.

Prof. DONNAN, occupant of the chair of general chemistry in the University of London, was educated at Queen's University, Belfast, and at Leipzig and Berlin. From 1904 until 1913 he was professor (the first to be elected) of physical chemistry in the Muspratt Laboratory of the University of Liverpool. Prof. Donnan is a Longstaff medallist of the Chemical Society.

Prof. MACLEOD, Nobel laureate in physiology and medicine in 1923 (jointly with Dr. F. G. Banting), was born at Cluny, Perthshire. He was educated at the Grammar School of Aberdeen and the University there. Six and twenty years ago he was demonstrator in physiology, and afterwards lecturer in bio-chemistry, at the London Hospital, and for a time he was working with Dr. Leonard Hill on the physiological effects produced on animals by compressed air. From 1901 until 1903 he was Mackinnon research student under the Royal Society, taking up afterwards the chair of physiology in the Western Reserve University, Cleveland, Ohio. In 1918 he was elected to a similar post in the University of Toronto. The Nobel prize was awarded for the discovery of insulin.

Sir JOHN CADMAN was born at Silverdale, Staffordshire. He was educated at the High School, Newcastle-under-Lyme, and Armstrong College. Formerly a mining engineer and colliery manager, he established a practical acquaintance with all branches of the mining industry. Sir John is professor of mining and petroleum technology in the University of Birmingham, and technical adviser to the Anglo-Persian Oil Company. He is an Officer of the Legion of Honour.

Mr. ROBERT L. MOND was born at Farnworth, Lancashire, and educated at Cheltenham and Peterhouse, Cambridge. He is honorary secretary of the Davy-Faraday Laboratory. In recent years Mr. Mond has rendered signal service as a student of Egyptology and conductor of excavations.

Dr. NORMAN COLLIE has been, since 1902, professor of organic chemistry in the University of London. A past president of the Alpine Club, he is an ardent mountaineer.

Dr. JEANS, one of the secretaries of the Royal Society, was educated at Merchant Taylors' School and Trinity College, Cambridge. Second wrangler in 1898, he was Smith's prizeman in 1900, and sometime Isaac Newton student. From 1905 until 1909 he was professor of applied mathematics in the University of Princeton. In 1919 the Royal Society allotted him a Royal medal for researches in applied mathematics; in 1922 the Royal Astronomical Society awarded him its medal for his contributions to the theories of cosmogony.

Societies and Academies.

PARIS.

Academy of Sciences, July 12.—Charles **Moureu,** Charles **Dufraisse,** and C. L. **Butler**: Rubrene peroxide: new experiments. Rubrene peroxide, when dissociated by rise of temperature, emits light. In an earlier note it was shown that light was essential to the combination of oxygen with rubrene.—Miécislas **Biernacki**: The theorem of Lucas and its generalisations.—J. **Neyman**: A property of the law of probability which obeys the coefficient of variation.—Jules **Drach**: The integration of partial differential equations of the second order and the explicit use of the characteristic variables of Ampère.—**Decros, Rebuffet,** and J. **Villey**: An electrometric recording dynamometer. N. **Gunther**: The movement of a liquid filling a domain with multiple connexion which is displaced.—Ernest **Esclangon**: The asymmetry of sidereal space and the phenomenon of tides.—Marcel **Laporte**: The measurement of the mobility of ions in gases.—R. **Forrer**: The structure of the atomic magnet. Its normal position with respect to the network and residual magnetisation.—A. **Bogros**: The resonance of lithium vapour. The resonance line of the alkali metals is known to be the first doublet of the principal series. Direct experimental proof of this has been given for sodium and cæsium (Wood): the author now gives experiments proving it for lithium.—J. **Heyrovsky** and B. **Souček**: The electrolytic potential of iron amalgam. From measurement of the electrolytic potentials of iron amalgam, it is concluded that this amalgam should be metastable and decompose spontaneously, with liberation of energy, into a mixture of solid iron and mercury.—J. **Consigny**: The stopping power of some metals for α rays.—A. **Hamy**: The absorption of iodine by precipitated magnesia. Studies in the amount of iodine absorbed as a function of time, concentrations of iodine and of potassium iodide.—J. **Dumont**: The separation of the finer particles and colloidal constituents of the soil by centrifugation. The solid matter remaining in a clay suspension in water after standing for a day can be separated into two portions by a high velocity centrifuge, the portion remaining in suspension being considered as a true colloid.—Marcel **Bouis**: The synthesis of allene hydrocarbons. In an earlier communication a method was given for preparing ethylallene starting from vinylethyl carbinol. It is now shown that the method is generally applicable, the vinylalkyl carbinol, $CH_2 : CH . CH(OH) . R$, leading to the allene $R . CH : C : CH_2$.—Charles **Prévost**: A new erythrite. The glycols (*cis* and *trans*) $CH_2 . OH . CH : CH . CH(OH) . CH_3$ were converted into the ether oxides

$CH_2 . CH . CH - CH - CH_3$.
\O/ \O/

Only from the *trans* glycol was sufficient ether oxide obtained to convert by hydration with water into the corresponding erythrite.—E. **Rothé**: The nature of the maxima inscribed in seismograms.—Albert **Baldit**: The periods of constancy of temperature at a station of medium altitude.—J. **Beauverie**: The modes of degenerescence of the chloroplasts, particularly in parasitism.—Mlle. H. **Popovici**: Contribution to the cytological study of the laticifers.—A. L. **Guyot**: Some parasitic fungi of the roots of Phanerogams.—A. **Rizzolo** and A. B. **Chouchard**: The quantitative study of the action of morphine on the cerebral cortex.—G. A. **Nadson** and N. **Meisl**: The mechanism of the action of chloroform on the protoplasm, the nucleus and the

chondriome of the cells of *Allium cepa*. The chondriome is the most sensitive to the action of chloroform; later, modifications are seen in the protoplasm, and last of all in the nucleus. The general character of the modifications produced by chloroform in the living substance is analogous with that of the changes provoked by X-rays.—Emile **André** and Henri **Canal**: Contribution to the study of the oils of marine animals. Researches on the oil of *Todarus sagittatus*.—Robert **Weill**: The problem of the cleptocnids. The nematocysts of *Hermœa bifida*.—André **Lwoff** and Mlle. Nadia **Roukhelman**: The variations of some forms of nitrogen in a pure culture of infusoria. From the point of view of the chemical transformations of the culture medium, and more especially from the point of view of the excretion of nitrogen in the form of ammonia and amides, *Glaucoma piriformis* (and perhaps all Infusoria) resemble bacteria.—A. **Vandel**: Triploïdia and parthenogenesis in the isopod *Trichoniscus* (*Spiloniscus*) *provisorius*.—M. **Lemoigne** and P. L. **Dopter**: The nitrogen losses caused by soil bacteria in pure cultures.—M. **Javillier** and H. **Alliare**: The existence of a nucleic phosphorus index of tissues.

July 19.—H. **Deslandres**: The law of distribution of terrestrial magnetic storms, and the corresponding law of distribution of the active regions of the sun. These are due to corpuscular radiation, which is subject to considerable periodic change.—G. **Bigourdan**: A means of improving the lunar co-ordinates deduced from the occultations of stars. The errors due to the irregularities of the edge of the moon's surface may cause an error of $1''$, whereas the error of observation gives the lunar longitude to about $0''\cdot1$. The application of lunar photographs is suggested as a means of reducing the error caused by the surface irregularities.—Charles **Moureu** and Adolphe **Lepape**: The determination of krypton and xenon in atmospheric air. An application of the spectrophotometric method previously described. The results (by volume) are: krypton, 1×10^{-6}, and xenon, 9×10^{-8}. These are about twenty times those obtained by Ramsay in 1903, but nearly identical with the figures obtained by Ramsay and Travers in 1900.—Charles **Richet** and P. **Lassablière**: The protective effects of chloralose in chloroform anæsthesia. From experiments on dogs it is shown that the administration of chloralose (which must be free from parachloralose) by the mouth prevents cardiac syncope by the action of chloroform.—Rolin **Wawvre**: The reduction of domains by a substitution with *m* complex variables, and the existence of a single invariant point.—Luigi **Fantappié**: A class of analytical functionals.—H. **Mineur**: Waves of discontinuity of the second order in an Einstein universe.—Henri **Bénard**: The limit of the laminar regime and the turbulent regime, revealed by the appearance of clear alternating vortices.—Farid **Boulad Bey**: The calculation of a continuous beam of any form when given vertical elastic deformations.—Da **Costa Lobo**: Correlation between the solar prominences and the filaments. The agitation of the surface of the faculæ. Results obtained with a large spectroheliograph set up at the astronomical observatory of the University of Coïmbra. This instrument is identical in dimensions and characteristics with the instrument installed by M. Deslandres at Meudon Observatory, and the results from one station will serve to fill up gaps caused by bad weather at the other.—W. H. **Keesom**: The curve of fusion of helium. Data are given for pressures and temperatures ranging from 77·09 cm. of mercury on the helium bath (T. 4°·21) to 0·057 cm. (T. 1°·13).—G. **Darrieus**: A relation between the gravitation constant and other fundamental constants.—Henri **Malet**: The mathematical synthesis of the laws of electrodynamics.—A. **Dauvillier**: The spectrography of X-rays of large wave-length.—Mlle. J. **Liquier**. The variation of the rotatory power of solutions of quinine salts as a function of the hydrogen-ion concentration. The rotatory power of asparagine and the salt effect.—Salomon **Rosenblum**: The retardation of the X-rays by matter.—Georges **Fournier**: The absorption of the β-rays by matter.—Henri **Belliot**: Experiments on photographic solarisation.—A. **Boutaric** and Mlle. G. **Perreau**: The existence of two zones of instability in the flocculation of certain suspensions by electrolytes with trivalent and tetravalent cations.—P. **Brun**: The miscibility of quaternary water-alcohol mixtures. Details of the study of miscibility of mixtures of ethyl alcohol and water with two other alcohols not miscible with water, isobutyl and isoamyl alcohols.—**Pariselle**: The tartrates of pyridine and quinoline.—A. P. **Rollet**: A new colorimetric determination of nickel. The colour reaction utilised is produced by the oxidation of nickel dimethylglyoxime and will show 0·0005 mgm. nickel in 1 c.c.—René **Girard**: The action of saline solutions on the ferrous metals.—Mlle. **Bardon** and Mme. **Ramart**: The action of organo-magnesium derivatives on the glycidic ethers.—Mlle. **Marthe Montagne**: Researches concerning the action of organo-magnesium derivatives on some fatty dialkylamides.—E. E. **Blaise** and Jean **Miliotis**: Researches on the transposition of functional groups.—Jacques **Bourcart**: The stratigraphy of the Bouches de Cattaro (Jugoslavia).—Paul **Caubet**: Eruption of the peak of La Fournaise, December 1925 to April 1926.—V. **Agafonoff**: The genesis of the black earth and other soils in the neighbourhood of Clermont-Ferrand.—Ch. **Jacquet**: Researches on the radio-active springs of the Puy-de-Dôme.—Henry **Hubert**: The general movements of the air in western Africa.—M. **Bridel** and C. **Béguin**: Biochemical researches on the composition of *Salix triandra*. Preparation of rutoxide, asparagine, and a new glucoside hydrolysable by emulsion, salidroxide. The leaves of this plant contain glucoside, which can be hydrolysed by rhamnodiastase and a glucoside which under the action of emulsion gives an essential oil smelling of rose.—René **Souèges**: The embryogeny of the Liliaceæ. The development of the embryo in *Muscari comosum*.—Jules **Amar**: Observations on the cellular pigments.—G. **Lafon**: The intimate mechanism of muscular contraction.—Charles **Perez**: The sexual characters of the caudal fin in the Galatheideæ.—René **Fabre** and Henri **Simonnet**: Study of the photo-sensitising action of hæmatoporphyrine.—F. **Vlès** and A. de **Coulon**: The receptivity of the organism for grafts of tumours, in relation with the iseolectric points of the tissues.—L. **Lutz**: The soluble ferments secreted by the Hymenomycetes fungi. Reducing actions.—E. **Fauré-Fremiet** and Mlle. Laura **Kaufman**: Remarks concerning the curve of annual decrease of eggs laid by the domestic fowl.—Constantino **Gorini**: The stimulation of the bacterial activities in milk.—A. **Paillot**: The etiology and epidemiology of the *Gattine* of the silkworm, or the transparent head disease.—H. **Bordier**: The action of diathermic d'Arsonvalisation on synovia.

Official Publications Received.

Bulletin of the National Research Council. Vol. 10, Part 4, No. 54: Quantum Principles and Line Spectra. By Prof. J. H. Van Vleck. Pp. 316. 3 dollars. Vol. 11, Part 1, No. 55: The Determination of the Protein Requirements of Animals and of the Protein Values of Farm Feeds and Rations. Report of the Sub-committee on Animal Nutrition. By H. H. Mitchell. Pp. 44. 75 cents. (Washington, D.C.: National Academy of Sciences.)

in the formation of protein chains a varied assortment of amino-acids is added according to a definite scheme. To build up the chain by the elimination of the elements of a molecule of water as each link is fastened to the next requires the expenditure of energy. This energy is supplied either by the radiant energy of the sun or by the oxidation of some other compound.

The mystery of life is not the creation of energy; it is essentially, as Prof. Driesch put it in a forceful address delivered this year, in London, the 'control' of energy—the control which out of a chaotic assemblage of materials whirling about in the fluid builds up a definite specific structure. The word 'regulation' coined by Driesch about 1895 to denote the mode of activity of his 'entelechy' and abhorred by the mechanistic school of which the late Prof. Loeb was the principal ornament and exponent, is creeping back into the vocabulary of experimental embryologists like Spemann and von Uebisch because the facts with which they deal will allow of no other explanation. The number of possible permutations of the order of the links in these protein chains is almost infinite, so that, as we have seen, the structure of the unfinished chain discloses no necessity of giving rise to a completed chain of a particular kind. Prof. Leathes speculates as to whether an occasional 'permutation' in this order may not be the cause of what biologists term a mutation. It is greatly to be desired that this word 'mutation' should either be rigidly defined or else removed from the scientific vocabulary altogether. Sometimes it is used to denote any change whatever in the hereditary potentialities of an organism, and then to say that evolution is explained by occurrence of 'mutations' is merely a truism. But the fact that this is a truism is often illegitimately employed to support another theory, namely, that violent and sudden divergences from type such as Prof. Morgan encounters in his cultures of Drosophila, and which form the 'sports' familiar to every breeder and gardener, constitute the raw material of evolution.

All the evidence at our disposal is hostile to such a suggestion: these 'mutations,' though they are certainly hereditary, are all characterised by weakened vitality and are unable to hold their own in the struggle for existence. This fact has been ably expounded in the address to Section D given by Prof. Osborn and printed in NATURE of August 21, who, in order to emphasise the view that the changes by which animals evolve are widely different from mutations, introduces the word 'speciation.' Further, as Prof. Leathes wisely says, a mutation is not eternal. This, indeed, is its most interesting characteristic; the sport transferred to a natural environment, where, in the absence of dangerous competitors, it has a chance to survive, will after a certain number of generations revert to type; like the feral pigs of Jamaica, which have gone back to the wild boar. We submit that the cause of a mutation is to be sought in the weakening or inhibition of one of the processes which make up the activity of the germ plasm, a weakening which under better conditions is transmitted to succeeding generations in ever-lessening degree and eventually disappears.

Prof. Leathes eloquently discourses on the relation of function to structure and rightly states that physiologists who study function are well fitted to make contributions to the doctrine of evolution. What is 'functional' survives, and structure is the expression of function. This is shown by the fact that the same type of cell, the fibroblast, or, as embryologists term it, the mesenchyme cell, will develop connective tissue fibres and give rise to tendon at the end of a muscle, and will form and deposit calcium phosphate where bone is required. Every particle of bone, he asserts, is the response of the organism to the strains which the exercise of its members brings about. These products of cell-secretion he terms irreversible, as opposed to the reversible changes which take place in muscle.

The difference, however, is after all only one of degree. Cary has shown that muscular fibrils are developed in mesenchyme cells under the influence of strain. In the embryo pig the gut-tube grows faster than its mesenchyme envelope, and the development of these cells into smooth muscles takes place in accordance with the elastic tension to which they are exposed, and, on the other hand, are not the osteoclasts which remove superfluous bone essentially identical with the osteoblasts which deposit it where it is required?

The fact is that the early exponents of evolution, being naturalists and morphologists, had only a superficial knowledge of function, and any structure the meaning of which was not obvious was ascribed to 'chance' variations which 'happened' to suit the environment. An example of this method of reasoning was the explanation of the dark pigmented spots found on the forehead of certain carnivora as devices intended to deceive their enemies into the delusion that the animal whilst asleep was really awake and gazing at them. As our knowledge of comparative physiology has progressed it has become more and more obvious that the whole body of the animal is an expression of its functions; or, as a zoologist would phrase it, of its reactions to its environment.

That the functions of cells are reactions to their environment was demonstrated in a beautiful way by Nageotte. He took a piece of sterilised bone from a rabbit's digit and implanted it in the cartilage of the ear. The introduced bone was soon surrounded by

"fibroblasts" drawn from the neighbouring fibro-cartilage and connective tissue. These invaded it and actually deposited new bone around it, although in the normal course of affairs these cells never would form bone.

Prof. Leathes also discusses 'the conditioned reflex.' This is most simply described as a new association of ideas, though Prof. Leathes interprets it as the establishment of a new machinery in the nervous system. The classical example is, of course, Pavlov's wonderful work on the dog, in which the animal was made to associate the sound of a bell with the arrival of food. As a consequence copious secretion of saliva was produced by the sound of the bell. Koffka in his book "The Growth of the Mind" has shown how powerless is the conception of fixed reflex arcs when examined in detail to explain the formation of the new associations. Leaving this special difficulty on one side, however, Prof. Leathes truly remarks that the establishment of new functional relations is only of importance in evolution if this rise of new functions—in a word, the acquisition of new habits in the parent—affects the offspring so that the establishment of the same functional relations in them is effected more and more easily as the generations succeed one another. As most people are aware, this is at once the most fundamental and at the same time the most hotly disputed question in biology. Pavlov has asserted that he has demonstrated, by his experiments on mice, that conditioned reflexes in parents do affect the children. These results have been received by the supporters of 'chance variations' with the same incredulity with which they have received other similar results obtained by investigators of less world-wide fame than Pavlov. Prof Leathes, as an impartial outsider, whilst awaiting confirmation by Pavlov himself of his own preliminary work, seeks to conciliate the more violent opponents by the use of the phrase 'parallel induction.'

By this phrase is meant the theory that whilst the body is incapable of affecting the germ cells which are embedded in it, yet an external influence may at one and the same time affect the body so as to provoke a new reaction and thus initiate a new structural change, and also affect the germ cells so that the next generation will show the same structural change. Surely this theory may aptly be described as the last ditch in which the opponents of the inheritability of acquired habits are prepared to die. Can it be seriously maintained that external changes in light and temperature can penetrate the somatic tissues and alter the deeply-seated germ cells, and yet that the body, which is in close physiological relation to these cells, is powerless to affect them?

Prof. Leathes makes a striking reference to the coincidence of the rediscovery of Mendel's laws of segregation in the hybrid offspring of different breeds, and the cytological discovery of the coming together of paternal and maternal chromosomes in the maturation of the germ cells and their subsequent disjunction into different cells. This 'meiosis' has been widely accepted as the physical basis of this segregation, and it is an hypothesis of seductive simplicity to take this view. But the whole history of physiology ought to warn Prof. Leathes of the peril of accepting simple mechanical explanations such as these. Again and again physiologists have believed themselves to be on the verge of simple physical explanations of vital functions, such as the diffusion of water from the blood through the glomerulus of the kidney, or the passage of oxygen through the alveolus of the lung, and each time closer examination has proved how disappointing and illusory such explanations are. In that wonderful school of cytological and Mendelian research established by the late Dr. Bateson in the John Innes Horticultural Research Institution, a body of devoted students have been studying Mendelian problems for years, and Miss Sverdrup's discovery that there are nine sets of independently segregating characters in the pea, but only seven chromosomes, is a result of just the same kind as physiologists have obtained in other fields.

In conclusion we may say that Prof. Leathes' eloquent appeal to his fellow physiologists to study functional evolution has our warmest sympathy. We feel convinced that if they respond to this appeal the whole aspect of evolutionary philosophy will be enormously changed and improved.

The Assaying of Brabantius.

The Assaying of Brabantius and other Verse. By C. S. Sherrington. Pp. iv+67. (London: Oxford University Press, 1925.) 4*s.* 6*d.* net.

THIS book of poems should interest all lovers of literature, not merely because of its author's eminence in the scientific world, but also for its own artistic quality. It contains the most accomplished verse that has been published in England by any man of science; and one of the most remarkable facts about it is that the point of view throughout is purely artistic. The poem on Keats, for example, is a poem of joy in the artistic handling of words. It shows them "in music swayed attire," shadows moved by the fire of thought. It shows them as "raised trumpets blown at morn," or as "foamed sea-capes calling through mist." It does not talk philology, but it finds them "still across this day of ours weaving fancy's storied woof."

The philistine who prides himself on his superiority

to 'words,' and on his inability to express his own ideas has conquered a large section of the literary world in recent years. Under a new disguise, as the advocate of a crude realism, and the opponent of what he calls 'rhetoric,' he has succeeded in convincing the thoughtless sections of the public that the incomparable language used by the rhetorical author of "Paradise Lost," with its infinitely subtle lights and shades, is less vividly expressive and less full in content than the broken-down jargon of the streets. Violence, the schoolboy use of the most conventional 'scarlet words,' is mistaken for strength, while the true use of language as an exquisite intellectual instrument, capable of the most precise expression of the subtlest ideas, is mistaken for smooth insipidity or what lisping school-girls now call, under the influence of weak-minded newspaper-ridden teachers, 'lack of guts.'

We are living, artistically, in an Aristophanic comedy. Prof. Ward in his really profound "Pluralism and the Realm of Ends" draws largely on Tennyson to elucidate some of the subtlest philosophical ideas of modern times. At the same moment a child of sixteen, quite unaware of any of those ideas, announced to her friends in Chicago lately, "I cannot wead Tennyson. He is so tewwibbly twite. But there's a poem in the *Little Weview* this month which I simply adore. It's so wed-blooded. It's about a bwothel." This is an extreme case; but it is a perfect illustration of the ignorance and conceit which have been allowed to mislead the arts, during the last decade or two, into the insane chaos where so much of the recent work has been floundering. It seems possible that if merely literary criticism cannot save the arts from self-destruction, the scientific mind may have to come over and help them, in the interests of our civilisation, with a little cool lucidity, and a few elementary lessons in rhythm, order, proportion, symmetry, and all that these things imply. When first principles go into the melting pot we may even have to re-demonstrate to our æsthetic agnostics that twice one is two. But science and art have one great common ground, in the ultimate unity of beauty and truth. That ground has never yet been fully charted or explored. The day may come when the golden mathematics of music, in its ascensions to heaven, and its unexpected opening of celestial gates, may unlock some of the most baffling problems of philosophy. Even now, when philosophical terms fail us, we can point to certain movements in a Beethoven symphony and say, "There—that is what I mean," not as an emotional, but as a logical solution. In the meantime it is all to the good that Sir Charles Sherrington in his lines on Keats appreciates so justly the æsthetic values of language. Words, to him, are not mere lifeless counters or labels, but creatures of the heart and mind of man, evolved through ages and having messages of "heavenly things to tell":

Words, deliverance of joy,
Words, blithe feet that move in dance,
Flute-throat words of girl and boy,
Pœaning the spring's advance,
Weeting death not nor mischance;

Words, heaped torrents swollen with rain,
Words, cloud voices league-long blown,
Words, begotten of human pain
Grief-matured through nights of moan;
Words like bell-towers sobbing in stone.

Art, as I suggested above, has its chaos; but philosophy has certainly its confusions. There is no precision of expression like the precision of great poetry. Modern thought would have been a century ahead of its present stage if certain famous philosophers had been able to express their ideas with the profound lucidity of Wordsworth's "Tintern Abbey." Sir Charles Sherrington's own verse has not that limpid depth. He is often a little wilfully tortuous and so he deliberately limits its effectiveness. But he strikes many chords that linger in the memory, and in his enthusiasm for great poetry his book is of real value to both science and literature.

The great dead—not they lie dumb,
Nor are their lips stopped with clay.
Listening fresh to their graves come
All the new-born every day.
We that breathe speak less than they.

There are many glowing pictures in the narrative poem entitled "The Assaying of Brabantius," of which perhaps the most immediately striking is the description of the sea-robbers' attack upon the lordly pleasure-house wherein Brabantius was losing his soul:

Where throngs
Of slaves flowed dancewise and made songs
To please the fanswept dwellers there
Pavilioned over perfumed air.
And how upon them broke a day
Brought, trespassing their sun-caped bay,
Fierce urgéd purple hulls of ships
With tumult filled from brine-caked lips,
And ear-ringed robbers little loath
Shook loose their knives, and, hoarse with oath,
O'erleaping row-bank, thwart and oar,
The beaked keels grounding, swarmed ashore
To clamber up the milky flights
Of graded marbles, till the heights
They won, and swept the pillared shade
Of court and dome and colonnade,
And slew, nor in their slaying stayed
Till all the dazzling streets bereft
Of life they left, and pool-strewn left
As market-stones are with wine lees
With blood the burnished terraces.

The influence of William Morris will perhaps be discerned in this. Here, as elsewhere, the remarkable fact is that there is scarcely a sign anywhere in the book that the author is interested in anything but his art. He never touches upon any scientific subject. But the scientific quality of his mind is revealed in the analysis of character in the "Assaying of Brabantius," which is certainly different from anything in William Morris, and more modern in feeling. It shows itself also in the sonnet entitled "Speech":

> And thus accomplished, after lapse of time,
> Dear meed of converse binds life's scattered ones,
> With healing of the schism of old prime
> As light rejoins the pulses of old suns.

Fragmentary quotation, however, is unjust to the book. It emphasises the somewhat deliberate archaism, and the twisted phrasing. Twisted though it be, it is artistically twisted, and there is a gleam of beauty on almost every page. The sonnet on Oxford is one that none of her sons and lovers who read it will easily forget:

> The night is fallen and still thou speakst to me,
> What though with one voice sole, with accents many,
> Tongued turret and tongued stream, tracked pasture fenny,
> And cloister spirit-trod, and centuried tree;
> And, bondsmen loosed in Time's tranquillity,
> Thy bell-dischargéd hours . . .
> And now, below, through shadows starred, a boat
> Steals by me laden with singing and young laughter
> And, higher, a wide-flung casement casts afloat
> Pulses of waltz the which white robes sway after;
> Sworn Priest of Beauty, these thy shrines among,
> That kneelst with old folk and that dancest with young.

ALFRED NOYES.

The Atom Again.

(1) *The Basis of Modern Atomic Theory.* By C. H. Douglas Clark. Pp. xx+292. (London: Methuen and Co., Ltd., 1926.) 8s. 6d. net.

(2) *Die Konstitution der chemischen Atome: Mechanische Theorien in Physik und Chemie.* Von Prof. Dr. Arthur Korn. Pp. 159. (Berlin: Georg Siemens, 1926.) 7·50 gold marks.

WHATEVER properties may ultimately be assigned to the atom, there is one which cannot be omitted—its power to seize and captivate the human mind. In fact, if we judged by the output of the printing press in the last few years, we might not unfairly assume that no sooner does any one fall within the sphere of influence of this radiating personality than he is seized with an irresistible determination to go home and write a book about it. Nor is this proselytising zeal confined to the pure physicist, whose protégé the atom may be presumed to be. We have books on the atom, some of them quite well done, by chemists, by mathematicians, by technicians, and by journalists, and addressed to all sorts and conditions of readers. Thus we have "Atoms for Amateurs," "Atoms for Adepts," "Atoms for Adolescents," "Atoms for Archdeacons," "All about Atoms for Anybody"—these are not the exact titles, but they indicate the scope of the volumes well enough—in fact, there seems to be a determination that no class of reader shall be left without an exposition of the subject suited to his condition and attainments. As these volumes continue to pour forth—there are two fresh ones before us as we write—we must assume that they find purchasers and readers. If we add to these the enormous output of serious scientific contributions from the many laboratories engaged in investigating the structure and properties of the atom, it is clear that this infinitesimal particle exerts an attraction unique in the history of science over the minds and imaginations of many types of men.

These reflections have been induced by the almost simultaneous appearance of the two volumes the titles of which are given at the head of this review. These differ in almost every conceivable way. One is in English, and is by a lecturer in chemistry; the other, in German, by a professor in a technical institute. One is a compilation involving an enormous amount of reading and abstracting; the other is an account of the author's highly individual speculations. They have only one thing in common. Both authors have been seized and fascinated by the subject, and cannot rest until they have expressed their enthusiasm in print. This, after all, is the only legitimate excuse for writing a book.

(1) Mr. Clark, in his enthusiasm, has read omnivorously and abstracted widely. In 282 pages he makes a clean sweep of the subject from Lucretius to Bohr, Sommerfeld and Debye. There can scarcely be any paper dealing with the atom which Mr. Clark has not consulted, and very few of which he does not make some mention. To have condensed so much into so small a space is a miracle of compression, and his difficulties have been increased by the fact that, as a chemist, he has thought it necessary to devote an appreciable part of his volume to the theories of Langmuir, Lewis, and the physical chemists which a physicist, straitened for space, would probably have been content to treat in a much more summary manner

It has evidently been the author's aim to include some reference to everything which has been either thought or discovered about the atom. To give anything like an adequate account of the subjects

touched upon in this book would require many volumes of equal size, and the author's treatment of the different parts of the subject is necessarily very brief and summary. We must confess to a personal prejudice against the author who skims lightly from flower to flower without extracting the last drop of nectar from each, and quotes formulæ without giving an adequate notion of the steps by which they are derived. For us, not only the chief value but also the main pleasure of science lies in the process rather than in the product, and we were inclined at first sight to regard Mr. Clark's book as falling under the ban of superficiality.

A closer reading, however, convinces us that the book performs a very useful piece of service. In geography we have original books of travel which give us minute accounts of various peoples and places; we have text-books, more or less voluminous, which give abstracted accounts of larger areas; and finally we have the atlas and gazetteer, which is content to tell us what places there are, and where to look for them; and each type of work has its uses. Mr. Clark has provided us with a gazetteer to the atom, and on turning over its pages one realises how much such a gazetteer is needed for this vast and ever-expanding tract of human knowledge. From this point of view the book is excellent. The student who uses it, and any one who is working on atomic physics may be recommended to do so, will find it a mine of information as to what there is to be known about the subject, while admirable lists of references and two good indexes will tell him precisely where to look for the information required. When next we are troubled by vague memories of a paper in some forgotten journal, by an author whose name we cannot for the moment recall and containing results which were probably important if we could only remember what they were, we shall certainly turn to Mr. Clark's book for assistance, and, if the paper has any reference to the atom, we shall not turn in vain.

We cannot congratulate the publishers on their share of the production. We recognise, with regret, that we cannot expect very many pages of print for 8*s*. 6*d*., and in this respect the publishers have not been ungenerous. The artificial increase in the mere bulk of the volume, produced by printing it on absorbent paper and appending a catalogue of general literature, adds nothing to our sense of its value, and does detract very materially from its appearance. The binding is poor and unattractive. The text is good enough to deserve a better dress.

(2) Dr. Korn's book differs widely in its purpose from the one we have just been considering. Whereas Mr. Clark records, almost without comment or criticism, the diverse views which are still current on atomic constitution, Dr. Korn's purpose is to develop and to popularise a highly individual theory of his own. He feels that his theory, as expounded in various papers in the *Physikalische Zeitschrift* and elsewhere, has not received the attention it merits; and surmising that this may be due to its highly mathematical form, he presents his views, in the present volume, in a way which he thinks will be within the capacity of physicists to apprehend. It is clearly outside the province of a book review to criticise original work of this kind. In brief, Dr. Korn proposes to add to the positive and negative particles which are known to be present in the atom, a third class of particles, gravitating particles, the existence of which has not yet been demonstrated experimentally. He then modifies the law of force between the particles by introducing an exponential term into the Coulomb law of force, and on these assumptions builds up a series of atomic structures the properties of which approximate, with some considerable degree of precision, to the properties of the known elements.

We think that physicists are more likely to be deterred from accepting Dr. Korn's theory by his assumptions than by his mathematics. The quantum theory in its applications to the Rutherford-Bohr atom is flowing on in a full current which shows no signs of abating. Unless and until it meets with some unexpected and quite unsurmountable obstacle, it is unlikely that the main stream of atomic science will turn back to flow along the alternative channel which Dr. Korn provides. Physicists, however, who wish to investigate this channel for themselves will find the theory excellently and fully expounded in Dr. Korn's book.

J. A. CROWTHER.

Aurora Polaris.

Australasian Antarctic Expedition, 1911–14. Scientific Reports, Series B, Vol. 2, Part 1. *Records of the Aurora Polaris.* By Sir Douglas Mawson. Pp. 191+6 plates. (Sydney, N.S.W.: Alfred James Kent, 1925.) 15*s*.

IN view of the connexion between ionisation in the upper atmosphere and the propagation of radio waves, special interest is likely to be taken at present in observations of the aurora and related phenomena, particularly in the regions where the aurora and associated ionisation are most strongly developed. The records of the aurora polaris from the Australasian Antarctic Expedition present the detailed observations from the three stations occupied by that Expedition between 1911 and 1914, and will be followed by two other parts in the same volume—" Records of Magnetic

Disturbances" and "Records of the Range of Transmission of Wireless Signals."

All three stations were situated fairly close to the southern auroral zone, a belt about the magnetic axis of the earth, but at some distance from it, in which auroral display is very frequent. Two of the stations were situated on the Antarctic coast and lay within the zone; the third, on Macquarie Island, lay outside it. Observations at Cape Denison (the main headquarters in lat. 67° 00′ S., long. 142° 40′ E.) were far more complete than at Macquarie Island (lat. 54° 30′ S., long. 158° 57′ E.) or at Queen Mary Land (lat. 66° 20′ S., long. 95° 02′ E.), which formed the western base of the Expedition. When combined with the results of previous expeditions, consideration of the azimuths in which the aurora was most frequently and least frequently observed from the different stations enables one to fix approximately the point of intersection of the magnetic axis with the surface of the earth in the southern hemisphere. This point lies, roughly, half-way between Cape Denison and the geographical south pole.

The visual observations of the aurora at the Cape Denison station are the most complete of their kind for any Antarctic observatory. The programme could not, however, be carried out as planned, since unfavourable weather rendered impossible the proposed photographic determination of the height of the aurora. The general sequence of events is what might be expected at a station lying a little within the auroral zone. The aurora is most frequently seen in the northern quadrants and least frequently in the southern. The normal quiet day sequence comprises a series of approaches from the north and retreats from the station, the aurora often passing overhead in the early morning, though the late afternoon is also favoured by the appearance of aurora near the zenith. During auroral storm periods, greater light intensity is accompanied by more vivid coloration and greater movement.

The most spectacular effects (the "intensity maximum") occur, however, shortly before midnight, at which time the aurora may pass to the south of the station. After the maximum southerly extension, the curtains may wane and retreat to the north, or rapidly spread in the heavens as a sheet of brilliant nebula. These very bright manifestations appear to be special phenomena superposed on the normal quiet day cycle, and it is worthy of note that certain short magnetic storms of "special type"[1] seemed also to be unusual phenomena occurring chiefly in the winter months and always very close to the time of the auroral intensity maximum at Cape Evans.

The local mean time of the intensity maximum differs at the various Antarctic stations and seems to occur, as in the north, shortly before local magnetic midnight, defined as the time when the station, the magnetic axis of the earth, and the sun all lie in the same plane. This relation is not indicated for the Queen Mary Land station, where, however, the observations were not so complete as elsewhere. Observations at the Macquarie Island station lying outside the auroral zone were also less complete than those at Cape Denison, but sufficient to show that strongly coloured displays were more marked at this station than at the others and often persisted for a long time.

Though the statistical method used is the only one adapted to bring out clearly the relative frequency of the aurora at different times of the day and its distribution in azimuth, an exceptional similarity in form is sometimes observed at the same time on successive days. These repetitions of form are much more striking than the repetitions occasionally observed on magnetograph traces, as indeed seems reasonable, since the magnetic disturbances are probably closely correlated with the *average* intensity of display in the auroral zone. This circumstance is probably in some measure responsible for the fact that the correlation between auroral activity and magnetic disturbance found by the British (*Terra Nova*) Antarctic Expedition was not more pronounced.

Special attention was paid by Sir Douglas Mawson to the observation at Cape Denison of the trend or orientation of the relatively straight auroral bands (arches) when near the zenith, which are a special feature of the early morning quiet day maximum. These were found to show a definite anti-clockwise rotation, a movement which may conveniently be expressed by the statement that the arches pointed roughly towards the sun during the dark hours when observation was possible. Probably, however, chief interest will be taken in the section of the report which deals with the observations of very faint auroral phenomena in the form of haze patches and arches. These very faint manifestations were quite impossible of discernment until the eye became fully accommodated to the dark, and could only then be seen by the most acute of the observers. They were seen to maintain themselves for many minutes and often for several hours, waxing and waning in intensity. The report does not, however, indicate what criteria were applied to distinguish these faint auroral effects from the night luminous clouds which have been observed elsewhere at a height of about 80 km.

Careful perusal of the report will probably leave the reader with the feeling that our knowledge of the aurora in high latitudes is still very incomplete and that, even in the field of investigation covered by the

[1] "British (*Terra Nova*) Antarctic Expedition, 1910–13"; 'Terrestrial Magnetism," p. 270; "Observations on the Aurora," p. 34.

expedition, there is much which requires further study. The occurrence of the very faint phenomena is a case in point. The anomalous behaviour of the aurora at the Queen Mary Land station furnishes another example, the fairly even distribution of the aurora in different azimuths at this station being difficult to explain in view of the relative infrequency of its occurrence in the zenith.

The enhancement of the diurnal variation in the magnetic elements in high latitudes on disturbed days during the winter indicates an associated ionisation comparable with that due to sunlight, and there seems no doubt that this ionisation is responsible for the interesting correlations between auroral and magnetic activity. Whether any effective correlation exists also between auroral activity and radio transmission in and across the polar regions is not known, but the promised Part 3 of the present volume should throw some light on this question.

Quite apart from these interesting correlations and the laboratory work in progress to determine the properties of the radiations responsible for the aurora and the constitution and form of matter which emits the auroral light in the upper atmosphere, an immense amount of research is still required to clear up the position. More determinations of height and more spectroscopic observations, particularly at great heights, are required at widely separated places and especially in the Antarctic. More work is necessary to determine the cause of the occurrence of unusual colours during unusually active displays and to determine the wave-lengths of the weaker lines of the spectrum and their relative intensities. The relation between the light of the night sky and the occurrence of the auroral green line seems to demand further investigation, as also the fact that the polar aurora appears nearer the magnetic axis of the earth in storm periods, while the occurrence of an aurora in low latitudes is on occasions of world-wide magnetic disturbance.

This list of problems is only a small selection from a very large number which require investigation before the accepted outline theory of the origin of aurora can usefully be elaborated.

Our Bookshelf.

Fourfold Geometry: being the Elementary Geometry of the Four-Dimensional World. By David Beveridge Mair. Pp. viii + 183. (London: Methuen and Co., Ltd., 1926.) 8*s.* 6*d.* net.

MR. MAIR states clearly in his preface the scope of his book, which deals essentially with the elementary geometry of a four-dimensional continuum of space and time, the existence of straight lines being assumed. His aim is to prepare the ground for an understanding of relativity geometry rather than to treat his subject as a special case of general manifold geometry. The terminology is evidently chosen from this point of view, and the distinction between 'time-like' and 'space-like' vectors is made early in the book and used throughout.

The author begins with an account of the line vector from which he builds the area, volume and super-volume vectors. He explains geometrically his frames of reference or lattices in two, three, and four dimensions in turn, deals with combination of vectors, defines the tensor operator and establishes the invariants for transformation of lattices. As examples he discusses the velocity vector, derives the Lorentz transformation and gives a brief account of the motion of a particle. One feels, however, that these results are not so much illustrations as part of the scheme of the book.

From the first the notation is carefully explained and chosen to foreshadow and fit the tensor operations which thus emerge naturally and easily. The style is lucid and precise. Such terms as 'perpendicularity' and 'parallelism,' for which new definitions are needed, are treated with admirable clearness. The dependence of results upon the straight line hypothesis is emphasised, and it is shown how the removal of this restriction leads to the wider problems of the curved fourfold, which, as Mr. Mair points out, are beyond the scope of the book, although he indicates the use of the geodesic. The idea of invariance for different lattices is well stressed so that the reader cannot fail to realise its importance. A knowledge of Cartesian geometry is assumed, but very little more. The careful diagrams and well-thought-out exercises interspersed in the text, together with solutions at the end, add to the value of this stimulating little book.

Essentials of Systematic Pomology. By Prof. Brooks D. Drain. (The Wiley Agricultural Series.) Pp. v + 284. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1925.) 13*s.* 6*d.* net.

THE increasing number of varieties of fruit and the uncertainties of commercial nomenclature render the study of pomology full of pitfalls, and the student and grower alike will welcome Prof. Drain's attempt to set forth the essentials of the subject in a lucid style, shorn of unnecessary detail. Though dealing with American conditions, the text-book should prove of value to workers in other countries also. In studying the principal varieties of hard and soft fruits the various points are tabulated into good and bad characters, with notes on distribution and extent of cultivation. Various keys for the classification of apples are considered, that of Carpenter and Stafford being regarded as the best, Shaw's key for leaves and Keil's group classification of the fruit also finding a place. Of special interest are the sections on fruit exhibition and judging, details of American rules being given with the appropriate methods of scoring points. Exercises for class work are suggested, with practical hints on the cold storage of soft fruits for examination at later dates. A glossary of pomological terms and a certain number of references are included.

The development of fruit varieties in North America has been closely connected with the settlement and

development of the country. The early explorers and settlers brought in varieties of fruit from their native lands, many of which successfully passed through a period of acclimatisation. Selection and breeding from these old stocks have resulted in the production of new varieties better adapted to the needs of the growing fruit industry. Inevitably, increasing confusion of nomenclature has resulted, and therefore the American Pomological Society has drawn up a code of fruit nomenclature, in an endeavour to simplify matters. This code has been considered as the final umpire since about 1865, the last revision of 1923 being that now in use. W. E. B.

Grundzüge der Paläontologie (Paläozoologie). Von Karl A. von Zittel. Neubearbeitet von Prof. Dr. Ferdinand Broili und Dr. M. Schlosser. Abteilung 1: *Invertebrata.* Sechste verbesserte und vermehrte Auflage. Pp. viii + 733. 17 gold marks. Abteilung 2: *Vertebrata.* Vierte vermehrte und verbesserte Auflage. Pp. v + 706. 15 gold marks. (München und Berlin: R. Oldenbourg, 1923–24.)

BOTH geologists and zoologists are much indebted to Prof. Broili, of Munich, and the enterprising publishers of Zittel's "Elements of Palæontology," for a rapid succession of new editions of this indispensable handbook, keeping it up-to-date. It is a compendium of facts, with references to the scattered literature of the subject, such as are needed for research in many directions, and the arrangement of the matter, as originally planned by Zittel, makes it easily used. It still tends to be conservative in admitting new hypotheses or schemes of classification, and most of the additional figures resemble those of the first edition in being actual illustrations of fossils rather than explanatory sketches. The work indeed retains all the essential features of Zittel's incomparable exposition.

In the sixth edition of the section on Invertebrata the mollusca have been particularly revised with the aid of Prof. A. Naef and Dr. J. Schröder. In the fourth edition of the section on Vertebrata, the mammals, birds, and fishes have been revised entirely by Dr. Max Schlosser. Prof. Broili has thus supplemented his own labours by securing the co-operation of other well-known specialists, and the result is an encyclopædic work which inspires confidence. There are more small misprints than should appear in technical statements that are so carefully edited; and the additions sometimes necessitate changes which are not attended to in the context. Until, however, another Zittel arises to re-write the whole from the beginning, the minor blemishes incidental to patchwork cannot be avoided.

The Natural History of the Oxford District. Contributions edited by Comdr. James J. Walker. Presented to the Members of the British Association for the Advancement of Science, Oxford Meeting, 1926. Pp. viii + 336. (London: Oxford University Press, 1926.) 10*s*. net.

IT was to be expected that the natural history of the country immediately surrounding a great and ancient university would have been studied with especial thoroughness. None the less, the naturalists attending the Oxford meeting of the British Association must have been impressed with the richness and variety of the plant and animal life and with the great geological interest of the district, as revealed in this handbook. The very abundance of the material at their disposal must have added to the difficulties of the task which the editor and his fellow-contributors set themselves and discharged with such conspicuous success. The volume consists of more than twenty short articles by authorities on their respective subjects. It opens appropriately with sketches of the physical history of the land forms and various other aspects of local geology. These are followed by accounts of the botany of the Upper Thames, and of the birds, insects, and other animals of the Oxford district. The final chapters deal with the entomological treasures in the Hope Department of the University Museum, the wonderful ethnological series in the Pitt-Rivers Museum, and the fine collection of early scientific instruments formed by Dr. Lewis Evans and housed in the Old Ashmolean Museum. The handbook constitutes a summary, and provides a record of local species, which will be of permanent value to such members of the University as are interested in biological studies, as well as to naturalists generally. It is perhaps permissible to suggest that, for the immediate purpose of its compilation, something a little less technical in style might have had an even wider appeal.

Clouds and Weather Phenomena: for Artists and other Lovers of Nature. By C. J. P. Cave. Pp. x + 31 + 23 plates. (Cambridge: At the University Press, 1926.) 5*s*. net.

FOURTEEN years ago, the Cambridge University Press published a book by Mr. Cave on "The Structure of the Atmosphere in Clear Weather," a well-known work on upper winds written by a meteorologist for meteorologists. "Clouds and Weather Phenomena," which is also published by the Cambridge Press, is of a very different type, and while a work on clouds by Mr. Cave will undoubtedly be read by most meteorologists, the book is not intended for those engaged in the study of the weather but for the general public, and more particularly for artists, whose knowledge of cloud forms is often shown by their works to be very slight. In accordance with this object, the book is written in the simplest manner and contains scarcely any reference to meteorological theory.

The first half of the text deals with the colour of the sky, including sunset colours, with rainbows, halos, and other optical phenomena, describing under what conditions and in which parts of the sky these are seen. The next section is devoted to clouds, the international nomenclature being followed and the types illustrated by twenty-two excellent photographs taken by the author, placed together at the end of the book. Some notes on the position and appearance of the moon at different seasons conclude the volume. Perhaps one may be allowed to express a doubt whether even an authority like Mr. Cave, backed by the Cambridge University Press, will be able to reform the ways of artists, but all meteorologists will extend a hearty welcome to the book and wish the attempt success. J. S. D.

Letters to the Editor.

Science and Psychical Research.

IN NATURE of July 31, Dr Tillyard, the well-known entomologist, reproaches Huxley for not being interested in the phenomena of what Sir Arthur Conan Doyle and others call spiritualism. He extends this reproach to all who consider the claim that from "the organism of the medium 'psychic stuff,' by the moulding of which they [the invisible operators] can produce at will the phenomena of independent voice, levitation, materialisations of portions of their personalities, and so on," so highly improbable that they refuse to spend their time and energy in the efforts required for obtaining or refuting proof. Yet it is by such limitations, and by them only, that science has hitherto obtained its results.

No doubt Dr. Tillyard, guided by the experience which he gained during a long and successful career in entomology, would refuse to investigate reputed cases of insects with bony skeletons suckling their young. Why then should he be so hard on the physicist who, on the ground of his experience, refuses to investigate levitation, or on the biologist who, mindful of Harvey's *omne vivum ex ovo*, considers his time better spent in his usual pursuits than in an investigation of reputed "materialisations of portions of personalities"?

Dr. Tillyard evidently approves of the scientific movement which displaced the medieval church from its position as the guardian of all knowledge—natural as well as supernatural. Why then should he object to that great majority of his fellow-scientists who think that the change would be for the worse if they accepted the guardianship of the medium? This, however, is what Dr. Tillyard really advocates; he is not satisfied with the liberty accorded ungrudgingly to any one willing to investigate even the most improbable phenomena; he wants physicists and biologists to leave "the broad highway" of science and to enter "The neglected side-path, foul with mire and overgrown with noxious weeds" along which the medium is anxious to guide them. If science did so help, its name would be superstition.

J. P. LOTSY.

LIKE Mr. Campbell Swinton, Dr. Lotsy confuses psychical research with spiritualism; he then charges me with reproaching Huxley for refusing to be interested in the latter! If he will again read carefully through the third paragraph of my article and follow it logically with the beginning of the fourth, he will see how far he has wandered from my meaning. He then selects the rarest and most puzzling of all psychical phenomena, namely, the ideoplastic moulding of teleplasm into forms resembling "portions of personalities," and says that I extend my reproach to all who refuse to consider this as a valid phenomenon worthy of scientific study! This would be rather like reproaching a peasant who lived in the middle of Asia for refusing to believe in the existence of submarines when he had never even seen the sea!

Dr. Lotsy is quite sure about what I would do if I were confronted with reputed cases of "insects with bony skeletons suckling their young." I am not! If one of our leading entomologists were to write to me and state that he had observed a case of one of the higher pupiparous Diptera suckling its young, I should most certainly want to investigate it, though I might feel sceptical about his use of the term "suckling." The more improbable the reputed facts, the more I should consider the weight to be attached to the reputation of the man who made the statement. If the fact were vouched for by three entomologists of the standing in their own science that Lodge, Crookes, and Richet hold in theirs, I should consider that a good case for investigation had been made out. The weak point of Dr. Lotsy's argument is that he tries to draw a comparison between something in entomology which has never been even 'reputed' to occur and something in another branch of science which many leading men of science state clearly has occurred in their presence under test conditions; so that the only question which remains is to decide whether it is really true or whether they are liars or under delusions.

As for Harvey's *omne vivum ex ovo*, I doubt very much if modern biologists are compelled to regard this as a strictly accurate statement of the origin of life. Certainly Dr. Lotsy himself does not, for he has been trying for years to get them to accept instead his own emendation of *omne vivum ex hybrido*! Personally I prefer Harvey's dictum, but I do not think that the first unit of life that appeared on our world was either an egg or a hybrid. Moreover, the phenomena of teleplasm do not controvert Harvey's statement. For the 'psychic stuff' itself is admittedly drawn from the physical organism of the medium, and the medium is "ex ovo." Even if the ideoplastic moulding is really done, not under the control of the subconscious mind of the medium but by the will of an invisible operator who has once lived in the flesh, that operator by his own claims and admissions was once "ex ovo." The facts of psychical research do not *contradict* any of the broad principles of biology.

Finally, Dr. Lotsy makes the usual blunder of those who, knowing nothing of the elementary principles of psychical research, persist in regarding the medium as the 'guide' in the experiments, whereas the medium is actually in trance and does not know what is going on. I can only repeat that the conditions of the experiments are just exactly what the researchers choose to make them; the facts can be studied and tabulated like other scientific facts. My plea is simply one for assistance instead of obstruction in the attempt to obtain them. To parody Dr. Lotsy's last sentence, "If Science do not so help, then her name is stagnation

R. J. TILLYARD.

Zürich, Switzerland,
August 26.

MR. CAMPBELL SWINTON'S account in NATURE of August 28 of the incidents connected with the Combermere photograph is both inaccurate and misleading. Since he uses my name so freely perhaps you will permit me to state shortly the true version. The whole story, with the photograph, will be given in the next number of *Psychic Science*—the organ of the Psychic College.

This photograph, which shows plainly the outline of an elderly man seated in an armchair, was sent to me with the endorsement of the Combermere family, who may be expected to know as much about the matter as their relative by marriage. On the back was written that it was taken by a certain lady at the time of the old peer's funeral, and that the shadowy figure was supposed to be the wraith of the

deceased man. This I showed (among fifty other psychic photographs) at the Queen's Hall, simply giving the facts as supplied by the family, and making no assertion myself, since I had no personal knowledge of the matter. Shortly afterwards, several violent letters appeared in the press from Mr. Campbell Swinton, in which he used such injurious terms as "photographic fraud." As to the seated figure, he gave in successive letters three different contradictory explanations; the first that it was a photographic flaw, the second, that the butler had crept into the room and seated himself in the chair; and the third, that plates if kept for some time before development may show strange images. He wound up by challenging me to publish in the *Morning Post* the 'ghost' photograph, alongside of a photograph of the peer taken in life. I at once sent up my photograph without any suggestion whatever that it would not reproduce. That statement is pure invention upon the part of Mr. Campbell Swinton. The editor refused to take the risk of an inferior reproduction, and could only guarantee a good one by touching up, which would be objectionable. A reproduction was afterwards made by the *Daily Sketch*, but whether touched up or not I could not tell.

That is all a technical question with which I had nothing to do. What was, however, strange and rather amusing was that when the photograph of the peer was finally published he proved to be remarkably like the 'ghost,' having a very high forehead and some indication of a short tufted beard. Thus the result of Mr. Swinton's labours was to add one more point to the argument for the authenticity of the picture. There is clear evidence that there was no male visitor or servant in the house who wore a beard.

ARTHUR CONAN DOYLE.

September 1.

[No useful scientific purpose would be served by the discussion in NATURE of the production of spirit photographs or of the reality and origin of the various phenomena manifested during séances with a medium believed to be in a state of trance and to know nothing of what is occurring. The main point of Dr. Tillyard's article in NATURE of July 31 was that scientific men generally presented an unscientific attitude to the subject of psychical research; and he pleaded for critical inquiry in a field hitherto mostly neglected by scientific investigators. This alone is the matter which we think may be usefully discussed in NATURE, or to which we are inclined to devote space.

In his letter Mr. Campbell Swinton raised the question of the alleged spirit photograph of the second Viscount Combermere, his uncle by marriage, and it is only just that Sir Arthur Conan Doyle should be given an opportunity of replying. We do not propose, however, to let other correspondents range themselves on either side in regard to the authenticity of the Combermere photograph, or to submit or expose evidence of psychic phenomena of any other kind. For the present, at any rate, correspondence must be limited to the plea made by Dr. Tillyard for "the *scientific* study of what are called *supernormal phenomena*."—EDITOR, NATURE.]

The Three-dimensional Reproduction of Tracks of β-particles Ejected by X-rays.

THE use of a stereoscopic camera by C. T. R. Wilson in the photography of tracks of β-particles ejected by pencils of X-rays led to the revelation of two types of asymmetry of initial direction of ejection (*Proc. Roy. Soc.*, A, 104, 1923). One is characterised by an excess of tracks having their initial portions in or near the plane containing the X-ray pencil and its electric vector; the other by an excess of tracks having a forward component in their initial velocities. They have been termed 'lateral' and 'longitudinal' asymmetry respectively. The former distribution reveals the partial polarisation of the primary beam, the preponderance of primary X-rays the electric vector of which is in the plane containing the cathode stream. The latter distribution has been accounted for qualitatively on the basis of Richardson's hypothesis that the absorption of a quantum $h\nu$ of energy by the electron is accompanied by the transference of the momentum of the absorbed radiation causing a resultant motion in the forward direction. A third feature of interest and importance revealed by Wilson's photographs was the existence of short, unidirectional, fish-like tracks with tails towards the X-ray source and produced only by X-rays of wavelength not exceeding about 0·5 Å.U. The phenomena of fish-tracks are most completely and satisfactorily explained by the application of the Compton quantum theory of scattering of X-rays.

In further examination of these features other investigators have adopted the stereoscopic method. F. W. Bubb, in an examination of the initial directions of β-particles ejected by polarised X-rays scattered by a paraffin block, has photographed the tracks directing the camera lens axes end-on to the X-ray pencil for the observation of lateral asymmetry and broadside-on for the observation of longitudinal asymmetry. O. K. de Foe and D. H. Loughridge have examined independently longitudinal asymmetry by stereoscopic photography from the broadside-on position. The latter calculated initial direction of ejection from measurement of depth in the photograph of the end of the initial straight portion by means of a stereocomparator, and of height and breadth by direct measurement by dividers.

The work of F. Kirchner involving the stereoscopic photography of tracks produced by Compton electrons was described by Prof. W. Wien in his paper "On the Direction of Electrons emitted by the Photo-electric and Compton Effects," read before Section A of the British Association on August 10, 1926. Prof. Wien referred to the difficulty of ascertaining correctly, by examination of the photographs stereoscopically, the initial directions of the tracks with reference to the primary X-ray pencil. This difficulty had been met to some extent by the co-option of observers who could not possibly have any 'Compton bias.' I myself experienced this difficulty in some work done in 1924 in which I examined stereoscopically tracks produced by $K\alpha$ copper radiation homogenised by reflection from rock-salt, and was led to consider the possibilities of photography in two directions at right angles eliminating the stereo-vision difficulty and at the same time increasing very considerably the precision with which the forms and initial directions of tracks could be determined. It appeared, too, that such photography would avoid two other difficulties inherent to stereoscopic examination of lateral asymmetry in which photographs are taken end-on to the pencil. Tracks would be formed across the full width of the cloud-chamber (15 cm., say), and it is impossible under the conditions of the experiment for all to be sharply in focus. Also, even in the absence of this difficulty overlapping and confusion is inevitable.

It was at once evident that the most suitable directions of the lens-axes, using separate single lens cameras and the direction of the primary X-ray pencil being horizontal, would be the vertical and horizontal perpendiculars to the pencil. The photographs so obtained would give the projections of

tracks on two perpendicular planes. Measurement of the angles made by the initial straight portions of the projections with the direction of the X-ray pencil makes it possible to calculate the angle between the actual initial portion of the track and the plane containing the pencil and the electric vector (δ) and the angle between that portion and the direction of the X-rays (θ). Statistical examination of values of δ and θ might then be expected to show most probable values of these angles and the existence of lateral and longitudinal asymmetry. Further, it would be possible to determine the three co-ordinates of any point on a track and therefore the true path of the β-particle in its flight through space.

In practice, adopting the Wilson mercury-lamp flash method of illumination and directing the illuminating beam almost horizontally on the line of the X-ray pencil, it was found that whilst ample light was scattered forward, giving good records in the horizontal camera, so little was scattered at right angles, that is, vertically, that the tracks were not recorded on the negative in the vertical camera. This difficulty was overcome by placing in the appropriate position on the base of the cloud chamber a right-angled glass prism and producing total internal reflection of the illuminating beam in a direction bisecting the angle between the axes of the cameras. Photographs so obtained were of satisfactory and approximately equal density.

Measurements have been made by low-power microscopic observation of the negatives directly and the advantages anticipated by the substitution of right-angle for stereo-photography realised. Using heterogeneous X-rays and moist air in the chamber, the existence of both types of asymmetry has been found. Experiments are now in progress in which homogeneous X-rays produce tracks in gases other than air.

Spatial and Time Relations in Dreams.

IN NATURE of August 7, Dr. J. H. Kenneth refers to my letter which appeared in the issue of March 17, 1923, and he describes further observations of hypnopompic images.

In my letter I referred to an observation at the high-speed extreme end of the scale of time, in which the speed was so high that the image consisted only of blurred fleeting parallel lines, seen in an almost unconscious state. Curiously enough, after more than a year without any observations worth mentioning, I was enabled this very morning to confirm my statement that "the speed of succession (I ought to have said, of translation) of the images is an inverse function of the degree of wakefulness," by an observation at the other extreme end of the scale, thereby completing the series of observations necessary to establish the relation between speed and consciousness on a sound scientific basis.

I had just been roused from a deep sleep (the whole of the previous night having been spent journeying in a railway carriage, and therefore practically sleepless), I had exchanged a few words on the weather with the person who had awakened me, and I was therefore *quite awake*; I had closed my eyes for a few minutes before getting up, when, to my surprise and delight, an image at an *absolute standstill* appeared suddenly. The image represented a grassy rising slope with outcropping rocks, the details being so clear that, had time permitted, I could have counted the rocks; it lasted some eight or ten seconds before vanishing, and during that time it remained quite motionless. While observing its details I was fully realising that I was witnessing the process of unconscious mind-picture forming at the hitherto unobserved zero end of the scale, and verifying the relation I had expressed several years ago, and to which my attention had been again called by reading, last night, Dr. Kenneth's letter.

It is perhaps significant that, two days ago only, I was in North Wales and I had climbed the Moel Siabod (2860 ft.) alone, and therefore with my mind entirely free from diversions, and naturally concentrated on the orographic feature which had faced me during most of the time taken by the ascent, namely, up to the final steepest climb, a grassy slope from which emerged innumerable rocks.

I have used above the word 'mind-picture,' but it must be understood that such a hypnopompic image is quite different from a mind-image, as usually conceived, every detail of which is necessarily the result of an act of volition on the part of the person whose mind forms the image. A hypnopompic image appears as a whole, in all its intricacy of wonderful details, without any volition whatever. In the *Journal of the Society for Psychical Research* I have stated that the image seems capable of gradual modification at the result of volition, but on the whole my observations do not seem conclusive enough on this point, and it remains doubtful.

This study of hypnopompic images is not only very interesting, but it is also perhaps the only direct path of approach towards the elucidation of the *modus operandi* of the formation of an image by the mind and its perception as such, with all its minute details. Occasions in which such images come under reasoning observation are necessarily few and far between, and all students of psychology are greatly indebted to NATURE for keeping on record such scanty observations as are available, and which otherwise would be lost, or fail to fall under the notice, and awake the interest, of others.

The principal features of interest are, besides the speed relation referred to above, the possible simultaneous existence of several superposed 'films,' their variable inclination and the possibility of their snapping, referred to in my letter. Dr. Kenneth has established a most important feature, namely, the relationship between the inclination of the line of motion and the position of the observer, which I have so far failed to notice. I have forgotten the details of the observations described in my letter to which Dr. Kenneth refers, and I must therefore abide by my notes; these seem to imply the simultaneous existence of several films, superposed and at different inclinations, and this is at variance with Dr. Kenneth's observations. As the latter appear to be much more precise than mine, so far as this particular question is concerned, mine consisting but of one single instance, noted in passing, while my mind was concentrated on other details, I think that they should be given more weight, until my own observations are confirmed. Both states can possibly occur, according to circumstances.

Pernicious Grafting.

THE question raised in a letter on this subject from Dr. Grabham in NATURE of July 17 is one of very real interest to horticulturists in Great Britain as well as to growers in Madeira. Examples of 'incompatibility' between stock and scion occur in practically all the commercial fruits which are propagated

by budding or grafting. Moreover, there is a very complete graded series, ranging from the case in which perfect harmony apparently exists between the two individuals, to that in which they are quite incompatible and no growth at all takes place. It may be, for example, that the dwarfing influence of certain stocks upon scions is the result of incomplete harmony. The phenomenon is more distinct in the case of stocks sometimes used for pears, upon which some varieties will grow perfectly satisfactorily for one or even two years, after which growth ceases and the plant eventually dies. A slightly different aspect of the matter may be observed in the case of plums, in which it is a matter of difficulty to induce the budded scion of some varieties to grow at all on certain stocks, and it should be emphasised that success depends upon both stock and scion. Whilst a variety which does not 'take' well on one stock grows quite satisfactorily on another, at the same time a stock which is unsuitable for one scion proves a good 'mother' to others.

It has been established at this Station that even seedlings which are closely related may vary considerably in their capacity to unite with a scion. The seedling Myrobolan plum stocks of commerce are an example of this variation. One Myrobolan seedling, for example, gives 95 per cent. success with buds of Czar plum, whilst another from the same batch gives less than 50 per cent. of satisfactory unions with the same variety. A similar range of variation exists within single groups of seedling stocks used for peaches; for example, the S. Julien group.

The problem is somewhat complex physiologically, and at present it is not even possible to state it accurately, although observations are now accumulating to this end.

From a practical point of view, there are two possibilities of circumventing the difficulty. Some pear varieties are incompatible with quince stocks, but a satisfactory tree is obtained by the process of 'double grafting' or 'intermediate grafting,' which involves grafting a compatible scion on the stock and regrafting the desired variety on the first scion a year later. There appears to be no reason why this method should not succeed with peaches.

A more certain method of avoiding the effects of incompatibility is to discover a stock which is suitable for the desired variety and to propagate that stock vegetatively. In this way the variation which is involved in the use of seedlings is obviated.

R. C. KNIGHT.
RONALD G. HATTON.

East Malling Research Station,
East Malling, Kent,
August 17.

THE ill effect which often follows the grafting of the peach on seedling stocks described by Dr. Grabham in NATURE, July 17, is very common in peach nurseries on the Western Frontier of India, especially when the peach is budded on the almond. In the summer of 1919, a few weeks before our service in Baluchistan came to an end, we paid some attention to this matter, the results of which are published in the *Indian Forester* of December 1919. We found that the restricted growth which often follows budding was due to imperfect sap circulation caused by an abnormal amount of callus tissue at the point of union between the stock and scion. Analyses of the peach leaves of affected trees in September 1919 showed that they contained less nitrogen, ash, phosphorus, lime, and potash, and much more starch, than normal leaves. Consequently root development was far below the average.

The trouble can be avoided (1) by ring budding the peach either on seedling peach or seedling almond stocks and (2) by destroying all weakly abnormal plants in the nursery before planting out. Ring budding is best done when the peach or almond seedlings are growing vigorously in the early summer. At this time a ring of bark, with one bud, is easily removed from the parent peach tree. This is placed in water and at once fitted on the cylinder of wood of the seedling stock, care being taken to push it well home and in contact all round with the living bark of the stock. Union is rapidly established and the peach bud begins to grow in about ten days.

The adoption of this method of propagation in Madeira, combined with the elimination of all abnormal plants in the nursery stage, would probably solve the difficulties described by Dr. Grabham.

The Constitution of the Stars.

ON the theory of radiative equilibrium of stellar interiors, as developed mainly by Eddington, the assumption appears to be implicit that the density, mean molecular weight, and other contingent properties of stellar material, vary in a *continuous* manner from the star's surface to its centre. This assumption appears questionable.

Considering for simplicity a star consisting entirely of like atoms, it would appear probable that with the removal of each successive electron from the atom, due to increase of temperature with depth, or at least with the removal of all the electrons constituting each successive quantum-shell, abrupt discontinuities of state would occur comparable, in a general sense, with the separation of atomic matter into its phases.

The recent confirmation by Adams of Eddington's prediction of an abnormally high density for the 'dark' companion of Sirius may be held to prove that an assemblage of 'atoms' entirely 'stripped' of their electrons cannot result from a mere extrapolation of the laws of a perfect gas—or, for that matter, of any phase of atomic matter—to matter in this sub-atomic condition. Eddington's application of his theory of radiative equilibrium to stellar substance obeying the gas laws throughout makes the density at the centre of the star only 'fifty' times the mean density; it seems possible that 'fifty million' would be nearer the truth.

The suggestion is, then, that the central portion of every luminous star consists of 'stripped' atoms and electrons—or possibly in the earlier stages of its life-history at least of protons and electrons—surrounded by successive shells of atoms in various stages of association. As the density, so the pressure and temperature in the sub-atomic core of the star would be enormously higher than on the assumption of continuous variation, and, conjecturally, high enough to condition the building up of the more complex nuclei from the simpler, with the consequent conversion of mass into radiation.

The mean temperature, the effective temperature, and the absolute magnitude of the star would depend mainly on the mass of the central core, and would continually adjust themselves to its variation, so that stability would appear to be assured. But it is easily conceivable that for different stars the total mass may bear very different ratios to that of the central

core, in which case the output of radiation per unit mass of star would correspondingly vary. The view expressed by Russell and Jeans, that differences in this quantity depend on differences in amount of a hypothetical active material, is thus in accord with the hypothesis.

The question of reconciling it—or otherwise—with current views of the course of stellar evolution, is another matter which, if further consideration appears to warrant it, may be dealt with in a future communication. At present I remark only that it suggests an origin for stars in an assemblage of protons and high-speed electrons—the problem of whether and how these have a beginning lies deeper—and an unforced explanation for the occurrence of 'white dwarfs,' differing entirely from either of those proposed by Dr. Jeans or Prof. Eddington.

University of Adelaide, July 5.

The Volatility and Dissociation of Borax.

KOLTHOFF (*J. Amer. Chem. Soc.*, 1926, **48**, 1447) states that he has been unable to confirm our statement (*Jour. Chem. Soc.*, 1925, **127**, 150) that fused borax loses sodium oxide. He reports that "even after the substance had been heated for two hours at 800° the weight did not change." His experiments, however, appear to be scarcely precise enough to prove that borax on heating (1) is not volatile, and (2) does not change in composition; as a matter of fact the volatility of borax at high temperatures is well established, having been observed by Hoskyns-Abrahall (*Jour. Chem. Soc.*, 1892, **61**, 650), Leonard (*Chem. News*, 1898, **77**, 104), and Smith and Van Haagen ("The Atomic Weights of Boron and Fluorine," *Carnegie Inst. Washington*, Publication No. **267**, 1918).

We would direct attention especially to the last-mentioned publication, where it is stated that "it is certain and not at all surprising that borax cannot be fused for any considerable time without loss" This evidence is so conclusive as to require no emphasis here. There is, however, another interesting piece of evidence. The inside of the silica muffle used for the fusions of borax in our investigation was completely coated with a white opaque enamel, about 0·06 inch thick, of a product of a reaction between the volatilised material and the silica. Clearly the salt had volatilised in some quantity, and with such a volatile substance, selective loss of the constituents could be detected only by analysing the residues We believe that the analyses given in our paper can only be interpreted to mean that borax on prolonged fusion leaves a residue poorer in sodium oxide than is required by the formula $Na_2B_4O_7$, and afford definite evidence of a preferential loss of sodium oxide.

Photographic Theory.

IN the course of photographic investigations at the Royal Observatory, Edinburgh, it has been found by Mr. E. A. Baker that the initial stages of the photographic action, including the deviations from the reciprocity law, are calculable and well represented by assuming that the developable product is formed in two stages, each requiring one quantum; and that the product of the first stage returns in the absence of further stimulus to its original sensitive state, according to the usual law governing the progress of a mono-molecular change. In the case of process plates, where the grains are small and nearly uniform in size, the experimental results agree so closely with those deduced on this theory as to warrant the belief that the departures from it with fast emulsions, where not due to the reversal action, are to be accounted for by the diversity of grain size. The results of these investigations will be submitted to the Royal Society of Edinburgh during the coming session.

Experimental results for single layer fast emulsions and weak light are much to be desired in this connexion. The purpose of the present note is to express the hope that some of the researches at present in progress at different places may be directed to that end, and that results already obtained may be published.

Kaufmann's Experiment and the Spinning Electron.

IN NATURE of August 21 Dr. L. C. Jackson quotes Wentzel as having supposed a *force*

$$(\mu[vX])/c \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

to act on a magnetic electron with moment μ moving with velocity v in electric field X (c is the velocity of light). He deduces from (1) that Kaufmann's experiment shows that the electron cannot have a magnetic moment as large as a Bohr magneton.

Wentzel, however (*Zeitschrift fur Physik*, **37**, p. 911), used (1) as *Storungsfunktion*, *i.e. energy*. (For an electron describing a periodic orbit in an atom energy

$$(\mu[vX])/2c \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

would, I think, lead to the correct first order perturbation, but the equations of motion are not of Hamiltonian form and (2) would not apply in general.) Thus Dr Jackson's argument rests on a mistake. His formula can be seen to be wrong dimensionally. 'He' has not the same dimensions as '$X\mu/c$.' In fact, extra force on a magnetic electron will depend on the gradient of the field. Kaufmann's experiment in no way precludes the electron from having a Bohr magneton of magnetic moment.

Trinity College, Cambridge.

Liver Extracts in the Treatment of Malignant Disease.

THE letter from Dr. J. R. Howitt in NATURE of August 21, p 263, appears to be based upon an extraordinary presumption. The liver, in early fœtal life, is large because it is an active blood-forming organ, but Dr. Howitt seems to suppose that it must have some endocrine function relating to growth. If this idea were correct, it would seem rational to presume that it was a growth-accelerating hormone, for the embryo is growing rapidly. Dr. Howitt seems to think that it is a growth-retarding or, at least, a growth-regulating hormone. That the method advocated may have clinical value is, of course, possible, but it is difficult to understand the theoretical basis of the treatment. I have no knowledge of decreased activity of growth in tumours when associated with enlargement of the liver due either to simple hypertrophy or to resumption of its blood-forming activity.

Oceanic Isostasy in Relation to Geological Tectonic.[1]

By Sir JOSEPH LARMOR, F.R.S.

1. A CENTURY ago geodetic and gravitational universal surveys were mainly concerned with determining the effective (gravitational) ellipticity of the earth, after due allowance had been made for local anomalies, with especial view to the exact purposes of physical astronomy. One of the chief of these anomalies was exhibited by a remark of Airy, after scrutiny of the available data in his treatise (1830) on figure of the earth in the "Encyclopedia Metropolitana," that the observations show gravity to be abnormally in excess on island stations. It appeared, for example, that this cause might make the mass of the moon uncertain up to 2 per cent. A very refined explanation of this anomaly of island stations (which will be seen presently to be only partially effective) was offered by Sir George Stokes, from whom this last remark is quoted, in the course of a memoir,[2] fundamental for theoretical geodesy, in which he demonstrated that no outside survey could lead to any certain knowledge of the distribution of mass inside the earth, even in its outer crust, except as a matter of probability when backed up by geological knowledge.

It is explained there that the form of the sea-level must be locally depressed over a deep ocean, owing to defect of density; and in consequence on insular stations gravity at sea-level is measured abnormally nearer to the centre of the earth as a whole, so that from this cause its value is greater than that belonging to the mean spheroidal surface. In fact, the form of the ocean is an equipotential surface, including therein the potential of the centrifugal force of rotation in the familiar manner: but the part of the potential arising from the local water is abnormally small on account of its low density, and this defect must, in absence of local compensation, be made up by a greater potential of the earth as a whole, which demands depression of the local ocean surface towards the earth's centre.

The opposite result would arise from excess matter of an adjacent mountain or island peak: that would raise the ocean level in its vicinity and thereby indirectly diminish gravity, measured at sea-level as determined by levelling operations.

For example, at the centre of a circular oceanic basin or radius b and uniform depth h, its defect of potential would be with sufficient accuracy $\int \gamma\rho' h 2\pi r dr/r$, where ρ' is the defect of density of the water below that of the average terrestrial crust; thus it is $2\pi\gamma\rho' bh$, where γ is the constant of gravitation given by $\gamma E/a^2 = g$. Here $E = \frac{4}{3}\pi a^3 \rho$, ρ being $\frac{11}{2}$, is the mass of the earth of radius a. As the potential of the earth as a whole is $V = \gamma E/r$, this change of local potential, say δV_0, would be compensated by change of sea-level δh, where $\delta V_0/V = -\delta h/r$. Thus in the present case the fall of level relative to depth of ocean is given by the expression

$$-\frac{\delta h}{h} = \frac{a 2\pi\rho' b}{E/a} = \frac{3}{2}\frac{\rho'}{\rho}\frac{b}{a} = \frac{9}{22}\frac{b}{a},$$

while

$$\frac{\delta g}{g} = -2\frac{\delta h}{a}.$$

If the radius b of the oceanic basin is 50 miles this fall would be the fraction $\frac{9}{22} \cdot \frac{50}{4000}$ or $\frac{1}{200}$ of its depth; if the radius were larger it would increase in direct proportion until it is a considerable fraction of the earth's radius. A cup-shaped ocean could be similarly treated.

The steady sea-level would thus be depressed by $\frac{1}{10}$ of a mile owing to local causes, at the centre of a basin of 500 miles radius and 2 miles deep, in free communication with the other oceanic waters: and this approach to the earth's centre would involve increase of g measured at ocean level, given by $\delta g/g = -2\delta h/a$, or here $\delta g = 0{\cdot}05$ cm./sec.^{2}, where g is about 981, which is over one-third of the order of magnitude of the observed excesses at island stations.

But this explanation fails because there is a predominant offset. The vertical attraction of the local ocean regarded as an extensive flat slab of water is abnormally small by $2\pi\gamma\rho' h$, where $g = \gamma E/a^2$, that is by $g\rho' 2\pi a^2 h/E$ or $\frac{3}{2}\frac{\rho'}{\rho}\frac{h}{a}g$; thus this direct defect in g may be much the greater, being $\frac{1}{2}a/b$ times the indirect excess. There is however some effect in the other direction due to excess density of the local land, which is usually a substantial correction. This preponderance destroys and even reverses the Stokes explanation of the oceanic anomaly. Indeed closer examination shows that, as based by him,[3] rather confusedly as it seems, it depends on a potential equation used by Laplace which can, in limited manner, apply only to a locally infinitely thin spherical layer. The principle of depressed level became familiar, simple examples being worked out, *ab initio* and so correctly, by way of illustration in Chap. IV. of Col. A. R. Clarke's standard treatise on geodesy (1880), from the point of view however only of levelling operations, not of gravity.

But soon the discussion of the data of the Indian geodetic survey, by Archdeacon Pratt in India, revealed new features,[4] by showing strong residual defect of gravity on the Himalayas, such as could only be accounted for by a large defect of density underneath the mountains. Airy's idea that the mountains might be buoyed up by extensive roots floating in a denser magma, existing beneath a *thin* crust, could not of course now be maintained, at any rate in that form, in view of the high rigidity of the earth as a whole. But there was much to be said, on various counts, for a thinner and deeper viscid stratum, lying between the crustal material and the solid core, in which in the tendency towards equilibrium the pressure due to the weight of the crust must in course of ages have become

[1] Abstracted, with Sections 2 and 3 added, from *Proceedings of the Cambridge Philosophical Society*, Feb. 8, 1926.

[2] *Cambridge Transactions* (1849): reprinted in "Math. and Phys. Papers," vol. ii. Some idea of the great debt owed by the Indian and other gravitational surveys to the continuous amateur advice of Sir G. G. Stokes, spread over half a century of their development, may be gleaned from the collection of his "Scientific Correspondence" (Camb. Univ. Press), vol. ii. pp. 253-325.

[3] "Math. and Phys. Papers," vol. ii. p. 153. Stokes did not make any correction in this reprint in 1883; but Dr. Bowie states (*loc. cit. infra*) that there is no generally accepted explanation other than compensating excess of density beneath the ocean.

This analysis of Stokes in fact establishes as a general proposition that the effect of *distant* irregularities of surface mass consists of a direct vertical attraction, say g'', together with an indirect part due to change of level, equal to $-4g''$, thus countervailing four times: this influence, of wide range and presumably actually small, is superposed on the *local* effect here considered.

[4] In 1855-59: cf. A. R. Clarke, "Geodesy," pp. 96-98.

equalised laterally, at any rate partially, and the load upon it thus made uniform to that degree everywhere. It is implied that there are no local abnormalities of density in the core, which is reasonable as the core is probably metallic. This is the hypothesis of isostasy, propounded as a universal principle by Dutton and worked out systematically by Hayford and his colleagues of the American Survey, who found that it gave a fair account of the usually slighter anomalies (mainly of levelling) revealed in that great undertaking.[5]

Circumspection is, however, suggested in applying these ideas to the anomalies at oceanic stations; for the Stokes explanation already claimed to be an effective *vera causa*, without aid from compensation of density underneath. It happens that the subject is amenable in a general way to simple elucidation: and as the essential circumstances for submarine mountains and landscapes can perhaps be more directly estimated, it seems indeed to provide in some respects a closer test. On an ideal very narrow island-peak of negligible mass, in a wide ocean of uniform depth, with adjustment as a whole to general isostasy by denser horizontal strata underneath, there would be but slight resultant abnormality of the local part of the attraction. For the totality of the strata could almost be regarded as an extensive thin flat sheet, while local defect of potential on which change of sea-level depends would be still more closely compensated by the extra mass below.[6] Hence, in contrast to the Stokes uncompensated case above, under isostatic conditions gravity and level ought both to be regular over a wide ocean of nearly uniform depth with strata nearly horizontal underneath.

2. The distribution of gravity over an oceanic surface, beneath which local compensations of terrestrial density are taken to be complete, may thus be envisaged, perhaps most simply, by drawing a widely extended arbitrary horizontal boundary beneath the water, and marking out all above it up to the level surface as ocean separately compensated beneath, the law of depth of the compensation being for that hypothetical layer of the density of water unimportant. There will then remain the effect of the surplus of density, over the oceanic water, of the solid parts situated above this arbitrary flat boundary; and it is from this reduced submarine mountain-landscape alone, together with emergent peaks with density undiminished, and the nature of its compensation, that the amount of the actual local excess of gravity is to be estimated on the hypothesis of isostasy, the circumstances thus being analogous to those of a range like the Himalayas, but modified, as all the observations now belong to the same level near the tops of the submarine mountains instead of the bases. The nature of the compensation, in the deep-seated material, of this effective local excess load, would thus permit of being judged by itself; in particular, for steep submarine island peaks it is almost negligible, whatever varying distribution in depth be assigned to it, provided only it extends deep down, say towards the order of 10^2 kilometres.

The long-recognised excess of gravity at island stations was thus really evidence quite as forcible, and also as direct, as the subsequent records of Himalayan surveys, indicating that the defect of density of the masses of water is actually compensated, even over wide uniform oceans, at any rate to a very considerable degree, by excess of density below.[7] The systematic discussion of the level and gravity surveys of America, primarily by Hayford, has enlarged and forced into prominence the same very striking and surely fundamental type of conclusion, as extended even to the usually smaller and less abrupt anomalies there revealed.

The evidence, then, is on all sides remarkably strong, that with increase of depth the terrestrial material gradually becomes softer, so to say, possibly owing mainly to rise of temperature, down to a limit which perhaps at an outside estimate may approach 10^2 kilometres: that below some such depth the mass of the earth presents again a perfectly solid, though doubtless elastically deformable, foundation on which the softer strata directly above have flowed gradually in the course of ages towards an equilibrium nearly hydrostatic, depending in detail, however, on the distribution and range in depth of the softness, in a way that is scarcely much amenable to scrutiny. To effect such adaptation, the displacement of deep-seated material need be only over slight distances, unless the yielding layer is thin. An unyielding foundation underneath is essential to any approach to local isostasy; the earth as a whole must be solid, as it is known to be for dynamical reasons. As regards the relatively shallow upper terrestrial layer which thus becomes viscous with depth, in a way not necessarily uniform nor to the same depth everywhere, the question of rupture or damping of transmission of internal earthquake tremors in crossing these softer layers arises, and is probably ripe for discussion; such a stratum may of course be even completely yielding for slow secular stress while thoroughly elastic for the rapid alternations in seismic oscillations. It is to be remarked, however, that as a result of theory superficial travelling waves, at any rate on uniform elastic material, could scarcely arise from other than a superficial cataclysm, secondary it may be, so that purely superficial seismic undulations would have to come from sources located within their own quite small range of depth. But the velocity would change (dispersively) with wave-length, and this conclusion may be modified, as Prof. Love pointed out, if the elastic quality or density, instead of being uniform, changes notably within the depth of a wave-length.

Why distinct settlement of the strata towards isostasy such as is thus variously confirmed should be necessary at all, affords direct scope for fundamental tectonic speculation, of an interest quite apart from geological detail. Is this abnormally small density beneath mountain ranges due to higher temperature or to lighter material? How could such locally varying temperatures have become established over a consolidating earth? If the height of the mountains is determined largely by the defect of density beneath, they must to that degree have been pushed up hydrostatically from below rather than elevated by lateral stresses; yet folding of the mountain strata is con-

[5] Cf. the chapter in H. Jeffreys' recent treatise "The Earth."

[6] In the case illustrated above, with radius of ocean about 500 miles and depth of compensation 100 miles, about 10 per cent. of the anomaly both of attraction and of potential would remain after compensation of the ocean.

[7] For recent special estimates see a note by W. Bowie, *Proc. Washington Acad.*, Dec. 1925.

spicuous. Subsidence towards isostasy might perhaps induce folding to some degree. If the depression of the Pacific Ocean is thus determined in the main hydrostatically, is there not less room for the cosmic theory that it may represent the cavity from which the moon was originally shed away?

3. *Postscript.*—One observes that these and cognate questions, insistent and fascinating, form the subject-matter of Prof. Joly's recent path-breaking book, "The Surface History of the Earth," which invokes steady evolution of heat by radioactivity of the rocks, interacting with isostatic influences, as the cause of periodic outbursts of surface activity which have fashioned the existing features. There are to be compared the views developed in H. Jeffreys' recent comprehensive treatise, "The Earth." For a condensed account over an extensive range *cf.* "A Symposium on Earthquakes," by F. A. Tondorf, N. M. Heck, W. Bowie, A. L. Day in *Journal Washington Academy*, May 4, 1926, pp. 233-254 (also more recently G. R. Putnam). In a less special way, such questions have been prominent since the treatise of E. Suess on the earth's surface features. There is also the problem of the time-scale of development, projecting into vast æons of the past, yet with clues arising mainly from the fossil traces of the succession of forms of life.

A few special remarks may be significant here.

It appears that the lag in compensation of accumulating great depths of sediment is but small, compared at any rate with the time of accumulation, for the compensation is always well advanced.

Tidal pulls on these adjustable surface-sheets would on Newtonian principles be differential, and so extremely slight. Thus even the extreme case of an elastic earth surrounded by an ocean of molten lava of the order of 10^2 kilometres in depth, in which continents would be analogous to ice-sheets and mountains to icebergs, is not unthinkable dynamically, however it be thermally; though the existence of the actual oceanic tides would demand a rigid and deep crustal layer.

But even if the lagging tidal pull were large enough, it could only cause a westward drift of the fluid surface material around the earth as a whole, not of continents and mountain ranges floating thereon. For the principle of Archimedes asserts itself; as regards the uniform field of force the floating mass can be replaced by the magma which it displaces, up to the level surface; thus it is the same as if the tidal forces acted on a uniform sheet of magma without surface excrescences and no differential drift could arise—except in so far as a uniform drift may be obstructed or deflected locally by the more solid roots of the floating continents that are carried along with it.

The earliest table-lands, of primitive rock, must have been pushed or floated up, and to great heights; it would appear from the literature that their subsequent denudation by aereal influences accumulated stratified deposits along the coasts of the oceanic hollows, which gradually sank into the magma by their own extra weights, perhaps most in the middle so as to curl over by the lateral pressure,—themselves sinking down while the adjacent denuded high land is floated up, until by accumulation combined with sinking, and helped by effusions from below, they attained to considerable slopes and great thicknesses, even five miles or more, that then somehow they were pushed up again bodily, yielding after repetitions of such processes folded mountain-ranges of stratified rock such as geologists know, the primitive elevations having passed largely out of sight. At any rate nothing more plausible seems to have been hitherto thought of.

The Golden Eagle.

By SETON GORDON.

"Thrice the age of a dog the age of a horse,
Thrice the age of a horse the age of a man,
Thrice the age of a man the age of a stag,
Thrice the age of a stag the age of an eagle,
Thrice the age of an eagle the age of an oak tree."
—*Old Gaelic saying.*

THE golden eagle is the most magnificent bird of the Scottish highlands. Up to the middle of last century, the erne or white tailed eagle shared the cliffs of the western seaboard and islands with the golden eagle, but the erne is now extinct, although so late as the middle of the last century almost every headland of the Isle of Skye had a pair of these fine birds nesting upon it.

The flight of the golden eagle has inspired many poets, and from the earliest times it has been looked upon as lord of the air. In the Book of Proverbs we read:

"The way of an eagle in the air,
The way of a serpent upon a rock,
The way of a ship in the midst of the sea,
The way of a man with a maid."

These, says the writer, are the four things too difficult to understand. Keats wrote in 1818 "Eagles may seem to sleep wing-wide upon the air," and how descriptive are Wordsworth's lines "Faint sound of eagle melting into blue." Scott writes that the eagle from her rocky perch on Ben Venue "spreads her dark sails to the wind."

The eagle is the royal bird of Greek mythology; an eagle of gold was the standard of the Romans. At least three countries have the eagle as their emblem: Assyria, Persia, and Rome. It is, or was, the national arms of France, Germany, Russia, Italy, Austria, and Poland.

At the present day the golden eagle is confined to the central and western highlands of Scotland. In the more accessible districts it is terribly harried by egg collectors, and here very few eyries escape. It is unfortunate that the golden eagle, almost alone among Scottish birds, should never lay a second time in a season, even if its first clutch of eggs be taken when quite fresh, but, despite the egg collector's zeal and the keeper's gun, I do not think the eagle is on the decrease, except here and there. Each pair of eagles has two, sometimes three, eyries. The same eyrie is seldom used two years in succession, because the eaglets remain long (about eleven weeks) in the nest and from

the accumulated remains of prey the eyrie becomes foul towards the end of the time and needs more than a twelvemonth to be thoroughly cleansed by winter frost and summer sun. Some of the Scottish eyries have been used regularly for at least half a century, and probably much longer.

The nesting site may be a tree or a rock. In the central highlands a tree is frequently chosen, and I have seen nests in a Scots fir, and, rarely, in a birch. In her choice of nesting material the golden eagle is most particular. The eyrie may be from six to eight feet in diameter, and the crown on the nest is composed entirely of green fir branches (if there are any fir trees in the district), which the eagle breaks off the trees with her powerful bill. Near one eyrie that I know of a solitary fir grows, and each spring the eagles fly to it and strip it of some of its branches. The lining of an eyrie is, when possible, always made of the great woodrush, *Luzula sylvatica*.

FIG. 1 —The hen golden eagle preparing to feed the family.

Eagles build early, and I have seen a large branch being carried to the nest on January 27. In the more sheltered nesting-places the eggs are laid in mid-March, and the eaglets hatch between April 29 and May 1.

It is not known whether the cock bird takes his turn at hatching the eggs. In April of the present year I was watching an eyrie when the male bird flew up the corrie and settled on a branch a few yards from where his mate was brooding her eggs. I hoped that I might witness the 'change over,' but, after apparently satisfying himself that all was well, the cock shook himself like a dog (there had been a heavy hail shower a few minutes before), spread his great wings, and was gone from my sight.

Although the golden eagle usually lays two eggs, she frequently rears only one bird, and there is no doubt that one eaglet sometimes kills the other. Last season my wife and I built a hiding tent thirty feet from an eagle's eyrie, and spent between two and three hundred hours in it photographing and observing the home life of the birds. As usual, one eaglet was a hen, the other a cock. In birds of prey the female is the larger, and when the eaglets were ten days old there was a marked difference in size between the two. During the early days of their lives the young hen frequently drove her brother round and round the eyrie. The attack was always entirely unprovoked. Sometimes when the cock eaglet was lying asleep in the nest his sister rose and walking unsteadily over to him aimed a deliberate and vicious blow at him. Fortunately for him the young cock was the quicker of the two on his feet, and I am convinced that on more than one occasion his superior speed alone saved his life. Each time his sister pecked him she tore out much of his down, until the eyrie and the heather around were strewn with this white down. The victim never once retaliated; indeed he was a miserable young person at this stage.

Sometimes, after almost exhausting herself by her attacks on her unfortunate brother, the aggressor stood up unsteadily in the eyrie and flapped her downy wings (her feathers had not as yet commenced to grow), uttering as she did so a wild yell of defiance. It was a weird and very extraordinary cry, and I shall never forget it. Once the mother eagle returned in the midst of this bullying and calmly watched the down being torn from her unfortunate son. Perhaps she thought it better that he should be brought up in a Spartan school.

This pair of golden eagles brought to the eyrie a varied collection of prey for the youngsters. Blue hares, grouse, and ptarmigan were brought regularly, and, more astonishing, the birds hunted squirrels and brought them to the nest. Although the eyrie was in a deer forest no red deer calves were brought, but two roe deer calves were carried up to the eyrie from the low ground. My wife had the good fortune to

be in the 'hide' when one of the calves was brought. The calf was minus head and entrails, and even then its weight was such that the cock eagle had to rest several times upon trees on his way to the nest. He

Copyright.] [Mr. and Mrs. Seton Gordon.
FIG. 2.—Cock golden eagle tearing up a hare for the eaglet.

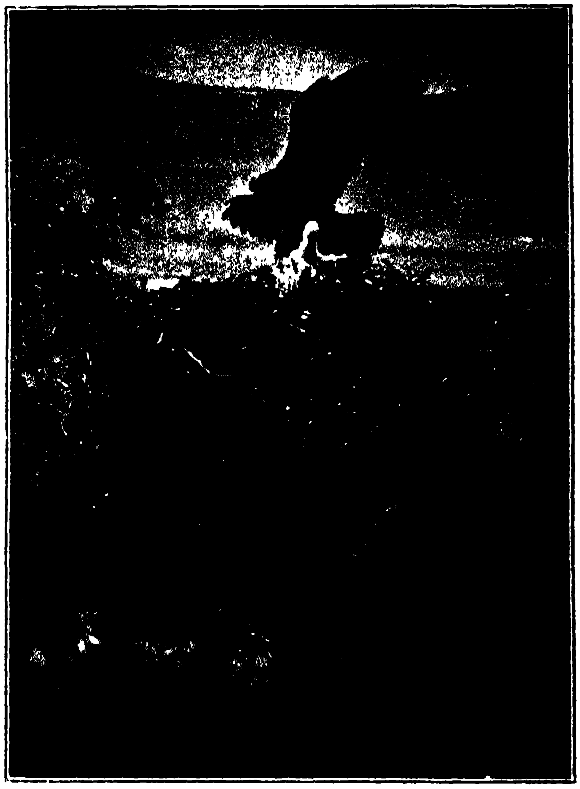
was carrying the calf in one claw, and when he arrived he threw down his burden and stood breathless at the edge of the nest. The eaglets were filled with excitement, and the young hen pounced upon the calf with the same weird yells of triumph she had uttered after her fierce attacks upon her brother. The latter picked up a feather from the floor of the eyrie and dashed about holding it in his mouth!

The cock eagle was a magnificent bird. He was smaller than the hen, and his plumage was lighter than hers. He was dashing and debonair; the gleam of his eye was magnificent, and he was a true king of the hills.

One sunny afternoon the interior of the 'hide' was so stuffy that I put my head half out of the entrance to get a breath of air. Against the blue of the sky I saw a small black object which I thought at first glance was an insect. But with incredible speed the dark speck grew in size until I saw that it was the cock eagle rushing down towards the eyrie from the high snow-streaked corries above. He was travelling like a thunderbolt. In one claw he held a ptarmigan, and this extra weight no doubt increased his speed. I suspect that I shall be accused of exaggeration when I say that his speed was at least two hundred miles an hour, but I am convinced that this is no over-statement. I have seen nothing in the bird world to equal that splendid downward rush, and to see it was worth many hours of patient watching.

Regularly about three o'clock each afternoon the cock eagle arrived at the eyrie from his hunting. In the eyrie he laid his prey, and, after looking at his yelping brood for the space of about a minute with indifference, he spread his great wings and sprang into space. On these occasions his mate must have been watching him from a neighbouring tree, for almost immediately he had left she glided down to the nest and fed the family on the prey he had brought.

When the eaglets were small there were days of wild west wind, when the squalls of hail pattered like small shot against the sides of the 'hide.' The eagle's tree rocked in the wind, and the mother eagle, as she guarded her young after having fed them, swayed gently to and fro, balancing herself with all the skill of a sailor when his ship is meeting heavy weather. The young hen eagle left the nest early in July, but the cock, being more backward (partly, no doubt, because of his ill-usage in his early days), was not ready to follow her. For some days the parents fed him in the eyrie, but then seemed to decide that he was ready to leave. Each day they brought him less food, and at last the eyrie was bare. The parents were starving him, and daily he became weaker and constantly



Copyright.] [Mr. and Mrs. Seton Gordon.
FIG. 3.—The cock golden eagle brings in a rabbit.

scanned the skies for his father or mother. He practised wing exercises repeatedly during these days, and also practised 'grabbing' exercises with great ferocity. At last, on July 16, the eyrie was vacant—starvation had compelled him to take his first flight, the biggest step in his young life.

The Regional Balance of Racial Evolution.[1]

By Prof. H. J. FLEURE.

THE Oxford meeting of the British Association naturally recalls to one's mind the famous controversy about evolution, the fact of which is now universally accepted despite little outbursts where old modes of thought survive on the fringes of civilisation. The application of the idea of evolution to the study of mankind has been carried very far, and we have especially Elliot Smith's recent summary with its emphasis on correlated improvements of eyes, brain, and hands. I shall not venture upon the ground so well covered by one of our greatest leaders, but shall merely add a few points necessary for my main purpose, which is an attempt to outline the field of research into the distribution of the characteristics of modern living men.

First may be mentioned the very probable, not to say certain, lengthening of pre-natal life from about 220 to 280 days, with consequent continuance of growth of brain and delay of hardening of frontal and facial elements and the passing of the stage at which hair was previously developed now under new conditions conducive to the maintenance of embryonic, downy hair (lanugo), rather than to the growth of the definitive hair. Thus the lengthening of pre-natal life seems to have been an important factor in that reduction of hairiness which is a feature of mankind. It has also contributed to the increase of skull volume and of consequent difficulty in head support, so that infancy and opportunities for lengthened maternal care have been prolonged. The postponement of fixation of characters, the maintenance of more or less embryonic conditions with resulting unfolding of new features in response to opening up of new possibilities, has thus become a cardinal fact for the human race.

The prolongation of infancy has also contributed to differentiate women's work from men's work, and it may well have accompanied the growth of the hunting habit in man; woman remained more a gatherer. This differentiation increased personal relations and gave two mutually supplementary types of food, doubtless a valuable step forward at that stage of evolution. The consequent enrichment of social life is an obvious fact, but in mentioning this one must emphasise that human society does not so much result from the coming together of individuals as that human individuality results from the liberation, bit by bit, of individual initiative within groups.

The stone implements of early Pleistocene man are generally of a few types only, though they may be wonderfully executed. The heavy hand of tradition has often limited initiative, but also often allowed the compensation of the craftsman's joy. Mid-Pleistocene man, at least, seems to have made ceremonial burials and thus, perhaps, to have begun to dream of a future life. It is with the Aurignacian phase, or the beginning of the late Pleistocene, or, to use another name, the beginning of the neanthropic period, that we note a great liberation of initiative, and it is from this phase that we have the earliest assured evidence of modern types of man, so far all or almost all from the north-western quadrant of the Old World.

Efforts have been made to estimate the climates at which men's bodies and minds function best and to argue thence to the home under the conditions of which they became men of modern type. The best conditions for bodily efficiency are not very different from those of our present British climate, for mental efficiency they are like those of our cooler (but not too bitterly cold) spells. Olbricht has ventured the suggestion that there was probably a big mental advance during a cold period such as a late phase of the ice age; but at such a time a climate like our present one favoured the south Mediterranean and the belt from the Sahara to Mesopotamia, perhaps only this belt. This belt seems to give abundant evidence of inhabitants of, possibly, mid-Pleistocene date.

We may venture provisionally to place the early modern men in the zone from the Atlantic edge of the Sahara to Persia, and should think of a fairly large population not all exactly alike. What sorts of men were they?

They may have been more or less brown-skinned with blackish hair and brown eyes, with jaws and brow ridges much reduced from the conditions known in many of the earlier forms of man, with heads almost balancing on the vertebral column, but the erect posture not yet attained in all cases.

The well-known youth and old woman from the lower layers at the Grotte des Enfants, currently known as the Grimaldi type, were short, with broad noses and strongly projecting mouths, but without brow ridges. Their heads were long, narrow, and high. They have often been said to be negroid, but it would be wiser to say that both in them and in many living Africans we find some of the same characters.

The name of Cro Magnon has often been used as a label for nearly all the types of the late Palæolithic except the Grimaldi skeletons just mentioned. Giuffrida Ruggeri urged a more restricted use of the term, but his views were held back from general acceptance for a while owing to exaggerations due to Klaatsch, exaggerations which Klaatsch retracted before he died. Using the term more carefully and more strictly, it applies fully to about four skeletons and partially to two or more of presumed Aurignacian date as well as to other later ones. In the Cro Magnon type the head is long absolutely, but only moderately long relatively, the cephalic index being about 74, 75, or 76. The height of the skull is much less than its breadth, the nose and chin are strong and narrow, the brow ridges do not stand out separately in front of the forehead, the stature is great, the cheek bones are large and project laterally, and the face is short and broad.

It is difficult to accept either the Brünn or the Brüx calotte as suitable objects from which to name a race, and there are difficulties about naming it from the Combe Capelle skull. We await anxiously the full description of skulls found at Predmost. The general characters here are extreme length and narrowness of the head, so that the cranial index is rarely so high as

[1] From the presidential address to Section H (Anthropology) of the British Association, delivered at Oxford on August 9

73 on the skull; the height of the skull is usually greater than the breadth, the brow ridges are well marked and in this connexion the rather exaggerated term 'Neanderthaloid' has often been used. There are a few skulls otherwise belonging to this type which are low in the vault.

Skulls from Solutré show high heads without strong brow ridges, but heads which are so much shorter as to make the usual index 78-83. We await confirmation of the date and detailed descriptions of the Solutré skulls.

Reviewing these early skulls comparatively, we notice that great length of head is a very general feature. This is combined with a very narrow and rather high-ridged form in some cases, and a less narrow and less high-ridged form in some others.

The great majority of the apes and the extinct types of man do not seem to have been relatively long-headed, if we are careful not to include the enormous brow ridges of some of them in measuring the head length. Comparing the skulls of Aurignacian men with these others, we note a marked growth in length, especially in front of the ear. This implies special additions along the coronal suture. Now the temporal muscles were of very great importance to the flesh hunters of the late Palæolithic age, who doubtless had to tug at flesh food. They had been important, no doubt, in earlier times as well, so they may be looked upon as an ancient feature persisting for a while and exerting an influence on the new growth. The early closing of the sagittal suture gave a firm anchorage to the temporal muscles and limited growth in breadth anteriorly at least; increase of anterior space must thus be secured mainly by increase in length. It is therefore permissible to suppose that a great lengthening, extreme in some cases, was a feature of skull growth among most, but not necessarily among all, early representatives of modern types of man.

In several cases the two sides of the skull roof seem to have been pulled down, or in other words the sagittal line was ridged up, and this is found frequently associated with a deep temporal hollow, so that the brow ridges are left outstanding. In other cases the temporal muscles seem to have pulled the sides down to a lesser extent, and the head is less narrow and the brow ridges less outstanding. Lest too much importance be attached to the pull of the temporal muscles, it is well to remember that the face was still heavily developed in most early examples of modern man, and that to balance this the head tended to grow so as to project backwards, *i.e.* to grow in length.

It is thus possible to think that in the evolution of modern men we may have:

(*a*) Types with little of the additional growth just mentioned. These would be sub-brachycephalic and small.

(*b*) Types with considerable growth, almost entirely growth in length, and with the sides of the skull sloping steeply from the sagittal ridge. These would be hyperdolichocephalic and usually high-headed, often with strong brow ridges.

(*c*) Types with considerable growth in length but without the sharp down slope of the sides. These would be more moderately dolichocephalic than (*b*), less high-headed and usually with less strong brow ridges.

(*d*) Types with considerable growth more generally distributed along the various sutures. These would be mesaticephalic or sub-brachycephalic with parietal rather than frontal breadth as a distinguishing feature.

I think it useful to figure the great lengthening as a feature in the main groups of early modern men in the early home zone, and then to think that there were fringing groups who remained without this lengthening. These fringing groups on the hot south side, probably subject to unfavourable conditions, would have relatively small growth and would remain as small mesaticephals. On the cooler north side they, then or later, were able to accomplish longer continued growth and so gave better grown, larger headed mesati- and sub-brachycephals.

The first group seems illustrated by the Andamanese, Semang, Aeta, Tapiro and other pigmies of south-eastern Asia, and the Akka and other small peoples of equatorial Africa, the last being much less strongly pigmented than the others. All have flat, broad noses, the Tapiro less than the others. It seems almost necessary to think that some of these types have left their mark on the population of various parts of India, and some of their characters seem to survive also among various African peoples other than the equatorial pigmies. The Bushmen, on the view here sketched out, would be types showing some measure of head lengthening, and the Tasmanians also.

I have not mentioned hair. The downy hair has fairly straight roots even in Bushmen, and the spirally curved hairs so characteristic for Africa develop that curve with a sharp angle between it and the root. As ape hair also has fairly straight roots, it thus seems likely that spirally curved hair is a specialisation among some early types of modern man, chiefly, I think, types on the south side of the early home zone under hot conditions, where hair reduction and the pressing of the roots up toward the surface would allow the freer giving off of heat.

Next we may think of cases in which head lengthening had taken place fully. Broom's Hottentots and Koranas fall here, and so do most of the African peoples. Among some the pressing of the hair roots up to the surface has made possible a large growth of blood vessels in the skin, and the reduction of hair has gone very far in certain cases. The thin supple epidermis without many dry non-conducting layers, the everted lips, as well as the development of skin blood vessels and the reduction of hair, all promote cooling.

It was mainly types with broad, flat noses, prominent mouths, feeble brow ridges, and spirally curved hair that drifted southwards in Africa, from the south flank of the early home zone, but a brow-ridged type also went that way.

The south-eastward drift was a drift rather from the end than from the flank of the early home zone, and for this reason it was more varied. Pigmies with spiral hair and medium broad heads; dark Tasmanians with spiral hair and partly lengthened heads; south-east Australians with lengthened but often low heads, dark colour, and wavy hair; North Australians with lengthened and high heads, dark colour and wavy hair; Papuans and Melanesians with long high heads, dark colour, and spirally curved hair and so on— an interesting series of drifts through a long and relatively narrow

belt. This contrasts with the African drift through a wide belt lying on the south flank of the early home.

Let us turn now to the northern flank of the early home zone and think of migrants across from Tunisia to Sicily and Italy, migrants mostly with very long heads, the bearers of Capsian culture to Europe. In addition to these we have to think of people drifting northward between Elburz and Hindu Kush as the ice diminished. Once north of this barrier the human drifts could spread either north-eastwards in the lowlands or north-westward to the European loess. These early drifts have been pressed upon by subsequent streams and their survivors are now found in peripheral situations and in a few refuges on the way. Survivals of these early characters are shown in types found at Plynlymon. The new work on blood constituents is interesting in that it is tending to show that the blood of the peripheral, longheaded peoples is inherited with little alteration from a phase before certain specialisations occurred in the composition of the blood of many human stocks.

When the belt of the westerly winds from the Atlantic shifted northward as the ice sheets diminished and the land sank in north-west Europe, inner Asia lost its rain to a large extent, but melting ice seems to have kept it moist for some millennia. Mesopotamia remained moist for the same reason for a good while. The change of climate in north-west Europe produced a human crisis: the spread of the forest broke the old schemes of life, especially as the first phase was that of a pine forest, very unfriendly therefore to man. In south-west Asia, wild barley and possibly wild relatives of wheat have been found. Somewhere then, probably on the northern fringe of the early home zone, there arose sooner or later a culture complex, including cultivation of wheat and barley, the art of stone grinding perhaps developed through the use of stone for digging, the consequent invention of the stone wedge, and so the rise of new power over wood to haft tools, to make palisades that kept animals under man's command for milk, etc., the making of pots, the dawn of metallurgy and so on. I think of this complex, provisionally, as spreading among hill folk rather than plains-men, for the latter might more easily keep up their old habits of following herds of animals, and it seems that it spread through Anatolia to Hungary and so, after a long history, ultimately to western Europe probably about the end of the fourth millennium B.C. There is, however, no need to picture the awakening west as copying exactly from old and distant cultures.

The mastery of a wood technique, food production, and the potter's art all helped home-making and the provision of soft food for infants, delaying the hardening of the skull or, in other words, prolonging infancy. In this connexion one pictures diminution of jaws and brow ridges and freer growth of the skull along many sutures leading to a maintenance of the mesati- and sub-brachycephalic skull form. This form and the brachycephalic form, which I believe is derived from it, are mainly characteristic of the great mountain belt of the Old World.

Another factor that enters into the story here is the probable increase of chewing at the expense of tugging, and Prof. Thomson and others have associated with this an increased width of the malar bones to which the masseter muscles are largely attached. Increased width of face and jaws is likely to have encouraged increased width of head as well. It is important to note that there has been no suggestion that some functional change in the jaws led to a transformation of dolichocephaly into brachycephaly. The suggestion is rather that the brachycephals have originated from fringing mesaticephals or sub-brachycephals. I appreciate and accept Prof. Thomson's observations and views on the lower jaws of the typical broadheads. These thoughts make me incline to criticise our present use of terms for skull forms.

Brachycephals give one the impression of evolution and drift from Anatolia and surrounding regions. It is noteworthy that Pamir broadheads are much like Alpo-Carpathian and Cevenole. For the present, I look upon the extreme broadheads of the high plateaux of east central Asia as showing in some cases a flattening of the nasal bones and an insinking of the nasal chambers, but others have the profile prominent enough. The broadheads of the high plateaux have yellow-brown skin, the early brown being retained and the yellowness being increased by the insinking of blood vessels, and the thickening of the dry superficial layers—both protective devices in a region of intense winter cold. The very variable extra fold of the upper eyelid may have begun as a consequence of the facial flattening, and once developed would be a valuable protection against glare.

The well-known diagram of Ripley shows the distribution of broadheads in Europe as known in his day, and its relation to the mountain zone is very marked. A preliminary attempt has also been made to design a map of types in Europe. Around the mountain zone the broadheads have spread and the longheads are mostly peripheral in the north-west and in the south-west. In the north-west, climate encouraged long continuation of growth and diminution of pigment, and I look upon the tall fair Nordic as to a large extent a regional specialisation. In the south-west the Mediterranean type links on to the Hamitic type of North Africa and the longheads of the Arabian wastes, all having among them an element surviving with little change from the early days of modern man, but many showing somewhat more general growth along the various sutures, and therefore less extreme length of heads. The fundamental element of the British population I look upon as drifting from the continent in late Palaeolithic times, with a southern element fairly well represented but, nevertheless, on the whole neither fully Mediterranean nor fully Nordic, but, as I think Sir Arthur Keith would say, just British.

I have tried to suggest that development of the individual depends on hereditary factors of a conservative nature, and on environmental influences which have changed with climate, food, and equipment. Thus they have affected plastic infancy, and in the end have moulded race types blending hereditary characters sometimes brought from afar with other features in which the changes of environment have had more power. A doubt persists in my mind as to the assignment of more than a somewhat limited value to taxonomic treatment of the question. It seems

worth while to think rather of regional gatherings together of physical characters.

Changes of environmental influence are usually cumulative, for natural processes are essentially irreversible even if, as in climate, there is something of a cyclic scheme of change. The cumulative change may be said to draw out the course of development more and more from its original path, thus creating a state of internal strain. No two embryos are exactly alike, and in some the hereditary units may vary towards, in others away from, a condition which would diminish that internal strain. Those varying so as to diminish the strain would probably grow best. So we have a theoretical possibility of variation of the germ limping after variation of the soma. In the case of man, whose development is so closely linked with varying balances of the influence of endocrine glands, the adjustment of the variation of the germ to the variation of the soma may not be very slow.

A special attempt has been made to suggest the part played by the development of social life in the evolution of human physique, and the importance of parental care. These factors seem in particular to have led in certain circumstances to a vast liberation of individual initiative within our human societies, especially after the development of intercourse between groups.

We must speedily undertake more and more biological observation and measurement among ourselves, and we must exercise ever more care in the treatment of our measurements. Averages of cases which are not properly homologous should not be made lest we mask the biological truth in mathematical abstractions. If our anthropological work can but go on becoming more biological, gaining insight into physiology, especially of the brain and the endocrine organs and their correlations with growth, I venture to think that racial study will develop great practical value for education, for the fight against tuberculosis and other diseases, and for race-improvement. Evolutionary race biology seems to be a hopeful sphere of work that may bring about a much-needed enrichment of public opinion on social questions, a diminution of race-arrogance, and a check on schemes that do not sufficiently allow for the mutual adaptations between diverse human stocks and diverse environments. I would ask for faith in the future of such work to bring out its great possibilities for nobler races with freer personal initiative in societies both more stable and richer in the things that are not seen.

The London School of Hygiene and Tropical Medicine.

HYGEIA, the goddess of health, daughter of Esculapius, was included among British *lares et penates* some fifty years ago, when the Public Health Act of 1875 was adopted. Since that time Great Britain has been a world pioneer in the achievements of its public health service. Attention was concentrated in the earlier years on drains and sanitation, but gradually the scope of the work of the public health authorities has widened. The results, as seen in the reduction of the death-rate to 12 per thousand and the consequent increase in the span of human life and in the health and happiness of the people, have undoubtedly had a bearing on industrial efficiency and national prosperity. But much remains to be done. Official evidence before and during the War relating to national physique and the statistics of diseases indicate the need for sustained effort in the health crusade. Even the layman can form some conception of the vast field for scientific research from the wonderful discoveries of which information is published from time to time, such as those relating to the curative power of natural and artificial sunlight and chemical methods of preventing goitre.

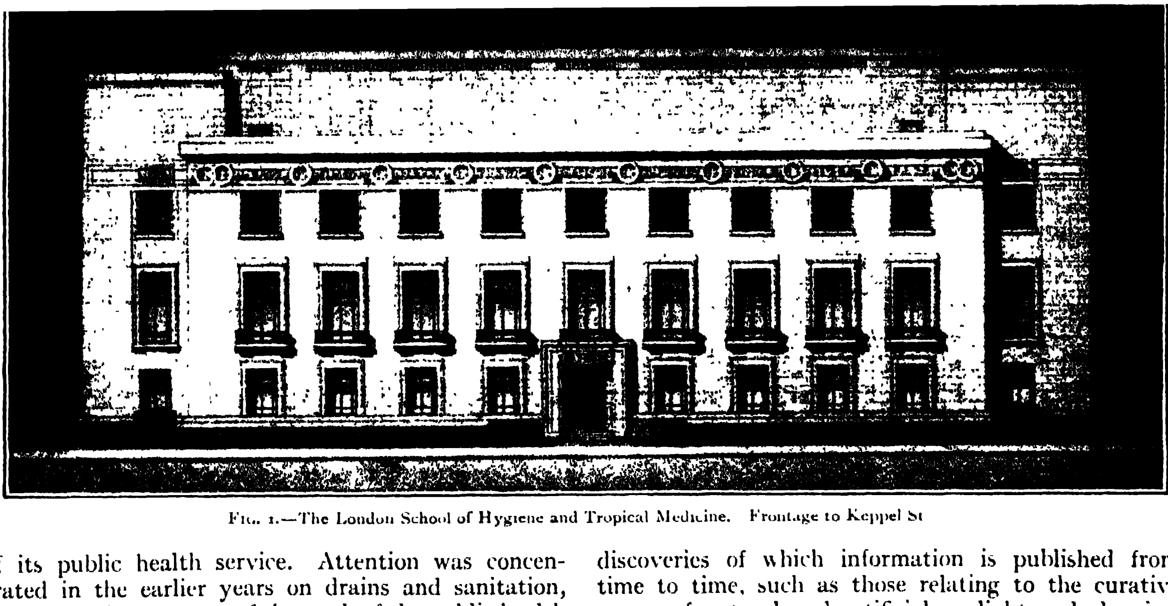


FIG. 1.—The London School of Hygiene and Tropical Medicine. Frontage to Keppel St

The Ministry of Health, as in duty bound, early recognised the need for extending facilities for instruction and research in preventive medicine. A committee appointed by the Ministry and presided over by the Earl of Athlone submitted a report in

May 1921 advocating the establishment of a post-graduate medical school in London and also an institute in State medicine. An expert committee was afterwards appointed to consider the recommendation as to a new school of hygiene. Financial difficulties, which may well have appeared insuperable, were miraculously removed by the generous offer of the Rockefeller Foundation to provide two million dollars (400,000*l.*) towards the cost of the building, on the understanding that the Government would accept the responsibility for maintenance, the cost of which was estimated at about 25,000*l.* a year. The appointment, in October 1923, of Dr. Andrew Balfour as director enabled definite progress to be made in the planning and organisation of the new school, the foundation stone of which was laid by Mr. Neville Chamberlain, Minister of Health, on July 7.

Such is the brief but honourable history of an enterprise representing one of the most important educational

FIG. 2.—The design of the seal adopted by the London School of Hygiene and Tropical Medicine owes its inspiration to a coin of ancient Sicily, believed to have been struck to celebrate the deliverance of one of the cities from a pestilence caused by the stagnation of the waters of the river. The design shows the deities Apollo and Artemis proceeding slowly in their chariot, Artemis driving while her brother, the sun-god, discharges arrows from his bow. The arrows are the healing rays of the sun, which drive away the malaria mists; and Artemis is beside him as the goddess who eases the pains of women labouring with child. The fruitful date palm has been added to symbolise the tropical side of the work, and at the foot is the serpent staff of Esculapius.

and scientific developments of our day and generation. For the London School of Hygiene sets a new standard in building and equipment, a standard worthy of the subject and of the Imperial city in which that subject is to be studied and investigated. The School is also the most important example—Oriental studies and history are other examples—of the new and proper method of organising higher instruction and research in selected subjects in London under the ægis of the University, a method which will inevitably be followed for many other academic and professional subjects if and when the University, through re-constitution, obtains the necessary powers and driving force.

The main frontage of the new building, of which an elevation is reproduced (Fig. 1), faces Keppel Street, looking southwards towards the impressive north façade of the British Museum, across the vacant site purchased by the Government for the University of London, and recently re-sold to the vendor, the Duke of Bedford. Return frontages, considerably longer than the main frontage, face Gower Street and Malet Street. The architects, Mr. P. Morley Horder and Mr. Vernon O. Rees, have produced a design combining simplicity and economy with dignity and the maximum of light and air. The building will be faced with stone drawn from Portland—the veritable womb of London. In addition to the teaching of hygiene in all its branches, provision has been made for tropical medicine, the London School of Tropical Medicine in Endsleigh Gardens having been amalgamated with the new institution. Altogether, the School will accommodate 250 students, including 100 students of tropical medicine. Routine instruction will be directed towards the various degrees and diplomas in public health, which form a necessary qualification for the public health service at home and abroad. The general shape of the building is a letter H closed at the south end by the Keppel Street frontage. The north court will be left open, and the south court will contain the lecture theatre. Ventilation, it is interesting to note, will be by 'natural' means, a provision for which those who have worked in buildings ventilated by 'scientific' methods will be grateful. Possibly, however, the School may itself devise new methods of ventilation, a worthy subject of hygienic research. One-sixth of the total accommodation will be reserved for research, the large lecture theatre and museum, as well as numerous class-rooms and laboratories, being regarded for the purpose of this computation as accommodation for teaching.

The division of the subject of hygiene adopted by the School has had reference to the regulations for the Diploma of Public Health, and is as follows: (1) applied physics, physiology, and the principles of hygiene; (2) chemistry and bio-chemistry; (3) immunology and bacteriology; (4) medical zoology, parasitology, and comparative pathology; (5) epidemiology and statistics; (6) principles and practice of preventive medicine, general sanitation, and administration. Dr. Andrew Balfour, in his interesting address to the Society of Medical Officers of Health on December 12, 1924, has explained the many ramifications of these subjects. Thus applied physiology includes nutrition, ventilation, illumination, physical exercise, not only in relation to adults. One of the most encouraging developments of recent years has been the increased attention to the special hygiene of infants and children. The hygienist approaches the realm of the educationist and psychologist in such questions as rest, sleep, and fatigue; the physiology of speech, reading, and writing; tests of intelligence. In his discussion of the position of chemistry, Dr. Balfour attaches little value, from the view-point of the training of the public health officers, to pure chemistry, but stresses the importance to bio-chemistry. "The future, in many directions, lies with the bio-chemist." In Division 3, the order "Immunology and Bacteriology" is deliberate. Division 4 relates mainly to tropical medicine. As regards Division 5, Epidemiology and Statistics, Dr. Balfour recognises the need for more stimulating teaching of epidemiology, and has a good

word to say for the methods adopted at Johns Hopkins University, under Prof. Frost. He admits that statistics is a "difficult and deadly subject for any one who is not blest with a gift for mathematics." Division 6, though placed last, is the largest and most important of all. Not less than thirteen special courses are grouped under the main heading. The subject is so wide and is developing so rapidly that Dr. Balfour's hint that "refresher" courses may be arranged for medical officers of health will not cause surprise.

It remains to add that the planning of the building corresponds to this comprehensive programme. Full details are given in the *British Medical Journal* (July 10, 1926). The lecture theatre (the flat roof of which will be laid out as a garden-court) and the museum (occupying 15,000 feet of floor space) are important features of the building. The library, a large and imposing room 35 feet by 120 feet, occupies the place of honour in the front of the building. There is a "Publications Department," in which provision will be made for informative and propaganda work. The Chemical Division in the north-east corner of the building will accommodate 70 students and the biochemical and nutritional laboratory 35 students; and there is also a number of staff and research rooms and a class-room with 70 seats. The third floor is mainly occupied by medical biology, and will absorb the greater part of the work of the old London School of Tropical Medicine in Endsleigh Gardens. It is hoped that the building will be completed in two years.

T. LL. H.

News and Views.

THE sixth annual report of the Forestry Commissioners (Sept. 30, 1925) is a document of considerable interest if only for the summary it contains of a forest policy recently enunciated by the Government. A century or two has elapsed since any Government in Great Britain can be said to have held definite ideas on the subject of what a forest policy for the country should aim at. The Government of the day has now publicly recognised that the development of such a policy is largely dependent upon State action continuously applied over a period of years, a point which has for long been beyond dispute in many European countries. It is further recognised that large areas of land in many parts of Great Britain are more suited to the production of timber than food, that private forestry should be encouraged by a system of grants, and that the systematic establishment of forest workers' holdings at the rate of 5 holdings per 1000 acres of afforestable land should be aimed at. It may be said at once that this definition of the Government's opinions and aims in this matter is admirable. If persevered in, the progress of forestry should be assured.

THE total area of land acquired by the Forestry Commissioners to Sept. 30, 1925, was 286,198 acres, of which 177,633 acres were classified at the time of acquisition as plantable. Of the plantable area 100,244 acres (56 per cent.) are in England and Wales and 77,409 acres in Scotland. The Crown Woods, *e.g.* Forest of Dean, New Forest, and so forth have now been placed under the Commissioners. When the Commission was appointed it was laid down that 150,000 acres should be afforested in the first ten years. In the Acland Report the rate of planting per year was prescribed; 50,000 acres to be planted by the sixth year. This acreage has been slightly exceeded. In some respects the laying down of rigid planting prescriptions by area is unfortunate, since the effort to maintain the planting figure may result in poor or bad work and takes no account of possible losses from drought and so forth, experiences well known to all foresters. It also results in waste. For example, in the table of cultural operations in the 1925 report, 22,615*l.* is shown as expended on planting and 9526*l.* on beating up, *i.e.* filling up plantations in which deaths have occurred. This represents nearly 40 per cent. of the planting expenditure. Forestry, like agriculture, has to face unfavourable climatic factors, but the excessive expenditure alluded to above appears difficult to justify.

THE debate, which is a usual feature of the *Forum*, in the issue for August deals with the question "Is Civilization Contagious?" and is opened by Prof. Elliot Smith with a statement of the case for 'diffusion.' The argument proceeds on the lines which he has already made familiar in putting the case for Egypt as the place of origin and centre of diffusion of culture. The reply is by Dr. B. Malinowski, who argues ingeniously that the opposition between 'diffusion' and 'independent invention' is misleading. He maintains that 'invention' is not a single event for which one single individual is responsible, but a process consisting of a series of infinitely small, infinitely many, steps for which many individuals are responsible. Every cultural achievement is due to a process of growth in which invention and diffusion have equal shares. The familiar example of the 'diffusion' of a match he regards as futile because the match does not become an element of the culture of the native, but is merely a mechanical importation. So far Dr. Malinowski's formal answer to the 'diffusionist'—in effect a compromise which would commend itself to the average anthropologist, if not to the out-and-out upholder of 'independent invention,' should there be any such, whom Prof. Elliot Smith holds up to scorn. But Dr. Malinowski's quarrel goes deeper, and it is this which constitutes the real value of his contribution to the discussion. Only in the field, he maintains, can the problem be solved as a live issue and by functional analysis. Then it appears that every aspect of culture corresponds to a specific need of human nature, to the local environment, and to the general character of given civilisation. The problem is resolved then by the writer's conclusion that diffusion never takes place; it is always a readaptation. Culture is neither

invented nor diffused, but is imposed by "the natural conditions which drive man upon the path of progress with inexorable determinism."

THE Rothamsted Experimental Station has renewed its offer to Chambers of Agriculture, the National Farmers' Union, Students' Societies and the like, to supply, during the coming winter, lectures on a variety of subjects. These lectures are offered by way of supplement to the provision already made by county education committees and agricultural colleges covering the general field of agricultural education. Coming, as they do, from workers engaged on agricultural research, the addresses should prove of extreme interest to their hearers. The agricultural sciences have now become so highly specialised, and the volume of research published daily is so great, that there is a great field of exposition open to those whose duty it is to keep in touch with new things in the branch of research with which they are specially concerned. On the other hand, the director of Rothamsted may be assumed to be fully aware of the value to the experts themselves of direct contact with the actual workers on the soil. While it is true that the pursuit of knowledge should be the sole object of the research worker, that pursuit is in danger of becoming too academic when confined to the laboratory alone. The list of subjects upon which lectures are offered is some indication of the scope of work with which the Rothamsted Station deals. Following the transference of the workers in phytopathology from Kew and Manchester, the station now deals with every aspect of plant life in health and disease, as it concerns the farmer. It may be added that a recent addition to the roll of lecturers is Mr. C. Heigham, whose thoughtful articles on the business aspects of farming were, until recently, a feature of the Saturday page in a London journal. The main headings of the syllabus which accompanies the Rothamsted circular are: soil micro-organisms; agricultural botany; agricultural chemistry; soil physics; insecticides and fungicides; entomology and mycology.

THE weather of August in the British Isles has just been dealt with by the Meteorological Office, in a tentative way, as a supplement to the *Daily Weather Report*, similar summaries being issued on the first day of each month. The promptness of the issue adds much to its value, dealing with facts while fresh to the memory. In many respects the weather of August this year is said to compare favourably with the average August weather. At Kew Observatory temperature and sunshine were both above the average, while rainfall was remarkably low—the lowest since 1899. During the last ten days of the month high barometric pressure spread over the southern districts, giving generally fine weather; at Kew there was no appreciable rain after August 21 until the early morning of September 1. About 12 hours' sunshine were enjoyed daily in south-east England on August 26-29, while day temperatures rose until August 30 when 83° and 84° were registered in London. Some abnormally high night temperatures were recorded during the latter part of the month. On the night of August 24-25 the thermometer remained well above 60° F. in many places, and did not fall below 65° F. in several parts of London. The mean temperature for the month at Kew was 64°·1, which is 2°·5 above the normal; winds were chiefly westerly and the barometer was high. Thunder only occurred on two days in London. The duration of bright sunshine at Kew was 207 hours, which is 20 hours more than the normal.

THE present status of long-range weather forecasting is dealt with by Prof. R. De C. Ward, of Harvard University, in an article written for the American Philosophical Society. The subject is being very actively considered not only in America but also in many of the European weather offices. Prof. Ward's purpose is to take stock of the subject rather than to offer any contribution to the discussion. He mentions that man's natural craving for advance knowledge of coming weather extends thousands of years back of any attempt at scientific weather forecasting. Allusion is made to the group of animal weather proverbs which have come into existence. Prof. Ward asserts that animals have no foresight which people credit them with, but these are simply characteristics of food supply and other conditions. Some credit is given to the very general forecasts based on sequences in the character of the seasons, but it is pointed out that just when a definite sequence seems to have started the chain is somehow likely to break and the sequence ends. With further and closer study something more definite may develop along this line. Allusion is made to the weather fluctuations associated with sunspot cycles, and it is stated that the results of these studies have not come up to expectations. A longer period generally recognised as having been fairly established is known as the Brückner 35-year cycle, but this may vary between 20 and 50 years. At present, and until such periodicities or variations are more fully understood, long-range forecasts definite and trustworthy cannot be based upon them. Prof. Ward, with high authority behind him, sums up the subject with the statement that the results reached are not yet generally applicable to definite seasonal forecasts, but there is, however, promise for the future.

AMONG the news items published in the *Bulletin for International Relations* (July) are the announcements of the adoption of the metric system in Greece on March 1 last, and of a decree of the Soviet Government for its introduction into Russia on January 1, 1927. A list of international scientific meetings to be held in 1927, 1928, and 1929 is also included. In 1927 there will be a congress of the International Institute for Cold, at Rome; a general assembly of the International Institute for Anthropology; a general assembly of the International Commission for the Investigation of the Air, at Prague; the sixth international Congress of Medicine, at Leyden; the seventh international Congress of Statistics, at Cairo; the fifth international Congress on Seed-Testing, at Rome, in May; the fifth international Congress of the Science

of Heredity, in Berlin (the first international congress to be held there since the War); the second Australasian Medical Congress, in Dunedin (N.Z.); in February; and a congress of the International Association of Medicinal Hydrology, in Italy. In 1928 there will be held an international Congress of Mathematics (the first to be held since the Toronto meeting in 1924), and in 1929 the seventh American Scientific Congress, at San-José, Costa Rica. The bulletin concludes with the communication, already announced in our columns (July 3, p. 21) that the International Research Council has decided unanimously to modify its statutes in order to make possible the adhesion of all States, without distinction; and to invite Germany, Austria, Bulgaria, and Hungary to join the Council.

AN important branch of engineering at the present time is the manufacture of water turbines and electric generators for operation in hydro-electric stations. In the July number of the *Journal of the English Electric Co.* an interesting account is given of a 25,000 horse-power water turbine which they have manufactured for the Sao Paulo Electric Co., Brazil, and which has now been running successfully for some considerable time in the Sorocaba Power Station. The station is on the river Sorocaba at a distance of sixty miles from Sao Paulo. The hydraulic power is converted by three 15,000 H.P. units, also made by the E. E. Co., and by this new turbine which acts in parallel with them. The new machine operates under a head of 670 feet of water and it has its rated output at 600 revolutions per minute. At full load the discharge of water is 400 cubic feet per second and the velocity of the water relatively to the vanes is 130 feet per second. As a very close speed regulation was desired the turbine guide vanes are closed in 1½ seconds when the load varies from full load to zero. The casing has the form of a logarithmic spiral. This gives a perfect intake vortex ensuring that the water all round the guide apparatus has the same entrance velocity. The formation of disturbing eddies is therefore avoided. The efficiency is about 90 per cent.

OUTDOOR switchgear, although in fairly common use in America and on the Continent in connexion with electric power transmission, is still rarely used in this country. The account given therefore by the English Electric Co., in the July number of its journal, of the switchgear the Company has erected in the open air for connecting the electric supply systems of the Preston and Blackburn Corporations by means of high-tension transformers and a 33,000 volt cable, is of interest and value. The two necessary sub-stations are almost identical. The switchgear is carried on a light steel structure supported by a concrete plinth on which stand four 2900 kilovolt ampere transformers, the ratio of transformation being from 6600 to 33,000 volts. On the low-pressure side the circuit is broken under oil, but on the high-tension side air-break switches are employed and are mounted with 'arcing horns.' The scraping action of the type of contact employed ensures the pushing away of any sleet or snow and thus renders the switches satisfactory for use under any weather conditions. The parts are so strong that the contacts can be separated even when they are frozen together. As this type of gear can be employed up to 110,000 volts, it is probable that it will soon become common.

THE National Research Council (U.S.A.) has published, in its reprint and circular series, an address on science and engineering by Prof. W. F. Durand, of Stanford University, California, in which the author deals in an interesting manner with a familiar theme—the nature and interdependence of fundamental and applied research. He points out that each element of material progress in civilisation is the final product of a vast number of interconnecting studies, all of which converge towards this product and have their source in fundamental facts or laws of Nature. He asserts that we can never get behind these basic facts, but he treads on somewhat debatable ground when he uses the term 'explanation' to connote description of phenomena in terms of basic concepts such as 'energy,' 'electrons,' and 'quanta.' As a good professor of engineering he believes that the results of fundamental research, and, indeed, that all knowledge, find their highest expression in terms of service to humanity; and he shows how certain types of industrial research are really fundamental, although all forms of research have their place as essential elements of progress. Engineering affords some excellent illustrations of the interdependence of academic and strictly utilitarian research, and the example of aeronautics, with its dependence on mathematics, physics, mechanics, thermodynamics, and chemistry, is a particularly happy one. In conclusion, Prof. Durand pleads eloquently for more intensive fundamental research in the United States, which he believes has been relatively neglected there.

MOST of the islands in the Azores are subject to earthquakes that occasionally attain destructive violence. One of the well-known centres, though not the most active, lies in the Horta district at the eastern end of the island of Fayal. In this zone a strong earthquake occurred on August 31. In Horta, hundreds of houses were completely ruined and there were few that remained undamaged. Heavy safes were thrown out of alcoves, steam boilers were displaced, and large fissures crossed the streets. Though the earthquake was felt in the neighbouring island of Pico and even at Ponta Delgada in the island of St. Michael, the disturbed area, as in most volcanic regions, seems to have been small, considering the strength of the shock at the epicentre.

THE following awards for the year 1926–27 have been made by the Salters' Institute of Industrial Chemistry and approved by the Court of the Company: Fellowships have been renewed to—Mr. H. S. Pink, University College, Nottingham, and University of Oxford (fellow, 1924–25, 1925–26), at the Massachusetts Institute of Technology; Mr. V. E. Yarsley, University of Birmingham (fellow, 1924–25, 1925–26), at the Polytechnic, Zurich; Dr. R. Campbell, Arm-

strong College, Newcastle-upon-Tyne, and University of Oxford (fellow, 1925–26), at the Department of Chemical Engineering, University College, London. Fellowships have also been awarded to—Mr. E. A. Bevan, East London College, University of London; Mr. R. M. Deanesly, University of Oxford; Mr. R. Edgeworth-Johnstone, College of Technology, University of Manchester; Mr. H. B. Spalding, University of Oxford. The Salters' Institute has also awarded fifty-one grants-in-aid to young men employed in chemical works to facilitate their further studies.

AN interesting addition has just been made to the exhibits in the electrical communication section of the Science Museum, South Kensington, by Messrs. Television, Ltd., who have lent to the Museum the transmitting portion of the original apparatus used by Mr. J. L. Baird in experiments which led him from the wireless transmission of outlines in 1925 to the achievement of true television nine months later, when, on January 27, 1926, the transmission of living human faces with light, shade, and detail was demonstrated before members of the Royal Institution. The subject of television was referred to in an article in our columns on July 3. The apparatus now placed on exhibition at South Kensington includes the original ventriloquist's head used in Mr. Baird's experiments, the revolving dial with lenses, the slotted disc which, revolving at high speed, interrupted the light reflected from the head, another revolving interrupter and the cell container with the aperture through which the flashes of light reach the sensitive cell.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant fishery officer in the Fisheries Department of the Ministry of Agriculture and Fisheries—The Secretary of the Ministry, 10 Whitehall Place, S.W.1 (September 20). Inspectors under the Agricultural Wages (Regulation) Act, 1924—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (September 24). A head of the Department of Commerce of the Witwatersrand Technical Institute—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (September 30). An assistant in the Essex Museum of Natural History, Romford Road, Stratford—The Principal, West Ham Municipal College, Romford Road, E.15 (September 30). An evening lecturer in botany at the West Ham Municipal College, Romford Road, E.15—The Principal (September 30). A pathologist to the Lancashire Asylums Board—The Clerk of the Lancashire Asylums Board, County Offices, Preston (October 1). Research chemists at the Chemical Research Laboratory, Teddington—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1 (October 7). An assistant master for engineering and workshop practice at the Kingston-upon-Thames Technical Institute—The Principal.

Our Astronomical Column.

SUSPECTED COMET.—Mr. Wilk, assistant at Cracow Observatory, who discovered a comet last year, has sent a telegram to the I.A.U. Bureau at Copenhagen announcing his detection of another cometary object of the sixth magnitude on September 1, $21^h\ 46^m{\cdot}0$ U.T., in R.A. $15^h\ 53^m\ 12^s$; N. Decl. 3° 55′ (position referred to equinox of 1855). The motion was stated to be direct (that is, in the direction of increasing R.A.), and according to the wording of the telegram it reached the extraordinary amount of one degree in four minutes, but it is doubtful whether this is the correct interpretation. If so, the comet was very near the earth, and no forecast of its position is possible until more data are to hand. The writer of this note swept for a few degrees round the given position on September 4 without detecting any bright comet.

FIREBALL ON AUGUST 13.—Mr W. F. Denning writes: "A large fireball was seen from various parts of England on August 13 at $9^h\ 13^m$ P.M. Among other places it was observed from Alford, Linc., Palling, Norfolk, Keynsham, near Bristol, and Derby. The meteor gave the impression of a brilliant rocket; for it illuminated the landscape and sparks followed the head along its somewhat lengthy course. As viewed from Derby it was described as being of an incandescent blue colour with a tail of similar tint and golden sparks. Another person says it emitted an intense bluish-white hue like lightning and that it vividly illuminated the country. I have compared the data and find that the radiant point is indicated at 303° – 13° near α Capricorni, and that the meteor traversed a path of about 84 miles, falling from 62 to 33 miles in height—velocity about 25 miles per second. The direction of flight was from south by east to north by west, and the meteor passed from over Huntingford to near Doncaster. The radiant point is a well-known one and has been often observed in July and August supplying slow and brilliant meteors."

THE PROBLEM OF 'ISLAND UNIVERSES.'—The true interpretation of spiral nebulæ, either as comparatively small bodies occurring merely as outlying members of our Galaxy, or, on the other hand, as very remote systems comparable both in size and nature with the Galactic system itself, still remains a matter of controversy. An important contribution to the problem is made by Dr. Hubble in the *Astrophysical Journal*, vol. 63, p. 236, in which a critical and detailed analysis is given of the naked eye spiral Messier 33, based on photographs taken with the great 100-inch reflector. The high resolving power of this instrument shows no difference between the images of so-called condensations and those of ordinary stars of the same magnitude. Ritchey's description of these objects as "nebulous stars" appears therefore to be no longer tenable. Numerous nebulæ, novæ, and variable stars have been discovered by Dr. Hubble in Messier 33, including 35 Cepheids. The distance as derived from the period-luminosity relation among the latter is about 263,000 parsecs. That this distance is of the right order of magnitude is confirmed by evidence from the novæ and from the luminosity function for the brighter stars. Dr. Hubble considers Messier 33 to be an isolated system of stars and nebulæ, far beyond the limits of the Galaxy; but as being more comparable in size and luminosity with the Magellanic clouds than with our own system.

Research Items.

REMISSION OF SINS AT THE SHRINE OF A MOSLEM SAINT.—A description of a fair at Pakpattan at the tombs of Bâbâ Farîd Shakarganj, which is quoted in the *Indian Antiquary* for August, contains several points of interest to the students of religious belief. The great attraction of this annual fair is the opening of the Gate of Heaven. On the death of the Bâbâ, who is credited in story with wonderful powers during his lifetime, it was published far and wide that whoever passed through his tomb between sunset and sunrise on the new moon in August would be forgiven the sins of the past year, and the fair was established for the benefit of the faithful attending at the tomb for this purpose. The fair is attended by worshippers drawn from districts so wide apart as the North-West Frontier and the United Provinces. On the final night when the gate is to be opened, all pilgrims collect outside the gates of the town, which are closed. On the signal by rocket that the sun is set, they are admitted to the town and all night long pass in single file through the tomb. At sunrise the door is shut. On one occasion the police used light switches to strike the people in order to hasten the movements of the crowd. The people, instead of avoiding the blows, courted them, and on inquiry as to the reason, it was stated that the switches represented the sword blades forming the legendary bridge between earth and heaven on which the feet of the faithful are cut, whereas the wicked fall between the gaps in the bridge into hell below. Those, therefore, who were hit by the police switches considered that they had had their feet cut by the swords of the bridge and were doubly sure of the forgiveness of their sins.

INTELLIGENCE AND FAMILY HISTORY.—Some interesting data bearing upon the question of how far superior intelligence is a family characteristic have been collected by Miss Grace Allen as the result of an investigation of 48 families to which belonged a number of children selected as the result of psychological tests by members of the Teachers' College, New York. The results have been published in *Bull.* 25 of the Eugenics Record Office of the Carnegie Institution of Washington. All the children were of exceptionally high character intellectually, and the study involved the more remote history of the family, present conditions, occupational and home ratings, physical and temperamental traits and birth conditions. Of these families 70 per cent. were Jews, and of these 20 per cent. of German extraction, and 10 per cent. more German on one side of the family. Only one child came of American stock on both sides, and in only three families were all four grandparents American born. As regards occupation, 70 per cent. of the fathers were professional men, and 25 per cent. did clerical or semi-intellectual work; 25 per cent. are college graduates, a frequency twelve times higher than in the population at large. Brothers and sisters and cousins tested for intelligence scored high. The fecundity was low, being about 0·8 of a reproducing child to each parent. First births occur twice as commonly as in the general population; but this is due to the fact that the intelligent groups have an exceptionally high population of first-born children only. The fathers are above the average age because this class marries late. Physically the families belong to a fine stock, being long lived and robustly built. The children show few physical defects. In a preface, Dr. Charles B. Davenport sums up the results of the investigation as showing that the highest intelligence comes out of a stock that is highly developed on both sides.

GLASS-MAKING IN ANCIENT EGYPT.—The technique of the manufacture of glass vases in ancient Egypt is obscure. Sir Flinders Petrie has suggested in connexion with the examples discovered by himself at Tel-el-Amarna, the use of a rod and a core of sand dipped into melted glass, while Mr. Harry Powell in the "Encyclopædia Britannica" suggested alternatively that they were blown. Mr. James H. Gardiner in *Glass* for July considers that the true method of production must differ from anything that has yet been suggested, basing his view on the examination of a number of examples of the XVIIIth Dynasty. The softening or plastic temperature is about 900° C., not a great deal below that of good English flint glass. Some, however, have been drawn from material which would have needed quite 1000° C. to form. In the case of a fish-shaped vase from Tel-el-Amarna, the body is a well-melted blue soda metal with fine seeds. The tail portion is solid and has been made and ornamented first and then squeezed on to the soft body. The indentation of the flat-nosed tongs used for holding can be distinctly felt. The coloured-glass pattern was made by threading coloured glass on to the surface. Notwithstanding the weighty negative evidence of an absence of any indications of blowing tools or fragments showing clear inside surfaces, the author is strongly of the opinion that the glass objects of the XVIIIth Dynasty show the beginnings of fabrication of glass vessels by blowing, which afterwards developed into the blown ware of the Greek and Roman period. It is suggested that the fact that in all cases there was a circular opening in the neck showing abrasion, as if a metal rod had been introduced and withdrawn, may have been due to the use of a metal funnel to introduce hot sand while the material was soft, and that the object was then buried in hot ashes to cool slowly.

THE GREAT RIFT VALLEY.—In a paper in the *Geographical Journal* for August, on the Nyasaland section of the great Rift Valley, Dr. F. Dixey advances the view that in early Cretaceous or possibly late Jurassic times, the initial uplift in the Nyasa region took the form of a gentle anticlinorium, or large anticline, and that the more or less meridional troughs so produced were occupied eventually by rivers. At a later date rift faulting began, and continued intermittently through a large part of Tertiary and Quaternary times. Intersecting faults also extended into the regions bordering the main rift on both sides. The volcanic history of the area seems to have been largely confined to late Tertiary or early Quaternary times. Dr. Dixey finds no evidence to support the hypothesis of a marine sedimentary phase of Oligocene age. Lastly, he gives reasons in favour of the rift-faulting of the region being due to long-continued tensional stresses rather than to compression. These are the absence of thrusts and folds and the development of much block faulting; the occurrence of subsidiary rifts parallel with the main rift; the existence of a reticulated system of rift valleys; low-step faults extending into the middle of the rift valley floor; and the successive tilting of the floor of the northern end of the rift in one direction.

TERTIARY FOSSILS FROM JAPAN.—No less than six papers on the tertiary mollusca of Japan, from the

pen of Prof. Matajiro Yokoyama, appear in the first volume of the Journal of the Faculty of Science of the Imperial University of Tokyo. Most of these fossils come from the central districts of the main island of Japan, but some are from the oil-fields in the north-western part of the "Main Island of Hokkaido" (formerly known as Yedo). Prof. Yokoyama's communications total 87 pages illustrated by 19 plates, which are very good, but not quite equal to the efforts of the Japanese artist at his best. The text, beyond brief statements as to the position and age of the respective beds in which they occur, is confined to systematic descriptions of the species, many of which are described as new.

BAXTER BASIN GAS-FIELD, WYOMING.—Mr. Julian D. Sears contributes an interesting account of the geology of the Baxter Basin Gas-field, Sweetwater County, Wyoming, in *Bulletin* 781-B of the United States Geological Survey. This field was first proved in 1922 by the completion of two wells of large yield; previously, drilling on the Rock Springs anticline, of which the Baxter Basin occupies structurally the highest part, had resulted in little or no success; even now there seems to be small prospect of oil being found in commercial quantity. Gas is found in commercial quantity, however, in each of the three domes developed along the crest of the main structure, and is produced from the Upper Cretaceous Frontier and Dakota sandstones. Each dome has its own gas-pool, there being no single continuous pool common to all three as they are separated by structural depressions and by faults that offset the reservoir beds. Twenty-three wells had been drilled in this field up to the time of survey; these ranged from 1000 to 3400 feet deep, finding the Frontier sands at depths from 1800 ft. to 2000 ft., and the Dakota sands at depths from 2500 ft. to 3400 ft., according to the positions of the wells concerned. Some remarkable yields are recorded: one well gave 2,000,000 cubic feet per day from the Frontier and 70,000,000 cubic feet from the Dakota; another well found water in the Frontier but yielded 21,000,000 cubic feet of gas per day from the Dakota; other yields from the Dakota (unquestionably the richest sand in the field) are from 17,000,000 cubic feet to 35,000,000 cubic feet daily. Water occurs high on the flanks of two of the productive domes, thus leaving very little room for an intervening oil layer between it and the gas; this is one of the reasons dispelling any hope of commercial oil production from this field.

CYCLONES OVER CEYLON.—Cyclonic movements in Ceylon are dealt with by Mr. A. J. Bamford, the superintendent of the Colombo Observatory, in the *Ceylon Journal of Science*, vol. 1, part 1, in continuation of the series that have appeared in the past in the bulletins of the Colombo Observatory. Any discussion of the movements of cyclones wherever dealt with is of general interest, as cyclones are so decidedly the centres of action with respect to the weather both over land and sea. In the discussion several storms are analysed, and much information can be gleaned as to the main seat of control in that part of the globe. Other special features are dealt with in detail, especially the heavy rains over Ceylon of September 29-30, 1924, falls up to 12 inches being reported which occasioned floods in many places. The weather over the island at the time was of the usual south-west monsoon type; the fall of temperature on September 29 is said to be the result and not the cause of the rains. Maps are given showing the rainfall over Ceylon.

CLIMATOLOGY OF FALMOUTH.—Weather observations at Falmouth for the year 1925 and the mean values for 55 years, 1871–1925, have just been issued by Mr. J. B. Phillips, the superintendent of Falmouth Observatory. The observations are of considerable value, as they show great equability of the climate throughout the year. The mid-winter month January had the day maximum temperature between 50° F. and 54° F. on 24 days, and there was only one day with the temperature below 45°; the minimum or night temperature was only below 40° on six days and on three days was above 50°. The mean temperature for January was 3°·4 above the average. In November and December, when periods of exceptionally cold weather were experienced over Great Britain, the relation of Falmouth to other parts of the country is interesting. The mean temperature for the year was 51°·5, which is 0°·7 above the normal; the warmest months with relation to the average for 55 years were January and October, both of which exceeded the average by 3°·4. The total hours of bright sunshine in the year were 1819, which was 69 hours above the mean, and it was the highest for the year since 1911, when the sun shone for 2056 hours. During the first six months of 1925, Falmouth had 43 per cent. of the possible duration of sunshine, while that for the British Isles was 35 per cent. For June, Falmouth had 77 per cent. of the possible duration of sunshine, while for the British Isles it was 50 per cent. The daily average sunshine at Falmouth for the several seasons was: spring 5·41 hours a day, summer 7·88 hours a day, autumn 4·33 hours a day, winter 2·36 hours a day. The total rainfall for the year was 49·77 in., which is 4·01 in. more than the mean. The outstanding feature of the year was the rainless period from May 29 to July 3, absolutely no rain falling in June, while the mean for 55 years is 2·24 in.

THE CRYSTAL STRUCTURE OF MAGNESIUM PLUMBIDE.—With the publication of J. B. Friauf's results on the crystal structure of magnesium plumbide (Mg_2Pb), in the *Journal of the American Chemical Society* for July 1926, the crystal structures of the three intermetallic compounds which magnesium is known to form with silicon, tin, and lead, are now completely determined. The plumbide, prepared by melting the calculated amounts of magnesium and lead under a protective layer of sodium and potassium chlorides, was ground to powder under kerosene, and a sample, covered with a little paraffin, rotated during exposure to radiation from a molybdenum target. The powder diffraction pattern was photographed, and the unit cell found to contain four molecules. The position of the atoms corresponded with the calcium fluoride arrangement.

SPIRIT THERMOMETERS.—The August issue of the *Journal of Scientific Instruments* contains an article by Mr. W. F. Higgins, of the National Physical Laboratory, of considerable importance to the makers and users of spirit thermometers. It has been noticed that the readings of certain spirit thermometers when placed in melting ice have decreased with age at rates of the order of 1° F. per month. Experiment has shown that the decrease is not due to loss of spirit, through minute cracks in the glass or to change of volume of the glass, but to the presence of small quantities of acetone in the methyl or ethyl alcohol used in the instrument. Ten per cent. of this impurity is sufficient to cause a lowering of the ice point at the rate of 1° F. every ten days for the first few months after the thermometer is made. The effect appears to be due to the polymerisation of the acetone under the influence of light.

Excavations in Kent's Cavern, Torquay.

AT the Southampton meeting of the British Association last year, a Committee was appointed to co-operate with the Torquay Natural History Society in investigating the important palæolithic site at Kent's Cavern, made famous by the researches of McEnery, Buckland, and Pengelly. For some time previously the future of the cave, which is in private ownership, and the possibility of dispersal to unknown destination of relics of antiquity which might be of the greatest moment for the early history of man in Britain, had been a source of anxiety to the local scientific society and to archæologists generally. It was hoped that the British Association Committee would be able to some extent to mitigate the dangers of the situation; but at the time of its appointment there seemed little hope of immediate excavation, and at the most it was hoped that it would hold a watching brief for archæology and ensure that any specimens of interest or importance to science which might come to light should, at least, be recorded and if possible made available for study. Early last winter, however, leave was obtained from the proprietor for a preliminary examination of that part of the cave known as the 'Vestibule.' Funds were raised from the British Association, the Royal Society, the Society of Antiquaries, and a fund for the employment of ex-service men; but the greater part of the work has been carried out voluntarily by members of the Torquay Natural History Society. A summary of the results of these excavations is contained in a report of the Committee which was presented at the Oxford meeting of the Association.

'The Vestibule,' which was selected for excavation on the advice of Prof. W. J. Sollas, is a chamber some 40 ft. by 32 ft., into which the northern entrance to the cavern leads. A trench was dug along the entire length of the northern wall slightly overlapping into the 'Sloping Chamber' and passing at its eastern end under the Magdalenian hearth discovered by Pengelly in 1866, which is known as the 'Black Band.' A beginning of a trench along the east wall in the direction of the entrance was also made. The depth of the trench varies from 2 ft. 6 in. to 13 ft. according to the nature of the deposit. The area which produced the greater part of the finds was near the east wall. Heavy blocks of limestone were present throughout. At each end of the trench crystalline stalagmite has appeared at the bottom of the excavation, but it is too early to say if this represents portions of a stalagmite floor.

The cave earth is quite unstratified and the fauna identical with that found by Pengelly at the higher levels. No hearths or workshops were found, but 135 flints scattered here and there have been recovered. Nearly all are patinated a dull white. Omitting waste fragments and neuclei, they fall into two classes: end scrapers and 'blades,' the latter being about 80 per cent. of the total. The end scrapers are of the usual type with primary flaking along the length of the implement, terminating at the broader end in steep, fanwise retouches producing a convex scraping edge. The reverse is a flake surface. The implement is in the Aurignacian tradition. The 'blades' have primary flaking along the length of the implement with two facets meeting in a carinated median line, or three facets, when the central facet makes a flat ridge. This would appear to be an industry of simple unretouched blades, and corresponds to the implements collected by Pengelly from the higher levels. The absence of bone, horn, and ivory implements suggests that it is not true Magdalenian; the absence of Chatelperron and Gravette points that it is not true Aurignacian; and of burins that it is not either Aurignacian or Magdalenian. Certain similarities to Solutréan are probably intrusive. It is, however, certain that we have here a culture of Upper Palæolithic type.

The abundance of remains of the horse would indicate a steppe climate suggestive of the Aurignacian and Solutréan periods of southern France, but reaching England at a later date. The study of the fauna suggests that the cave earth was in process of formation when the upper part of the base level and the lower part of the middle levels were laid down in Mother Grundy's Parlour at Creswell, of which the upper middle level roughly corresponds to the Black Band of Kent's Cavern. The deposits recently examined in the Aveline's Hole in the Mendips seem to correspond to the granular stalagmite excavated by Pengelly.

In a skull found in a crevice outside 'the Vestibule' Sir Arthur Keith finds a close correspondence in the palate and teeth to those of the human jaw found in the granular stalagmite. It is brachycephalic and compares closely with two brachycephalic skulls found at Aveline's Hole, also associated with an industry of simple unretouched blades.

Irish Limnology.[1]

ALTHOUGH the study of lake life has received considerable systematic attention by other countries, especially on the Continent and in the United States, there had been no definite institution set up for that purpose in Great Britain or Ireland until the year 1920. It remained for the War to direct attention to our lack of knowledge of British lakes and their possible economic value; and, as a direct outcome of consultations at that time, a limnological station was established in August 1920 on the river Shannon, one mile from the northern end of Lough Derg, Ireland being considered the most suitable country in which to tackle the problem on account of its valuable inland fisheries and large area of fresh water.

The first report from the limnological laboratory by Mr. R. Southern and Mr. A. C. Gardiner, now before us, deals chiefly with the Crustacea in the plankton of Lough Derg and the river Shannon. The research, which included two full years, 1921 and 1922, was carried out with a thoroughness and attention to detail worthy of the greatest praise. Five to seven stations were worked with regularity, the positions being chosen so that information could be obtained on the plankton of the Shannon River itself and of the northern end of Lough Derg in regions outside and within the effect of the river's current and in special localities in which the effects of wind action might be shown. The technique of the plankton collecting was carefully worked out, and it is satisfactory to note that the results are based on collections made by horizontal hauls, although vertical hauls were generally taken at the same time. A great deal of attention was devoted to making these horizontal hauls as uniform as possible, and an ingenious method of

[1] "Fisheries, Ireland, Sci. Invest.," 1926, 1. Reports from the Limnological Laboratory. I. The Seasonal Distribution of the Crustacea of the Plankton in Lough Derg and the River Shannon. By R. Southern and A. C. Gardiner. Pp. 1-170. Plates I.-XV. Text figs. 1-4.

drifting from an anchored boat until 100 yards of greased rope had run off a reel, and then rowing back through this 100 yards in a given time, was adopted, and ensured, so closely as is practicable, that fairly equal volumes of water were filtered on each occasion. Concurrently with the plankton collecting, observations were made of the following chemical and physical factors—temperature (air and water), wind, rainfall, water level, transparency of the water, hydrogen ion concentration, dissolved oxygen and complete chemical analysis of the water.

Examination of the physical and chemical conditions has shown that Lough Derg differs from many lakes of which the features have been described on the Continent and in America, in that its waters are practically homogeneous from surface to bottom throughout the year, any evidence of a thermocline, and hence marked changes between surface and bottom oxygen content, being absent. This, in Southern and Gardiner's opinion, can be accounted for by the general shallowness of the lake (rarely more than 20 feet in the northern half, although the southern end is deeper with soundings as great as 119 feet), its narrowness, and hence continual change of the body of water flowing through it and the general mixing action of winds over the shallow water. In consequence, all the water of the lake is capable of supporting an abundance of living plankton organisms and of fish life. The ratio $\frac{Na + K}{Ca + Mg}$ is low: the phytoplankton is characterised by the relative scarcity of the Desmidiaceæ and dominance of the Diatomaceæ. This supports Pearsall's theory that if the above ratio is low the conditions favour the growth of diatoms, and, if high, of Desmids. It was also notable that large numbers of different species occurred together, at the same time, in great abundance. A further report on the phytoplankton is to be published.

The distribution of the crustacean plankton is considered from all aspects—seasonal and diurnal, both horizontally and vertically. In the horizontal distribution great stress is laid on the wind as a factor in causing irregularity, and the detailed discussion of the effects of winds is being kept for a subsequent report. Of the crustacea, *Daphnia longispina* was the dominant form, though *Bosmina coregoni*, *Leptodora Kindtii* or *Diaptomus gracilis* were most prevalent at times.

The importance of plankton crustacea as food for fish is discussed. Of the fish present in the lake, the Pollan, *Coregonus elegans*, is a plankton feeder throughout its whole life; these crustacea were also found to be an important constituent of the diet of the fry of pike, tench, rudd, bream, and perch. A correlation between the growth-rate of perch fry and the abundance of crustacea is given. It is interesting to see that to a certain extent big trout were also found to be feeding on plankton. The fact that these sporting fish will feed voraciously on small entomostraca is perhaps not generally known. In this respect it is interesting to direct attention to an experiment carried out at the Jersey waterworks showing the remarkable growth of young trout which fed on the abundant crustacean plankton present in the filter beds.[2]

It is sad to see that, after such a good beginning, the limnological station on the river Shannon is now closed down. It is necessary that such well-planned work should be carried out through the course of many years before the true significance of many of the seasonal changes in the plankton community can be fully understood and the foundations laid for a close study of the actual fish-producing power of these lakes.

Messrs. Southern and Gardiner have made an important addition to the many valuable works that have been published from time to time by the fisheries of Ireland. F. S. R.

Studies on the Origin of Cultivated Plants.

THE history of cultivated plants is a subject which has attracted many botanists, and numerous theories of their origin from one or more wild prototypes have been published. Until recently the conclusions of Alphonse de Candolle have been accepted with a minimum of critical revision. The great increase in genetical research and the marked desire of many geneticists to link their studies with other aspects of biology is, however, leading to renewed interest in the taxonomic and geographical history of our common cultivated plants. Much new material has been accumulated and a few geneticists are even devoting time to collecting in person cultivated, feral, and wild examples of the genera and species they are studying in experimental ground and laboratory.

Prof. N. Vavilov, Director of the Institute of Applied Botany and New Cultures, Leningrad, is well known in Great Britain by the numerous important works on genetics and allied subjects which he has published. In a paper which has recently been received [1] he deals in a decidedly original manner with the origin of the common cereals and a few other widely cultivated plants. The conclusions reached are very largely based on the researches carried out by Prof. Vavilov and his assistants in Central Asia and the Nearer East in the years since the War. In addition, many thousands of seed samples have been obtained from all parts of the world and grown at one or other of the experimental stations under the control of the Institute. While it is certain that many details have still to be discovered for all the groups studied, there is no doubt that important problems have already been solved, and that further applications of the new methods will aid in the elucidation of many obscurities in the past history of all species and races which have been so long in cultivation that not even archæological researches can alone prove their origin.

The law of homologous series, expounded by Prof. Vavilov in an able paper in the *Journal of Genetics*, 12, 47, 1922, is applied here with the purpose of finding the geographical centre, or centres, of maximum varietal diversity within what is accepted as a "Linnean species." The data are set forth in tables and illustrated by exceptionally clear maps in the Russian text, to which is attached an almost full English translation. The results are comparable with the periodic classification of the chemical elements in that not only are the known variations classified, but also the existence of undiscovered varieties is postulated. In addition to the usual 'characters' of the taxonomist and morphologist, physiological characters, such as immunity to diseases and seasons of vegetative activity and of flowering, and cytological and genetical data are freely used. It was found that even for cultivated plants the variations are not haphazard in their geographical distribution, but that they occur about well-marked centres. The immense diversity of spring and winter forms of soft and club

[1] From *Bulletin of Applied Botany and Plant Breeding*, 16, 2, 1926, Leningrad.

wheats is concentrated in the mountainous districts of south-west Asia, while the polymorphism of the durum wheats is most marked in North Africa. Two centres of origin for the barleys are indicated in Abyssinia and south-east Asia. Cultivated oats are undoubtedly of polyphyletic origin, and five geographical and genetical groups are established. South-west Asia is recognised as the chief centre of diversity of rye. There is no reason to regard *Secale montanum* and *S. fragile* as progenitors of cultivated rye. Both oats and rye probably entered cultivation simultaneously and independently in different localities, primarily as weeds in crops of wheat and barley. Flax is referred to two principal groups: a large-seeded, large-flowered group connected with the Mediterranean, and a small-seeded, small-flowered one peculiar to south-west Asia. A third group may be centred in Abyssinia. It is shown that the mountainous districts of Asia and the Mediterranean region, being the centres of varietal diversity of nearly all the most important agricultural crops, were probably also the home of primeval agriculture.

The final paragraphs of Prof. Vavilov's stimulating paper form a fitting conclusion to this notice of his work: "Evolution proceeded in time and space, and only by coming near the geographical centres of the origin of forms, by establishing the links connecting species, shall we be able to master the synthesis of Linnean species (considering them as systems of forms). Only systematics and the knowledge of the geography of plants enable the geneticist to select consciously the initial forms for his crosses and to solve problems of experimental phylogenetics. The problem of the origin of species is thus considered as the problem of the origin not of separate varieties, which in Darwin's opinion differentiated into individual species, but of complex systems, such as are true Linnean species.

"As it follows from the above, the solution of the problem of the origin of species lies in a synthesis of thorough investigations of separate groups of plants by the differential systematical methods, by that of botanical geography (in the sense of establishing the centres of the origin of forms), and the methods of genetics and cytology. Only in using systematics, differential geography, genetics and cytology, can we find a way to the strongholds hiding the origin of species."

W. B. TURRILL.

University and Educational Intelligence.

LEEDS.—With the co-operation of the International Education Board of New York, an exchange of posts for the academic year 1926–27 has been effected between Prof. Olis F. Curtis, professor of plant physiology, Cornell University, Ithaca, New York, and Dr. W. H. Pearsall, reader in botany, the University, Leeds. Dr. W. H. Pearsall sailed for America in time for the International Congress of Plant Sciences, which was being held in Ithaca during August, and to which he communicated an account of his investigations of the aquatic flora of the Lake District, England. Prof. Curtis, who arrives in Leeds this month, has published interesting papers in many fields of plant physiology, but is best known for his work upon the channels in which food substances travel through the plant.

DR. NOEL J. G. SMITH, of the Department of Botany, University of Aberdeen, has been appointed professor of botany in the Rhodes University College (University of South Africa), Grahamstown. Dr. Smith was educated at the University of Edinburgh and at Cambridge.

BY the will of the late Sir John Williams, Bart., President of the University College of Wales and of the National Library of Wales, who died on May 24, leaving estate of the gross value of 123,742*l.*, the residue of the property, which will amount to nearly 100,000*l.*, is bequeathed to the two institutions of which he was president.

"MOTIVATION OF ARITHMETIC" is the title of a sixty-page report by Mr. G. M. Wilson, professor of education, University of Boston, published as Bulletin 1925, No. 43 of the United States Bureau of Education. It is based on some five thousand replies received from teachers in all parts of the country, and leads to the general conclusion that arithmetic, in spite of isolated attempts at motivation, is still largely a formal subject. Prof. Wilson's point of view is indicated by the question he urges teachers to think over: Should life be brought in to illustrate arithmetic, or should arithmetic be subordinated and become a means for the interpretation of life? There is, as he says, much work ahead for those who would realise the ideal of school work on a real life basis. Meanwhile his pamphlet with its examples of "actual life situations," of life situations used as a basis for school exercises, games, game devices, and other devices, representative of methods used by the most progressive and intelligent teachers in the public schools of the United States, will help substantially towards approximating school practices to his ideal. The bulletin is a good example of the levelling-up work undertaken by the United States Bureau of Education through making widely known among teachers the practices of the best.

THE report on the work of the Department of Petroleum Technology of the Sir John Cass Technical Institute for the session 1925–1926 has been issued. This department was established about five years ago to provide technical instruction for those engaged in or desirous of entering the petroleum industry. The courses include lectures on petroleum technology, on the properties, applications, and examination of petroleum, on the chemical and physical properties of petroleum, and on the applications of engineering, also mechanical drawing; provision is made for those possessing no previous knowledge of experimental science to take the preliminary course of elementary chemistry, elementary physics, and practical mathematics. The record for the session shows satisfactory progress, in the case of the petroleum lectures, Part 1, there being no less than 90 class entries engaged in all for 1343 'student hours.' The report comments on the educational value of kinematograph films of the petroleum industry, two of which were exhibited during the session; such films enable students "to see in true perspective the ramifications of the industry and the difficulties associated therewith." Those responsible for directing the work of this department deserve much credit for the valuable work accomplished in a comparatively short space of time. A strong feature of the organisation is the existence of the consultative committee composed of recognised experts in the industry; this committee is not only of use in advising on work schedules, but, acting in liaison with the principal oil companies in London, it also ensures what is so vital in all academic treatment of petroleum technology—constant contact with the industry itself.

Contemporary Birthdays

September 12, 1851. Sir Arthur Schuster, F.R.S.

September 14, 1849. Prof. Ivan Petrovitch Pavlov, For. Mem. R.S.

September 16, 1859. Mr. Basil Mott, C.B., M.Inst.C.E.

September 17, 1859. Dr. Frank Dawson Adams, F.R.S.

September 18, 1854. Sir Richard Tetley Glazebrook, K.C.B., F.R.S.

Sir ARTHUR SCHUSTER was born at Frankfort-on-Main, and he was educated at the University of Heidelberg, and at Owens College, Manchester. Professor of physics in the University of Manchester, 1888–1907, he was a secretary of the Royal Society from 1912 until 1919, and president of the British Association at the Manchester meeting of 1915. As chairman of the executive committee of the National Physical Laboratory for the six years' period, 1919–1925, Sir Arthur rendered important services, not only to the institution, but also to science in general. It is worthy of recall that in his article "Spectroscopy," in the "Encyclopædia Britannica" (11th edit., 1911), Sir Arthur remarks in a footnote that he believes he was the first to introduce the word 'spectroscopy' at a Royal Institution lecture. This discourse was delivered January 28, 1881, under the title, "The Teachings of Modern Spectroscopy."

Prof. I. P. PAVLOV, the distinguished Russian physiologist, is a foreign member of the Royal Society, and he was Nobel laureate in physiology and medicine for 1904. Prof. Pavlov's earlier researches related to the physiology of the circulation, and especially the nerve supply of the blood-vessels. Soon, however, he was concerned in chief with the physiology of digestion, establishing new methods of procedure in the examination of functions, and deducing conclusions which have proved of fundamental importance in the whole study and range of the subject. In 1915 Prof. Pavlov was awarded the Copley medal of the Royal Society.

Mr. BASIL MOTT received his early technical training at the Royal School of Mines. Mr. Mott was president of the Institution of Civil Engineers in 1924.

Dr. F. D. ADAMS is emeritus dean of the Faculty of Applied Science, and Logan professor of geology in McGill University, Montreal. Born in that city, he was educated at the High School there, graduating at McGill. He is Hon. LL.D., Toronto. Dr. Adams has conducted many researches in economic and experimental geology. An account of one of these (in collaboration with Dr. J. T. Nicolson), entitled "An Experimental Investigation into the Flow of Marble," was published in the *Philosophical Transactions* for 1901.

Sir RICHARD GLAZEBROOK, foreign secretary of the Royal Society, was educated at Liverpool College, and at Trinity College, Cambridge, graduating 5th wrangler. Sometime assistant director of the Cavendish Laboratory, he was afterwards principal of University College, Liverpool, from 1898 until 1899, retiring to become director of the newly established National Physical Laboratory, a post which he filled with acumen and distinction for fifteen years. He is now chairman of the executive committee of the Laboratory. Sir Richard was awarded the Hughes medal of the Royal Society in 1909. Author of a number of valuable text-books, the editorship of the "Dictionary of Applied Physics" is his latest service to scientific publications of permanent value.

Societies and Academies.

PARIS.

Academy of Sciences, July 26.—Gabriel **Bertrand** and M. **Macheboeuf**: Nickel, cobalt and diabetes. Injections of saline solutions containing small quantities of these two metals in some cases of diabetes proved to be without effect; in others, there was a marked improvement. Administered by the mouth, in one case of diabetes, the amount of insulin injected daily could be reduced by 25 per cent.—**Rateau, Leroux** and **Bourgeat**: The experimental determination of the coefficient of yield of tuyères working with a free flow.—Kyrille **Popoff**: The convergence of series in ballistics.—E. M. **Antoniadi**: Changes recently observed on the planet Jupiter with the 83 cm. telescope of Meudon Observatory. A detailed description of recent changes in the surface of the planet, with two reproductions of photographs.—Léon **Brillouin**: A general type of problems, allowing the separation of the variables in the undulatory mechanics of Schrödinger.—Louis de **Broglie**: Remarks on the new undulatory mechanics.—Lucien **Mallet**: The luminescence of water and organic substances submitted to γ-radiation. Under the influence of the γ-rays, water and certain transparent organic liquids exhibit a marked luminescence. The light from water contains ultra-violet rays of wave-length less than 3000 Å.U.—F. **Wolfers**: A probable action of matter on the quanta of radiation.—Pierre **Auger** and Francis **Perrin**: The distribution in space of the directions of emission of the photo-electrons.—Rodolphe **Berthon**: The projection and reproduction of reticulated photographs.—Pierre **Thomas** and Mlle. Mari **Sibi**: Contribution to the study of the structure of jellies. Organogels obtained with the benzoylacetal of sorbite.—P. **Dumanois** and P. **Laffitte**: The influence of the pressure on the formation of the explosive wave. From experiments $(2H_2+O_2)$ with initial pressures from 1 to 6·5 atmospheres, the distance travelled by the flame before the explosive wave is set up diminishes as the pressure increases, at first rapidly and then more slowly.—Michel O **Samsoen**: The dilatometric and thermal study of glasses composed of silica and soda.—Marcel **Laporte** and Mario A. da **Silva**: The mobility of the negative ions and ionisation currents in pure argon. From the results of earlier work, it was concluded that in perfectly pure argon the saturation current would be obtained with a much lower potential difference than in air: this prediction is now confirmed experimentally. The curves given show that saturation is obtained in highly purified argon at 50 volts, whilst in air, saturation is not reached at 1760 volts. The effect of impurities on the ionisation curve of argon is shown.—Georges **Denigès**: The action of hydrobromic acid and of the alkaline bromides in acetic acid solution on cupric bromide. A new cupric reaction. The reaction is based on the colour produced by the addition of a cupric salt to pure acetic acid containing some potassium bromide.—A. **Travers** and **Malaprade**: The constitution of solutions of molybdic acid. Solutions of molybdic acid contain a condensed acid, $4MoO_3 . H_2O$, which, by analogy with metatungstic acid, may be called metamolybdic acid.—R. **Cornubert** and Ch. **Borrel**: The action of benzaldehyde on cyclanones containing the groups $—CH(CH_3).CO.CHR\cdots$ or $—CHR.CO.CH_2—$.—G. **Bruhat** and V. **Thomas**: The dimagnesium compounds containing the benzene nucleus. An account of the general reactions of compounds of the type $C_6H_4(MgI)_2$.—G. **Vavon** and **Jakeš**: The catalytic hydrogenation of conjugated double bonds. So far

as concerns the addition of hydrogen by the catalytic method, the presence of a system of conjugated double bonds does not entail any special ease of hydrogenation, and does not permit partial hydrogenation in the 1 : 4 position. From this point of view, there are marked differences between the catalytic and nascent hydrogen methods of reduction. —Marcel **Sommelet** : A mode of preparation of tertiary amino derivatives of tertiary alcohols.— V. **Ipatief** and B. **Dolgof** : The hydrogenation of triphenylcarbinol and of phenylfluorenecarbinol under pressure. The end product of this reaction is tricyclohexylmethane $(C_6H_{11})_3CH$, the analysis and physical properties of which are given. The product previously described under this name by Godchot is shown to have been impure.—L. **Léger** and F. **Blanchet** : The grit formations of the isles of Port-Cros and of the Levant.—E. **Rothé**, J. **Lacoste** and Mme. A. **Hée** : Earthquakes in France in 1925. There were twelve earthquakes in France in 1925, only half the number in the preceding year. Details of the distribution and intensity are given.—Lucien **Mayet** : The fossil men of the Denise : the masculine frontal bone (the Frontal Aymard of the Crozatier Museum) at the Puy, Haute-Loire. A detailed study of this bone shows it to be clearly of the type *Homo sapiens*, and presents archaic characters in the sub-orbital region which are only found to-day in the most primitive existing race, the Australian aborigines.— **Michel-Durand** : The physiological rôle of the tannins.—Antonin **Němec** : A chemical method for determining the phosphoric acid requirements of agricultural soils.—Mme. Anna **Drzewina** and Georges **Bohn** : The influence of carbon dioxide on the sperm of the sea-urchin, as a function of the mass.—Max **Aron** : Experimental facts relating to the harmony of growth in the larvæ of frogs.—Charles **Dhéré** and Elphège **Bois** : The comparative study of the fluorescence of some natural and artificial porphyrins.— **Béguet** : The mechanism of agglutination (as regards *Br. melitensis*).—R. **Boyé** : The comparative action of quinine stovarsolate and chlorhydrate in quartian marsh fever.—F. **Rathery** and Mlle. L. **Levina** : The influence of salts of nickel and cobalt on some diabetic patients. Detailed accounts of the treatment and results with eleven patients.

August 2.—Jean **Perrin** and Mlle. **Choucroun** : The parallelism between the fluorescent power and velocity of reaction. Recent views on the production of fluorescence can be brought into line with the theory of Arrhenius (1889) on the existence of activated molecules. The velocity of destruction of a fluorescent body by a suitable reagent should be proportional to the average duration in the activated state, and consequently the probability of destruction of a given molecule should be greater at small concentrations than at high concentrations. Experimenting with methylene blue, it was found that (provided the pH remained constant) there was proportionality between the brightness of the fluorescence and the reaction velocity : changing from concentration 1/200 to concentration 1/1500, the brightness was multiplied by 10·5 and the reaction velocity by 11.— J. F. **Ritt** : Simplification of the method of Liouville in the theory of elementary functions.—**Akimoff** : The application of Fourier-Bessel transcendentals with several variables to the development in trigonometrical series of conditionally periodic functions.— **Mandelbrojt** : The trend of functions represented by Dirichlet's series and the growth of analytical functions round a singular point.—Georges **Alexitch** : The values of an analytical function taken on the circumference of the circle with radius unity.—N. **Podtiaguine** : The order of the growth of functions.—S. A. **Gheorghiu** : The theory of correlation.—Mlle. St. **Maracineanu** : Special actions of the sun on the radioactivity of polonium and lead. The experiments described appear to indicate that the solar radiation can cause the reintegration of radium E starting from radium F (Po), a reversibility in the radioactive series.—Pierre **Vernotte** : A regulator of E.M.F. and of current.—A. **Guillet** : The rectifying contact. A discussion of the theories of the action of the detector in wireless telephony.—A. **Dauvillier** : The telephote, an apparatus for television with the aid of vacuum tubes. Preliminary experimental results. —Eugene **Laborde**, Jean **Bressolles** and Léon **Jaloustre** : The influence of some radioactive elements on the catalytic activity of certain proteo-bismuth precipitates. The catalytic activity of the radioactive proteo-bismuth compounds (towards solutions of hydrogen peroxide) depends on the nature of the radioactive element present and its concentration in the medium in which the precipitate was formed. Barium alone is not without influence. Some possible therapeutic applications are indicated.—Mlle. **Choucroun** : The radio-chemistry of fluorescent bodies. Certain fluorescent organic substances (such as methylene blue) dissolved in a reducing medium are destroyed when exposed to light. Some irregularities in the velocity of this reaction have been traced to the influence of the pH of the medium. On adding a buffer solution (sodium acetate) the irregularities are greatly reduced.—A. **Travers** and **Houot** : The thermal study of electrolytic lead. The allotropy of lead. The dilatometric study of highly purified lead gives results consistent with the assumption that there are three allotropic forms of lead.—Robert F. **Le Guyon** : A new general analytical method : volumetric analysis, using a centrifuge. In volumetric precipitation methods of analysis, for which no suitable colour indicator is available, the use of a centrifuge is suggested. —J. **Orcel** : An attempt at the classification of the chlorites. The classification is based directly on the analytical results, using four characteristic ratios : s, f, a, and c, where $s = SiO_2/R_2O_3$, $f = FeO/MgO$, $a = Fe_2O_3/Al_2O_3$, and $c = Cr_2O_3/Al_2O_3$.—E. **Passemard** : The alluvial terraces of the Euphrates and the prehistoric implements they contain.—Henry **Hubert** : First observations relating to (electrical) atmospheric parasites in Western Africa.—Mlle. Laura **Kaufman** : The effect of the heterogeneous embryonic juice on the rapidity of emigration of the cells and the first stages of growth of cultures of tissues.—Paul **Camboué** : The prolongation of life in decapitated butterflies.— Baptiste **Roussy** : Unexpected and striking psychic facts manifested by a series of spiders of the genus *Epeire diademe* for keeping their webs in a vertical plane. These spiders attach to a line and lift to a distance from the soil heavy bodies (leaden wire, stones, snails), this serving the purpose of maintaining the web vertical. In one case the weight of the lead was 0·27 grams and the weight of the spider lifting it was 0·05 grams.—F. **Henrijean** and W. **Kopaczewski** : Researches on the composition of the squill and its tonicardiac principle.

August 9.—Jacques **Chapelon** : The minima of quadratic forms.—René **Lagrange** : Legendre functions of the first species and certain associated functions.—S. Piña **de Rubies** : The arc spectrum of europium. Measurements made at the normal pressure, between $\lambda 3500$ and $\lambda 3100$.—P. **Budnikoff** : The activation of the inert varieties of calcium sulphate. Natural anhydrite and the calcium sulphate obtained by dead burning gypsum do not set in contact with water, but can acquire this

the other hand, originative invention, although active in the wireless art, was during the War years largely diverted from the arts of peace. On the whole, therefore, there was a dearth of permanently useful originative inventions during that period, and it is to this circumstance that the present phase of unemployment may be largely attributed. If any doubt is felt on the subject, a comparison with the case of the wireless industry will afford conviction.

This is precisely the situation which can be ameliorated by wise improvements in the patent system, the purpose of which is to foster originative as distinct from intensive invention. Bearing that distinction in mind, we can obtain guidance as to the nature of the innovations needed by examining how far previous enactments have succeeded in promoting the grant of patents destined to live for a long term, as contrasted with those of inferior longevity: for the latter comprise the less successful originative patents together with the majority of the intensive patents. It must be remembered that in the British and German patent systems, as distinguished from the American, the inferior patents are progressively weeded out by renewal fees, which must be paid on an increasing scale from year to year if a patent is to be kept alive throughout the whole of the available term.

The various factors which might be thought to affect patent statistics can be eliminated only by means of an elaborate analysis, too intricate and tedious to be reproduced here. Such an analysis would leave no doubt, however, as to the effect produced by the Act of 1902, which introduced an official investigation as to the novelty of the inventions patented, the investigation being made for the first time in 1905. As regards the patents destined to live fourteen years, this Act had the effect of raising their number from a fairly steady average in the neighbourhood of 500 to a steady average of about 1200 per annum. On the other hand, it had only a small effect on the number of patents sealed annually, and no systematic effect on the number destined to survive for five years but no longer. The accompanying table gives illustrative figures only. It must be read in the light of the fact that the official examination was first made in 1905.

It will be seen, then, that the effect of introducing some sort of official investigation into the validity of patents before grant was precisely that which a patent system ought to have: the production was stimulated of originative patents having sufficient merit to earn a long life, as opposed to intensive patents and those of inferior quality. The Act of 1883, on the other hand, produced, by a general easing of patent fees, an indiscriminate multiplication of worthless as well as of useful patents.

The effect of the official investigation must be attributed to the enhanced value which was conferred upon patents by increased confidence in their validity, and if we wish to encourage originative inventions, and still more to encourage the exploitation in Great Britain of originative inventions, we must clearly seek some further methods of giving the patentee and his patrons an improved assurance that a patent, when granted by

Year in which patents originated	1902	1907	1913
Number of patents sealed (excluding patents of addition)	15,242	16,172	15,970
Number lapsing after four years	9918	10,625	9385
Number destined to survive for five years only	1497	1441	960
Number destined to survive for fourteen years	596	1175	[1250]*

* Extrapolated.

the Patent Office, shall not run a really serious risk of being found invalid if it should be tested by litigation.

At the present day more than 100,000 British patents are actually in force, and of these, fewer than 250 have ever been tested in the Courts. The Patent Office has investigated their validity so far as certain issues are concerned, but it has made no examination whatever as regards other important issues, and it is probable that a very large number of existing patents are bad in law. The Patent Office does not test the novelty of an invention by searching anywhere but amongst British specifications less than fifty years old, nor does it concern itself with 'prior user' or 'quantum of subject-matter.' Since, then, only a negligible proportion of patents ever have their validity fully tested, the effect of the remainder rests upon bluff. Litigation is so expensive that only the richest patentees dare undertake it, and in this situation the advantage lies entirely with the man of wealth and the large industrial companies. Now it usually happens that in the early stages of a new industry capital is hard to come by: the pioneers have no money to spare for fighting actions in the High Court, so that the high cost of litigation tends to defeat the main aim of the patent system. It favours intensive inventions, which abound in well-established and heavily capitalised industries, but it cripples the comparatively poor nascent industries which are based upon new originative inventions.

The Patent Office, then, cannot assure the patentee of the validity of his patent, because its investigation is incomplete: and the High Court will not assure him of it except at a cost which is prohibitive for men of moderate means. Can nothing be done to remedy

this state of things? A detailed answer to that question would lead us into a highly technical discussion affecting powerful vested interests and admitting of legitimate differences of opinion, but certain broad lines of reform can be indicated as almost indisputably sound.

There is a gap between the legal area investigated by the Patent Office and that which is relevant to the validity of an invention. This gap can be narrowed by expanding the former or contracting the latter area, or both. To take the latter proposal first: it must be admitted that patents can at present be invalidated on grounds which are purely academic and out of relation with practical requirements. In particular, the mere publication of an idea in some long-forgotten specification or journal in a foreign language will invalidate the monopoly of a manufacturer who wishes seriously to establish plant for the practical exploitation of that idea. The law as to novelty, therefore, requires searching scrutiny and reform: it should be borne in mind that mere academic suggestions on paper are of far less service in the establishment of new industries than are the details of a practical method which has been reduced to a commercial basis by exhaustive experiment. Encouragement must indeed be given to the theoretical inventor: but at present he gets more than his share of encouragement as compared with the practical industrialist.

Confidence in the validity of patents can also be improved by extending the scope of the examination made by the Patent Office. In particular, it has already been shown in these columns (NATURE, July 25, 1925, p. 121; Aug. 1, 1925, p. 157) that the investigation for novelty which is made by the Patent Office examiners could, without any subsidy from the State, be made effective over an area equal to that in which the German and American Patent Offices undertake to search. For this purpose it might be necessary to encroach upon the heavy financial surplus which is realised by the British Patent Office every year, but there is no justification whatever for that surplus. So long ago as July 14, 1891, Sir Michael Hicks Beach admitted on behalf of the Govermnent of the day that "he did not think that the country ought to look to the Patent Office as a permanent source of income," but the country has inadvertently done so ever since. Although it has been obtained without raising the pre-War fees, and by means of the admirably economical manner in which the Patent Office has been administered (see page 429 of the present issue), this surplus ought clearly to be used for the benefit of the patentees themselves. It should be remembered that, far from taxing invention, the United States considers it worth while to subsidise its Patent Office.

In the next place, patent litigation can be cheapened by extending the powers of the Comptroller-General and authorising him to deal with issues at present reserved for the High Court. His decisions would, naturally, be subject to appeal: but the poorer class of litigants could be safeguarded by the grant of certificates of validity which would secure them against heavy costs in the event of an appeal; and consequently against the intimidation which is at present practicable. The information obtained by means of a really extensive search for novelty would be of value to the Comptroller-General in deciding questions of 'prior user,' as to which he should also hear evidence. The issue of 'quantum of subject-matter' is entirely comparable with that of 'manner of new manufacture,' of which he is already empowered to dispose: and he might also settle actions for infringement where the damages claimed lie within some moderate limit. That the Comptroller-General and his agents are qualified to carry out these duties is beyond reasonable dispute.

The reforms which have just been mentioned would tend towards enhanced confidence in the validity of the patents granted by the Patent Office, and would diminish the extent to which the poorer are intimidated by the wealthier patentees. They would, therefore, presumably have an effect similar to that of the Act of 1902 in selectively enhancing the production of long-life patents for originative inventions: in this way they would make for the establishment of new industries based on newly created demands, and so would help to solve the unemployment problem. But this effect is conditional on one consideration of great importance. It is a fact that not much less than half of the patents granted by Great Britain are granted to foreigners (*ibid.* p. 428), and the question arises whether such grants tend, on the whole, to promote the establishment of new industries in Great Britain, or to hamper British manufactures in the interest of imports from abroad. The question is of vital importance, since such a very large proportion of our inventions are under foreign control. Legislation in this connexion is subject to various international agreements, but these do not necessarily affect all the participating nations equally, for Great Britain grants a specially large percentage of her patents to foreigners. The existing law makes apparently ample provision against the abuse of patent monopolies by foreigners; but how far it is evaded in practice, and how far its provisions are understood and utilised by British manufacturers, are questions which demand the most scrupulous and painstaking attention on the part of those who are responsible for the solution of the unemployment problem.

Descartes' "Géométrie."

The Geometry of René Descartes. Translated from the French and Latin by David Eugene Smith and Marcia L. Latham. With a facsimile of the first edition, 1637. Pp. xiii + 246. (Chicago and London: The Open Court Publishing Co., 1925.) 17*s.* 6*d.* net.

RENÉ DESCARTES (1596–1650), philosopher and mathematician, is of course universally regarded as the inventor of the method of co-ordinates in geometry; hence the common name for them, Cartesian co-ordinates. Yet, if it were a question of priority, a good claim could be put forward for Fermat (1601–1665), a contemporary, and an even greater mathematician; for, though Fermat's work "Ad locos planos et solidos isagoge" was not published until much later (1679), it was certainly conceived and perhaps written before 1637, the date of publication of Descartes' "Géométrie"; moreover, the method of co-ordinates comes out much more clearly in Fermat, and his analytical geometry generally is much more like ours than Descartes' is. Fermat's share in the new discovery nevertheless remained unknown until quite recent times, and the whole credit was given to Descartes by no less learned a geometer than Chasles, who, in a eulogy which now seems exaggerated, speaks of Descartes' doctrine as "prolem sine matre creatam" and one "of which no germ can be found in the writings of the ancient geometers." Anticipations of the method of co-ordinates are, however, as is now well known, to be found in Archimedes and Apollonius of Perga; the latter stated, for example, in words (without symbols), the fact that the locus of a point satisfying the equivalent of an equation of the first degree in two unknowns is a straight line, and the form in which he states the fundamental property of each of the three conics is the exact equivalent of the Cartesian equation referred to any diameter and the tangent at its extremity as axes. Descartes' actual achievement—and it was momentous enough—was to remove the impasse to which Greek geometry had come through want of notation, by introducing into geometry the unrestricted use of all the resources of algebra (then recently introduced into France from Italy) as a recognised and even indispensable auxiliary.

A mathematician of to-day who should turn to the "Géométrie" in the expectation of finding some sort of introduction to co-ordinate geometry such as is contained in our text-books would be disappointed. As Prof. Loria has observed in a recent study, there is a greater gulf between Descartes' work and a modern treatise on analytical geometry than there is between an ancient (*i.e.* a Greek) and a modern treatise on any other mathematical subject. Descartes uses his new method mainly for the purpose of investigating *loci* of a higher order than conics; he does not, for example, apply it to the geometry of the straight line or the circle. It is strange that the usefulness of the method of co-ordinates for elementary geometry appears to have occurred to no one for a long time. Lagrange saw it and illustrated it in a work published in 1773, but the first systematic exposition of elementary analytical geometry in our sense seems to have been given by S. F. Lacroix as part of his great work "Traité du calcul différentiel et du calcul intégral" (Paris, 1797).

It is not possible within the space of a review to describe fully the contents of the "Géométrie"; we can only notice a few of the outstanding features. Much of the work centres round "Pappus's Problem." This may be shortly stated thus. Given any number of fixed straight lines ($2n$, say, if the number is even, $2n+1$ if it is odd), suppose that from a point (P) not lying on any of them we draw a straight line to meet each of the given straight lines, at given angles respectively; if the lengths of these straight lines l_1, l_2 . . . are taken, and if (when their number is $2n$) the product of n of them bears a given ratio to that of the remaining n, or if (when their number is $2n+1$) the product of $n+1$ of them bears a given ratio to the product of the remaining n and another given length, it is required to find the locus of the point P from which the straight lines are so drawn. The Greeks solved the case of three and four lines (the locus being in general a conic) and also apparently (according to Pappus) one other case, and that not the simplest possible. Descartes in his second book shows how to solve a particular case of five lines, where four of the given lines are parallel and at equal distances and the fifth is at right angles to them, while they are all met at right angles by the straight lines drawn from the point the locus of which is required. Descartes solves this case by means of a curve constructed in a 'mechanical' way. Imagine a parabola and a point (L) fixed on its axis at a certain distance from the vertex. Suppose the parabola to move bodily in such a way that its axis slides on a given straight line, and suppose a ruler to move at the same time in such a way that it always passes through the point L and also through a fixed point A not lying on the straight line on which the axis of the parabola moves. The intersection of the ruler GL with the parabola at any moment determines a point C which lies on a curve of the third degree.

Descartes shows that the point required in the particular case of Pappus's problem lies on a curve of this kind. Again, he constructs two mean proportionals between two given straight lines, trisects any angle, and solves a cubic and a biquadratic equation by using

one *parabola,* along with straight lines and circles, in each case. In his third book (as a final *tour de force*) he solves an equation of the sixth degree in which all the powers of the unknown are present with an absolute term; this he does by means of the intersections of a curve of the kind above mentioned with a certain circle. He does not generally write down or use the equations of the curves as such; like the Greeks, he simply supposes them drawn and then shows that the points of intersection supply a solution of the problem. His solutions, in fact, amount to the Greek procedure carried further by means of the additional resources which the unrestricted use of algebra puts at the disposal of the geometer for the purpose of determining the parts of the figures required. Incidentally, Descartes explains an algebraical method of finding normals to a curve which depends on the principle that, if a circle be drawn with its centre at the point on the axis where the normal meets it and passing through the point on the curve, the circle *touches* the curve at the point instead of cutting it; this means that a certain algebraical equation must have two equal roots, and the use of this fact enables the normal to be determined. Descartes also gives a construction for the normal at any point of the conchoid of Nicomedes without using algebra. He does not say how he discovered it, but it must evidently have been by considering the instantaneous direction of the motion of the point describing the curve, and resolving the motion into two components, in the same way as Archimedes must have determined the direction of the tangent to his spiral at any point, *i.e.* by a sort of anticipation of the differential calculus.

Descartes lays down a number of rules, in regard to the solution of equations, *e.g.* the 'rule of signs,' the method of increasing or diminishing the roots of an equation by any quantity (which enables us to get rid of the second term in an equation), and so on. He explains how, in order to solve a cubic equation, we should first, by considering the several factors of the absolute term, try to find a linear factor, as $x - a$, in the expression equated to zero; and similarly with a biquadratic. In the case of a biquadratic, if the expression equated to zero appears to have no linear factor, it may be possible to separate it into two quadratic factors; by the method of undetermined coefficients Descartes shows that the possibility of this expedient depends on the solution of a cubic in another unknown, y^2, where again we may be able to find a linear factor.

Descartes' notation is interesting. He started the fashion of using the last letters of the alphabet (especially x, y) for unknown quantities. He writes powers from the cube upwards as we do, but generally expresses a^2 or z^2 by aa, zz. He uses the signs + and −; equality he denotes by a sign like that for 'varies as' in algebraical text-books, but turned the opposite way. For the square root he writes $\sqrt{}$, for the cube root $\sqrt{C}$. A horizontal line above an expression serves as a bracket. Where the coefficient of a certain power of the unknown in an equation contains more than one term he writes the terms vertically, one below the other, with a bracket stretching from the top to the bottom.

We congratulate the Open Court Publishing Company on the idea of including this great classic in their series. We would only warn the reader that the translation must be used with caution, as it is in many places inaccurate and sometimes wholly misleading. Two examples may be given. Descartes says that the ancients (*i.e.* the Greeks) were much hampered in their explanations of things by the fact that they scrupled to use arithmetical terms in their geometry; the translators render "le scrupule que faisoient les anciens d'user des termes de l'arithmétique en la géométrie" by "the considerations which forced ancient writers to use arithmetical terms in geometry," giving exactly the wrong sense. In another place Descartes says that, even if a certain change in the conditions were made, "ce point C ne laisseroit pas de se trouver tousiours en une ligne courbe, qui seroit de cete mesme nature," *i.e.* the point C would still always lie ("would not cease to lie") on a curve of the same kind; the translators say "the point C will not always lie on a curve of just the same nature."

The first edition of our treatise was originally published, not separately, but as the last part of the "Discours de la méthode," etc., in which it occupied pp. 297-413. The history of the copy from which the present facsimile was taken is interesting. It was first given by Descartes himself to his friend Letenneur, and it has Letenneur's signature as well as that of Chasles. Chasles gave the volume to Sylvester, who gave it to George Bruce Halsted, who again gave it to C. I. Palmer of Armour Institute, Chicago, by whom it was made over to the publishers.

The Origin of European Culture.

The Dawn of European Civilisation. By V. Gordon Childe. (The History of Civilisation Series.) Pp. xvi+328. (London: Kegan Paul and Co., Ltd.; New York: Alfred A. Knopf, 1925.) 16*s.* net.

ADVANCE in our knowledge of the various stages of prehistoric culture in Europe has never been uniform. This was necessarily the case in the earlier days of archæological investigation, when the material was drawn to a large extent from chance discovery.

Even now systematic exploration can be pursued only to a relatively limited degree, and fortune may at any moment bring to light evidence which will affect fundamentally our conceptions of the course of events in any given area at some particular point of time. It is, however, a remarkable, but not necessarily a surprising, fact that our knowledge of the neolithic and succeeding phases of the prehistoric period, but especially the neolithic, should so long have lagged behind that of the palæolithic stage. It is not surprising, if only because the high antiquity of palæolithic man and the mystery of his phylogeny have appealed strongly to the imagination, and this has tended to stimulate and systematise research. Greater attention, it is true, is now paid to the period immediately following the palæolithic and the break in continuity, which it was once imperative to recognise, has been filled by the culture of the epipalæolithic or mesolithic age. But in the neolithic age itself and in the later periods, although there is no lack of material, frequently the conditions of discovery in surface finds or in isolated hoards and caches have precluded the study of the material in its more precise chronological relations, which is necessary for the full understanding of the lines of development and the trend of events.

The greatest check on progress in the study of later prehistoric times has been the lack of anything like a comprehensive survey of the material as a whole which would have attempted to systematise our knowledge at any given moment, and to indicate the gaps which should be filled by future research. The time is now ripe for some such comprehensive study, if, indeed, it is not overdue. Much is still obscure; and the important investigations of archæologists on sites themselves well known but often isolated, have still to a large extent to be brought into relation. For the epipalæolithic period much has been done, and gradually from the material which is accumulating from North Africa, Spain, southern France, the Baltic, eastern Europe, and even to a limited extent from Great Britain, it is becoming possible to build up a picture of the movements of culture and more dimly of peoples directly ancestral to modern Europe. Further, in the Mediterranean area the researches of Sir Arthur Evans and others in Crete and in Greece, by demonstrating the relations of Minoan Crete to Egypt, to Asia Minor, and to Libya, and between Crete, the Ægean and the Greek mainland, are establishing something like a trustworthy absolute chronology for this area which ultimately will serve at once as a touchstone and a divining rod for the rest of Europe as it becomes possible to work out in detail the interrelation of the various centres of culture.

It has been necessary to dwell at some length upon these conditions in which intensive study of certain areas and sites has been accompanied by too general a lack of correlation of results as a whole in order to emphasise the special merit and the value of Mr. Childe's "Dawn of European Civilisation." It is the first attempt to summarise and evaluate the evidence relating to the various problems of the later stone and early metal ages as a whole. It follows the development of culture as we know it in each of a number of centres—Crete and the Eastern Mediterranean, Hissarlik and the coasts of Asia Minor, the Western Mediterranean, Spain, the Steppes, the Black Earth region comprising the Ukraine, Eastern Galicia and Rumania, the Danube, Scandinavia, "where east and west meet," the Baltic, eastern Germany and Poland, the lake dwellings of Central Europe and the culture of the Alps, the Atlantic seaboard, with its megalithic culture, and Great Britain. Mr. Childe, takes his readers from the epipalæolithic down to about the middle of the Bronze Age. In his preface he gives his reasons for thus setting the limits of his subject and defines his theme as "the foundation of European civilisation as a peculiar and individual manifestation of the human spirit." With the genesis of the common substratum of human culture, therefore, he is not concerned. At once, however, he finds himself confronted with the problem of the origin of this civilisation with which he deals. Does it come from the Ancient East, or are all the elements of this culture to be found in Europe itself? Mr. Childe modestly deprecates the attribution to him of an attempt to present a final synthesis. He lays claim to nothing more than "an earnest attempt to survey all the facts as a whole." In the end he seems on the whole to incline to the former view. The evidence he adduces certainly is in favour of those who look to the East, and it points to south-eastern Europe as the line by which the distinctive forms of early culture have come to the centre and west.

In attaching the importance he does to the culture of south-eastern Europe, Mr. Childe holds what is both strategically and tactically the inner position. His conclusions are to a great extent based upon, and coloured by, his intimate knowledge of the culture of Erösd and neighbouring sites in the valley of the Alt, which is described here for the first time in English. Erösd is a site in the Alt Valley in Transylvania just west of the Carpathians, which lies in the Black Earth country, so called from the fertile deposit which overlies the loess, a site eminently suitable for early agricultural settlers to whom the oldest traces here of postglacial habitation are due. It was explored by the late Dr. Ferencz Laszlo, who brought to light remains of a high civilisation of the type which appears as an intrusion in Thessaly. The people of the Black Earth

region produced a painted pottery, the ware of the Tripolje culture, which has led some archæologists to hope that these earliest inhabitants of the area might possibly be linked up with the early peoples of Mesopotamia, Elam, Anau in Turkestan, and their pottery brought into relation with the remarkable and characteristic painted pottery of these sites, which seems to extend as far afield as Honan in China. Mr. Childe holds that the culture of the Alt is the earliest in the Danube basin, and would regard it as the source of the culture known to archæologists as Danubian I. He has, however, no certain suggestion to offer as to the origin of the Erösd culture. So early a civilisation of high standard, with its knowledge of grain, painted pottery, copper and gold, offers a problem to the archæologist which is as dangerously tempting as it is momentous. Mr. Childe is fully alive to the dangers of over hasty attribution of an eastern origin, and with a fine impartiality points out the obstacles in the way—difficulties arising from both style and technique.

It would be tempting to follow with Mr. Childe the spread of Danubian culture along the Rhine into Belgium and France, of the culture of the Mediterranean into Spain, and the spread of the megalith along the Atlantic coast, but enough has been said to indicate the scope and quality of his book. Its extraordinary and, indeed, almost marvellous grasp of an enormous mass of detail, and its breadth and sanity of view in dealing with the larger problems, as well as the acute and critical judgment of the author, combine to make the "Dawn of European Civilisation" a contribution to prehistoric archæology of first-rate importance which will have a profound effect on future lines of study and research.

Chemical Aspects of Life.

Lectures on Certain Aspects of Biochemistry. These Lectures were given in the University of London during the Summer Term, 1925. By Dr. H. H. Dale, Prof. J. C. Drummond, Prof. L. J. Henderson, Prof. A. V. Hill. Pp. viii+313. (London: University of London Press, Ltd., 1926.) 12*s.* 6*d.* net.

THE attempt to interpret the phenomena of life in terms of chemistry resolves itself in practice largely into the study of the mutual reactions between living and non-living matter. Living cells exhibit the remarkable property of exerting chemical action upon certain components of their environment, and of assimilating and ultimately of obtaining energy from them. The terms 'machinery' and 'fuel' are often used—loosely, it must be admitted—to distinguish the assimilator from the assimilated, though there is evidence that the two are to a certain extent mutually replaceable, structural parts disintegrating to supply energy, and energy-holding materials being built up into the structure. The analogy is, however, quite a useful one so long as it helps us not to forget that the chemical phenomena of life are quite as much attributes of a particular physical state of matter as of a particular chemical structure. Both considerations are important, for life, like a flame, is a temporary shape set to an unceasing flow of matter of peculiar properties.

Life as a state of matter involves the conception of conditions of equilibrium which can only be maintained with expenditure of energy . . . it costs us something merely to exist, in more senses than one. The more delicate the state of balance, the more numerous and potent are the conditions which modify it.

The investigation of the chemical relationships of the equilibrium which is life is the main concern of biochemistry; for the equilibrium itself involves chemical reactions, and is subject to modifications by various chemical influences both from without and from within the cell. Advance in biochemistry, as in other sciences, is largely conditioned by the methods which are at hand for its pursuit. It follows, therefore, that while its main objectives are unaltered, certain aspects of biochemistry show periodic developments as a consequence of advances in the cognate sciences, or of special developments of technique which open up new lines of attack upon its central, unalterable, and perhaps insoluble problems.

The central mystery of life, from the chemical point of view, concerns the means by which oxidation and so energy liberation is effected, and it is fitting that such exponents of animal physiology as Dr. H. H. Dale, Profs. J. C. Drummond, L. J. Henderson, and A. V. Hill should present to us various chemical aspects of this fundamental problem. The control of the circulation in the capillary blood-vessels is a subject which owes much to the researches of Dr. Dale and his colleagues. The flow of blood to the tissues is largely controlled by chemical means in accordance with the need of the tissues for oxygen, more or less blood being made available by dilatation or by constriction of the capillaries.

One of the perpetual problems of biochemistry is the manner in which the living cells are enabled to satisfy their energy requirements by carrying out at low temperatures oxidative reactions which in the laboratory often necessitate the employment of high temperatures and powerful reagents. A considerable step in the elucidation, or perhaps, rather, in the transference to a different plane, of this problem, has been made of late, and has been discussed by Prof. J. C. Drummond. Two ideas have been introduced from the realm of pure chemistry, the importance of

small amounts of inorganic catalysers, chief among which appears to be iron, and the part which is played by hydrolytic oxidation-reduction reactions and oxidation by dehydrogenation. Closely bound up with both of these questions is the rôle played by glutathione, and by inorganic and organic phosphates.

In the carriage of oxygen and carbon dioxide, the blood has long been known to have essential functions, but it is only recently that the researches of Prof. L. J. Henderson, of Harvard, have shown us by what a beautiful physico-chemical mechanism the functions of the blood in this respect are controlled. In reading his three lectures, one not only finds much new physiology, but one also appreciates that the subject is capable of exact mathematical treatment. The study of the means by which the blood adjusts itself to alterations in the external environment, and thus maintains constancy of the internal environment of the cells, has proved to be a very profitable one indeed, in the physiology of biological integration.

The environment of the living cell is naturally a matter of fundamental importance, and we are often apt to forget, as Prof. A. V. Hill says in his lecture, that in systems of such small dimensions, the alteration of the scale necessitates alteration in other scales, such as the time-scale, as well. Diffusion, for example, which we are inclined to regard as a very slow process, may occur with such relative rapidity as to modify the chemical reactions very considerably. Among the chemical reactions which take place in living cells, the formation of lactic acid, which Prof. Hill discusses in another lecture, is a very fundamental one. There seems to be little doubt that the formation of this substance, and its subsequent oxidative removal, stands in the most intimate connexion with the phenomena of muscular contraction.

Another focal subject in biochemistry is that of growth and nutrition, and the lecture by Prof. Drummond on the phosphates and on the vitamins shows how much has been accomplished in recent years in this direction. The establishment of vitamin D, which plays such an important part in the formation of bone, the relation of this to the action of ultra-violet light, and the part played by phosphates in the calcification of bone, all appear to be connecting up to form a new and most valuable chapter in physiology.

The proper integration of the various functions of the body is effected in various ways, Nature using any means at hand to achieve this result; the chemical co-ordination by means of the hormones is one means of great importance, and Dr. Dale treats of recent investigations of two hormones, the pituitary principles, and insulin.

One leaves this book with the feeling of having not only read matter of first-class importance, but also of having had it presented in an altogether fascinating manner. Biochemistry has certainly done much to deserve the high esteem in which it is held to-day.

Neoplasms.

(1) *The Nature of Tumour Formation: the Erasmus Wilson Lectures delivered before the Royal College of Surgeons of England, on Feb. 23rd, 25th and 27th, 1925.* By Dr. G. W. Nicholson. Pp. xviii + 99. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1926.) 6s. net.

(2) *Malignancy and Evolution: a Biological Inquiry into the Nature and Causes of Cancer.* By Morley Roberts. Pp. 319. (London: Eveleigh Nash and Grayson, Ltd., 1926.) 18s. net.

THE mystery of new growths, their nature, treatment, and the possibility of prevention, has aroused more interest recently than at any other time in the history of medicine. For some years it has occupied the attention of research workers in every field probably more than any other of the great problems of disease. Innumerable facts and data concerning the subject have been recorded, yet we seem to be little nearer its solution than we were at the close of the last century.

(1) Dr. G. W. Nicholson, in the Erasmus Wilson Lectures of 1925 on "The Nature of Tumour Formation," has no new facts to place before us and no fresh discoveries to disclose. He brings what in our present state of confusion is of far more importance, a fresh point of view. Commencing with his own histological observations, which may be confirmed by any one with microtome and microscope, he attempts to establish a sequence of events of which the tumour is the last. He regards neoplasms as malformations arising in previously healthy tissues. All living cells possess the property of growth, and there is evidence that the power of multiplying to an excessive degree is potential in every healthy cell. Dr. Nicholson considers every tumour to be a manifestation of this excessive growth, to which absolutely healthy cells have been stimulated by some change in their environment. He sees in every cell of the new growth an effort on the part of that cell to be normal, *i.e.* physiological, in structure and function, and where it fails to be so, there is some inhibiting accident of position or environment, such as the absence of appropriate physiological stimulus to differentiation. It is in this point that his explanation differs from the theory of growth habit, in which it is postulated that the cells abandon their function for the purpose of proliferating.

In attempting a scientific explanation of neoplasms, Dr. Nicholson has disregarded all theories, perceiving that they are based on pure speculation. It may be alleged from some quarters that he has merely enunciated a new theory, but such a comment would be quite unjust. He has simply shown that in the sequence of events leading up to tumour formation, certain things happen in accordance with the general principles of physiology, biology, and embryology. With the reason for these happenings he is not concerned; little reference, mainly in an appendix to these lectures, is made to the nature of the change of environment which stimulates cells to proliferate, and in this connexion it is of interest to note that parasites are considered to be among the possible factors which can produce such a change.

It is evident in this book that one of the most important reasons for our failure to understand new growths is the lack of co-operation between the pathologist and the biologist. The former is blamed for his ignorance of the biological views concerning the constitution of living matter; the latter is criticised for his lack of appreciation of tissue reaction and adaptability under conditions familiar to every pathologist.

(2) With these censures in mind we turn with interest to the effort of the philosopher, untrained in the medical and allied sciences, to co-ordinate the observations of scientists and by reasoned thought to bring order out of chaos. Mr. Morley Roberts has approached the problem as an expert in no science save sociology, having to work on material provided entirely by others, and being at the outset of his researches quite unfamiliar with the structures and processes he proposed to investigate. Yet these apparently insuperable obstacles have by their very nature given him an enormous advantage over the scientific investigators, who, following their own isolated lines of work and thought in biology, pathology, or physiology, have attempted to solve mysteries requiring for their elucidation a clear perception of all three. We have previously had evidence that Mr. Roberts has mastered the general principles of these subjects, has acquired a sound knowledge of anatomy and histology, and possesses that clarity of thought which enables him to correlate the various features of the problem he sets himself. "Malignancy and Evolution" is a worthy successor to "Warfare in the Human Body."

In this work the author extends the views advanced in his previous book to cover the development of new growths. The aspect of the human body as a community similar to societies and nations, with tendencies to be checked and laws to be obeyed, leads him to conclusions very similar to those advanced in "The Nature of Tumour Formation." Aided by social analogies, he sees variation and disease as a breakdown of settled order, and concludes that disease and repair are essential factors of evolution. Neoplasms are regarded as manifestations purely of growth, resulting from the same mechanism which produces the liver and kidneys In this book we find suggestions as to the nature of the environmental changes causing cell proliferation; it is supposed that the community controlling factors are in a state of unrest and instability by reason of the rapid evolution of the race, and that this naturally results in variation and breakdown as it would in the life of a nation.

The author expresses acknowledgment for assistance in practical details to various scientific workers, including Dr. Nicholson; but the reasoning is entirely independent, and their conclusions concerning the actual mechanism of tumour development are related only in being confirmatory of one another. Mr. Roberts's views are well worthy of the attention of biologists and pathologists, and he is to be congratulated on the result of his efforts to shed light on a question of greatest importance to the human race.

Our Bookshelf.

Emotion and Insanity. By S. Thalbitzer. Translated by M. G. Beard. (International Library of Psychology, Philosophy and Scientific Method.) Pp. x + 128. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1926.) 7*s.* 6*d* net.

DR. THALBITZER'S book is a psychological essay the material for which is provided by a study of the manic-depressive psychosis. It is a brief attempt to explain certain mental phenomena on a physiological basis. The author first considers the generally accepted division of mentation into the psychical elements of thinking, feeling, and willing, a classification which he rejects in favour of that of intellectual activity, feeling, and psycho-motor innervation. He thus defines the mind as that which thinks, feels, and acts. It is with the element of feeling that this book is mainly concerned. It is submitted that this function must, like the other two specific functions of the mind, have its own centre in the brain, a postulation which involves Dr. Thalbitzer in a very damaging and convincing criticism of Lehmann's dynamic theory of emotion. The suggestion that this localisation is in the occipital lobes, and the evidence offered in support of it, do not carry so much conviction, but they are comparatively minor points.

Dr. Thalbitzer's physiological explanation of emotion is based on three well-recognised physiological laws. The application of the law of specific energy of cells isolates the element of emotion to one definite part of the brain. The law of tonus, or continual functioning of cells, explains the presence in every psychic process of all three elements of the mind, a fact well emphasised in the mood-psychosis, where any of these elements may function to an abnormal degree. The law which

limits the variation of function of a cell to increase or decrease confirms the observation that the differences between various feelings are quantitative.

Whatever the view taken of this fascinating explanation, there is one plea in this book which must be whole-heartedly endorsed. It is that psychiatric research should receive much more consideration in the effort to determine the nature of normal mental processes. The services rendered to physiology by pathology are well known; in the sphere of the nervous system and neurology they have been of first moment. Yet, apart from the very dubious conclusions drawn from the study of the hysteric and neurasthenic, psychology has learnt little from observation of the mentally abnormal. Perhaps this reproach applies more to psychology in England than elsewhere; in no other country is better provision made for the care of the insane; the field for research is correspondingly greater. If the hint from the Danish psychiatrist is taken, psychology may make even more progress during the next decade than it has in the last.

The 'Eötvös' Torsion Balance. Pp. 90. (London: L. Oertling, Ltd., n.d.) 21*s*.

WHEN a scientific instrument assumes a commercial value beyond its intended scientific use, trustworthy and detailed descriptions of its construction and of the method of its operation become scant if not altogether inaccessible. This class of instrument includes the Eötvös torsion balance, designed in 1888 by the Hungarian physicist, Roland Eötvös, for analysing the local anomalies produced in the normal gravity conditions by tectonic and geological abnormalities. Of this period, extensive literature is available both as regards construction of the balance and the results of measurements. But since the torsion balance proved to be one of the most useful instruments available for the location of mineral ore deposits, and a considerable refinement has been achieved in its design, trustworthy sources of information and details, from which an independent judgment could be drawn, have been deplorably lacking. The commercial necessity of secrecy by users of the torsion balance renders valuable observational data inaccessible for an indefinite period. The present book is the first comprehensive treatise on the balance published in any language, and it presents a host of informative details.

The subject is treated in two parts. Part 1 presents the theory of the balance, the derivation of working formulæ, the method of making observations, the relationship of the quantities derived, the classification of gravitational effects and computation and elimination of normal, terrain, and topographical effects. The second part embodies notes on the practical employment of the balance and recommends itself particularly to the physicist operating the instrument. These two parts, which comprise three-fourths of the book, constitute a concise and broad treatment of the balance and apply to any model of the instrument. The third part gives a description of the Oertling model, in which instrumental details are described and illustrated with commendable candour.

This book is no touchstone whereby, with the aid of the instrument, valuable mineral deposits or oil domes can be located in a trice. The collection of observational data is routine after preliminary training, but the rational elimination of effects extraneous to those of the deposit sought and the correct interpretation of the results thus obtained are problems of considerable difficulty calling for skill and extensive geological experience. Yet even in these difficult matters, this book offers a safe and instructive preliminary guide. Messrs. Oertling and the authors are to be congratulated on producing this well-bound, well-printed and arranged pioneer text-book on the Eötvös torsion balance, a subject the treatment of which on the lines here adopted has been long overdue.

E. R. F.

A Psychological Study of Immigrant Children at Ellis Island. By Dr. Bertha M. Boody. (Mental Measurement Monographs, Serial No. 3.) Pp. vi+163. (Baltimore, Md.: Williams and Wilkins Co.; London: Baillière, Tindall and Cox, 1926.) 18*s*. net.

EXAMINATION of immigrants at Ellis Island has been stimulated by fervid political propaganda maintaining that north-western Europe is better than south-eastern, and by sob-stuff propaganda dilating the hardships of those rejected by the apostles of eugenics. Mental measurements now permit exact inquiry.

Those more than sixteen years of age are expected to read. The Army 'Alpha' test seems to show the superiority of the north European, but in terms of Army 'Beta' the Latins are less inferior. The problem has been to invent new forms of performance tests which can be set in dumb show to a mixed group "of an Arab, a Greek, an Italian, a Welsh boy, an Armenian and a Russian. The members of such a group do not talk together; but they laugh together and spur each other on" (p. 103). The invention of such tests running smoothly and in silence without pencil or interpreter has been the great achievement (p. 132). Picture completion, form board, button holes, drawing stars, Binet weights, card sorting, bow knot are among the tests used.

The conditions of the examination are not ideal. Imagine a crowd of children of all ages, unequally seasick, exhausted, frightened, excited. What "recognition of the general emotional upset" would they demand? Attendance at the Island school is optional, and there is much interruption.

The tentative conclusion is that there are great differences, but that these differences are individual and not traceable to ancestral race or state nationality. But the numbers tested—27 Germans, 22 Armenians, 27 Hebrews, 15 Poles, 19 Italians, etc., of divers ages—seem too small to admit of any conclusion.

Chinese, Japanese, and Indians do not appear on the eastern seaboard. If the immigrant Irish are a mixed sample, it must not be assumed that they are a fair sample of those left behind in Ireland or that the sampling will not change as they segregate and settle industrially.

The direction of progress seems to be in examination at the home port of departure, maintaining exclusion of lunatics and deficients, and reliance on mental measurements rather than national quotas.

The book may be commended to schoolmasters, missionaries, and employers of native labour.

HUGH RICHARDSON.

Directions for the Dissection of the Cat. By Prof. R. P. Bigelow. Pp. xii+47. (New York: The Macmillan Co., 1925.) 4*s.* net.

THE directions for the dissection of the cat are here so arranged that the whole operation may be carried out on a single specimen, and the aim of the book is to give the student a clear survey of the organism as a whole and not as a system of organs. With this end in view, the dissection starts with the skin and muscles of the ventral body wall and works steadily through to the spinal cord and brain. Organs and structures are dealt with as they appear in the course of such a dissection and not in systems. The directions are clear and concise; necessary emphasis on particular points is given by heavy type, and the drawings which it is desirable for the student to make are indicated in their proper place and sequence. A useful introductory chapter gives valuable information on the preservation, embalming, and injection of material. The author believes that the dissection of the cat is a very desirable introduction to a course of human anatomy and physiology, and would be a valuable part of pre-medical studies: also that the size of the animal and the ease with which it can be obtained make it a favourable object for such studies. In such circumstances this book would be of considerable service, but the absence of any figures limits the value of the book and necessitates its use only in conjunction with standard works on the anatomy of the cat which are adequately illustrated.

The History of Arithmetic. By Prof. L. C. Karpinski. Pp. xii+200. (Chicago and New York: Rand McNally and Co., 1925.) n.p.

THE purpose of Prof. Karpinski's book is to present the development of arithmetical knowledge as a vital part of the history of civilisation. Particular attention is paid to the material of arithmetic taught in American elementary schools and to the historical phases of that work with which the teacher of arithmetic should be familiar. The book also contains a bibliography of the early American text-books of arithmetic printed before 1800, and refers to many of the early popular treatises on the subject used in England.

The volume is mainly intended to appeal to a popular audience desiring some acquaintance with the development of arithmetic from the earliest times. Prof. Karpinski gives a very entertaining account, based on the larger treatises of T. L. Heath, T. E. Peet, and D. E. Smith, of the progress of arithmetical knowledge from ancient Egyptian times until the present day. He also gives many carefully chosen diagrams which add interest to the theme. Most school libraries would be enriched by a copy of the book.

A Practical Handbook on Rat Destruction. By C. Leopold Claremont. Pp. vi+180+6 plates. (London: John Hart, n.d.) 3*s.* 6*d.* net.

THIS book deals in an exhaustive and essentially useful manner with the problem of the rat. A brief introductory chapter on the characters and habits of the brown and black rats is followed by an account of the destruction of rats by trapping, hunting, and the use of gas, and of the various poisons most effective for the purpose. These chapters are very exhaustive and of great practical value. The author then deals with the Rats and Mice (Destruction) Act of 1919, and discusses in detail its various clauses and the responsibilities of owners, local authorities, and the Ministry of Agriculture in carrying out its provisions. He pleads for more whole-hearted co-operation between these parties in combating the rat menace. Chapters on the relation of the rat to public health and disease, and on a general survey of what has been done and what may be done in the matter of rat control, conclude a very useful book, which should be of great service, particularly to those officers of local authorities whose duties include the enforcement of the laws relating to the destruction of these pests.

Travel and Travellers of the Middle Ages. Edited by Prof. A. P. Newton. (The History of Civilization Series.) Pp. viii+223+7 plates. (London: Kegan Paul and Co., Ltd.; New York: Alfred A. Knopf, 1926.) 12*s.* 6*d.* net.

THE contents of this volume, which is one of the series appearing as "The History of Civilization," is a course of lectures delivered in the University of London. The book does not profess to be a complete survey of the subject, but several of the lectures have been expanded and the editor has added an introduction on the conception of the world in the Middle Ages. The twelve chapters are by various writers, including Prof. M. L. W. Laistner, Prof. Claude Jenkins, Sir T. W. Arnold, Baron A. F. Meyendorff, Prof. E. Prestage, Sir E. D. Ross, Prof. A. Mawer, and Dr. E. Power. Those on Christian pilgrimages, Arab travellers, the routes to Cathay, and Prester John may specially be noted. Prof. Mawer, whose contribution on the Vikings has no references to authorities, apparently accepts the Norse voyages to Vinland, and does not mention the researches of Nansen and others with their conclusion that Vinland was a myth. The book has a few illustrations, but only two maps.

The Borderland of Music and Psychology. By Frank Howes. Pp. x+244. (London: Kegan Paul and Co., Ltd.; J. Curwen and Sons, Ltd., 1926.) 6*s.* net.

"ART and intellectual speculation are the two exceptional realms of the mind of which the psychologist finds it most difficult to give an account" (p. 147). Too much has been expected from psychology since it presumed to stand in its own right as an experimental science. Many who looked to it for immediate solution of age-long problems disappointedly turn away as from a charlatan. In doing so the valuable little that it already has to give is lost. The author, with sympathetic knowledge of current musical and psychological theories, has given a capable preliminary survey of an interesting no-man's-land lying between suspicious armed camps. If at times he laughs at both from the exalted heights of philosophy, we forgive him, for he never loses himself in the realm where the problem is of more importance than its solution, but ever returns to his theme with notes such as: "But this is not science, nor even musical criticism" (p. 142); "We step beyond psychology when, after saying what musicians and audiences do, we ask, 'What is music?'" (p. 40).

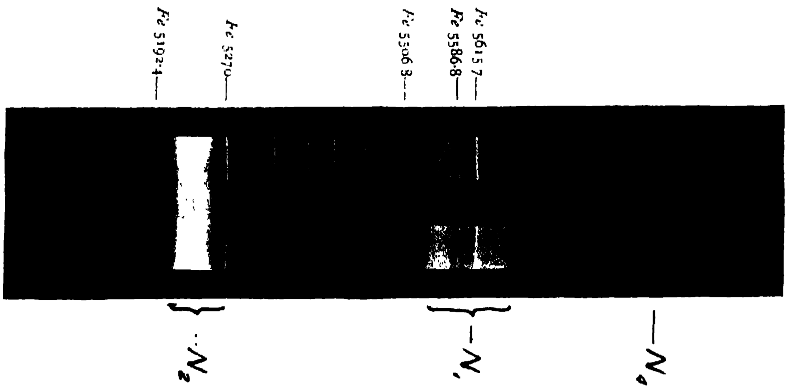
On the Phosphorescence of Nitrogen.

BY the use of a tube of a type recently designed by Dr. Coolidge of Schenectady, and kindly shown in action by him to one of us, we have recently been



enabled to extend our knowledge of the spectrum of solid nitrogen made luminescent by bombardment with swiftly moving electrons. The tube we used was provided with a window of thin nickel foil through which electrons under a potential of 125,000 volts were projected into the vacuum space of a german silver thermos flask of special design. The nitrogen was deposited and solidified on the inner wall of the thermos flask within the vacuum space, and the refrigerant used was liquid hydrogen.

The luminescence of the solid nitrogen was observed in our experiments through a fluorite window in the outer wall of the thermos flask, and its spectrum was photographed with glass quartz and fluorite spectrographs. All wave-lengths measured and given below are in Ångström units.

Photographs of the spectrum of the light emitted while the solid nitrogen was being bombarded showed :

1. A single sharply defined narrow band (N_4) at λ 5945.
2. Three broad diffuse bands (N_1) shading each into the other with mean wave-lengths of approximately λ 5554, λ 5617, λ 5658.
3. A series of eight clearly defined bands (N_2) with the wave-lengths λ 5204·4, λ 5210·4, λ 5214·3, λ 5220·4, λ 5224·4, λ 5228·8, λ 5235, λ 5240 ; and
4. A number of faint diffuse bands each shaded off towards the red in the blue and violet spectral region between λ 4500 and λ 2460. Very approximate wave-lengths of the heads of these bands were found to be λ 4575, λ 4500, λ 4270, λ 3990, λ 3725, λ 3510, λ 3385, λ 3155, λ 2960, λ 2785, λ 2615, λ 2460. As regards these bands, some have been observed by Vegard already, and some, at least, appear to belong to the well-known second positive band spectrum of nitrogen.

Among a number of interesting results obtained by us, four are worthy of special note :

1. We failed to record on our plates, with twenty hours' exposure, any trace of a group of wave-lengths designated by Vegard as N_3 that were found by him to include one band at λ 6569, and one with its maximum intensity between λ 6320 and λ 6420. In this connexion it might be stated that our plates were highly sensitive up to λ 7000.
2. When the tube was in action and the solid nitrogen was strongly luminescent, we always found by visual observation that when the bombardment was interrupted, the wave-lengths of the group N_1 immediately disappeared from the radiation emitted by the luminous nitrogen, while the red band N_4 and the bands N_2 between λ 5204·4 and λ 5240 persisted some minutes, often very brilliant, but with slowly weakening intensity. Vegard has suggested that the groups N_2 and N_4 belong to the phosphorescence spectrum of solid nitrogen, and, as will be seen from the results given above, our experiments confirm this view.
3. As to the group of three bands N_1, we found that they were relatively strong when the solid nitrogen under bombardment had been freshly deposited. But with prolonged bombardment of a given layer of solid nitrogen, the intensity of the group of wave-lengths N_1 rapidly weakened and finally was scarcely sufficient to make the radiation observable. The intensities of the band groups N_2 and N_4, on the other hand, appeared to be unaffected by prolonged bombardment. Since exposures of long duration were required in photographing the complete

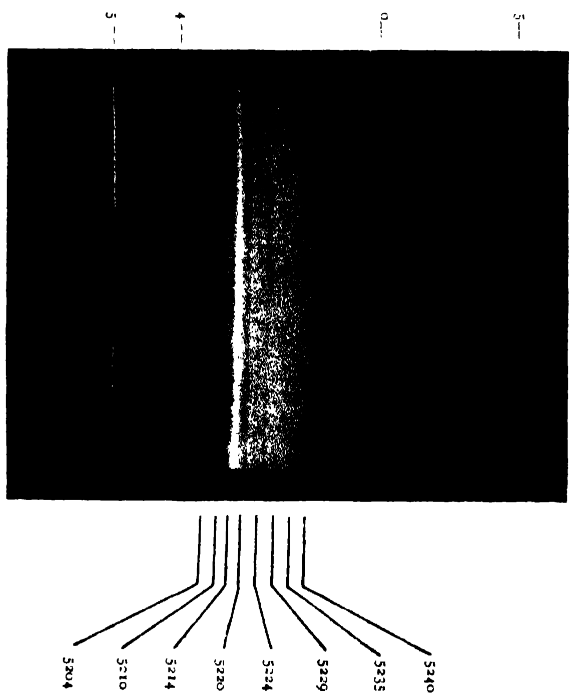


FIG. 2.—Band N_2.

luminescence spectrum, it was necessary therefore to deposit a fresh layer of solid nitrogen approximately every half-hour.

From these results it is clear that two spectra are obtainable from solid nitrogen, one of which includes the band group N_1, and the other the bands N_2 and N_4. This would go to show that solid nitrogen can exist in two forms A and B, the one, A, emitting the radiation constituting the band N_1, and the other, B, the radiation constituting the band groups N_2 and N_4. Our experiments support the view that the solid nitrogen is initially deposited in the form A, and that under electronic bombardment, and possibly otherwise, it is soon transmuted into the form B, this form B being the one that exhibits the phenomenon of phosphorescence.

4. The band group N_2 as originally observed by Vegard and by McLennan and Shrum, consisted of a single sharply defined narrow band at approximately λ 5230. This band has been found, however, to be more extensive than was originally supposed, for, as shown above, it is now known to consist of at least eight strong and well-defined members. Since no band of anything like this character has ever been shown to be a feature of the spectrum of the aurora, in the neighbourhood of λ 5230, it would appear that Vegard's theory that finely divided solid nitrogen exists in that portion of the upper atmosphere where auroral displays originate is not tenable.

The bands N_1, N_2, and N_4 are shown in Fig. 1, and the bands N_2 in Fig. 2.

Polarisation of Wireless Waves.

IT is now generally accepted that many of the phenomena of wireless reception are caused by the interference between two waves, one of which has received reflection or refraction in the upper layers of the atmosphere. Considerable evidence is also now forthcoming of a fact which was suggested in earlier days; namely, that the reflection is not simple but that a vertically polarised incident wave may be returned with polarisation of a much more complex form. On this are based explanations of night variations in bearing, fading, and similar phenomena; and the subject has also been discussed theoretically by Appleton, Hulbert, and Nicholls and Schelling.

These investigators have confined their attention chiefly to wave-lengths of a few hundred metres at most, and there have been doubts as to whether the longer waves were affected in a similar manner. In a previous paper (*Journal I.E.E.*, No. 353, page 587) the present writer has referred to the elaborate but regular intensity variations occurring at medium distances on long waves during the sunset period, and recent experiments have shown that the cycle given by the transmissions from Sainte Assise (UFT) on 14,350 metres at Slough on page 587 is regularly accompanied by a definite cycle of bearing variation differing slightly in intensity from day to day, but always possessing the same general form. Variations of bearing of as much as 35° have been observed at times, showing that the departure from vertical polarisation must have been large.

Measurements were, therefore, made to see if any quantitative deductions could be made from these results.

Although it is theoretically possible to make use of bearing variations for such a purpose, the accuracy of observation is low owing to the non-silent minima which often occur, and it was found preferable to take three measurements of absolute electrical intensity: (*a*) in the plane of propagation; (*b*) in a vertical plane at right angles to this; (*c*) in any convenient intermediate plane from which the results can equally well be deduced.

In some cases it has been found that the intensity (*b*) actually exceeded the intensity (*a*) for short periods.

Now, in the general case of elliptic polarisation these results do not admit of any further solution, but by making the further assumptions: (i.) that second reflections are not present; (ii.) that the downcoming wave remains plane polarised but that the plane of polarisation is rotated, it is possible to deduce figures for this angle of rotation and for the coefficient of reflection.

Observations taken at Slough and Exeter under these conditions show that during the sunset period a rapid rise in the coefficient of reflection occurs and also a rotation of the plane of polarisation of at least 90°, most of which persists throughout the night. It remains to be verified whether assumptions (i.) and (ii.) are justifiable, though there is evidence in their favour; but the two chief facts which emerge from the tests are independent of them. These are:

I. Long waves as well as short may be elaborately polarised by refraction in the upper atmosphere during the night.

This effect is also present, though in a less degree, during daylight in the winter, and occasionally even during daylight in the summer.

II. The effect persists during the hours of darkness, remaining fairly steady after the sunset period is over; and consequently it cannot be caused by the mere temporary displacement of the reflecting surface from its normal horizontal position owing to the ionic recombination which occurs at sunset; but must be an essential feature of the mode of refraction.

Further experiments on this point are in progress, but as the solution requires the construction of a vector triangle the conditions have to be very carefully chosen in order to avoid indeterminate figures due to the limitations of the geometrical process. The experiments referred to above were carried out for the Radio Research Board of the Dept. of Scientific and Industrial Research. J. HOLLINGWORTH.

Plastic Deformation of Single Metallic Crystals.

NATURE has published two letters from Mr. S. J. Wright and Dr. Goucher respectively (June 26 and July 31) in reply to ours of May 22 on the wedge formed when a single crystal of a metal is broken in tension. We desire in reply to stress most strongly the fact that our analysis of such a wedge is concerned with the final position of an atom after movement and has no reference to the path or the mechanism by which it arrived there. This concerns directly both of the communications.

Mr. Wright's insistence on the fact that the wedges examined by him were bounded by curved surfaces, means no more than that the ultimate displacement of the atoms of his test-pieces was greater in some localities than in others and has no bearing whatever on the validity of our treatment. His remarks *re* hard spheres are similarly wide of the mark, since we have not made assumptions of any kind as to the mechanical properties of the atom in its response to the stress.

Dr. Goucher's letter, however, is worthy of more serious consideration. His statement that our formula presupposes a type of slip which is inconsistent with experimental fact is surprising, since throughout our letter it was Dr. Goucher's own experimental results which were considered. It may be well, however, to review what assumptions were made. They were two, namely, that for a perfect wedge the atoms slipped on equidistant parallel planes and that the movement on these planes was equal. The only possible alternative to these assumptions would be that the slipping occurred on planes at different distances apart, but that then the extent of the displacement was in all cases proportional to the thickness of the slab of metal between one plane of slipping and the next. Such a supposition is so absurd as to carry its own refutation with it. Unless then all present ideas of the plastic deformation of metals are entirely inaccurate, and the displacement does not occur by slip, there is no alternative to the only two assumptions we have made.

Our analysis was concerned with one part of the wedge only, and there is no question of a difference in wedge angle between one half of the fractured test-piece and the other. Dr. Goucher emphasises what he had already found, namely that the wedges had an included angle of 39° or more than 50°. We are quite unable to see why he should imagine there is any difficulty in this, since not only have we considered the fact but have even offered a reasonable explanation of why it should be so. He complains further that we have not taken into consideration the fact that the larger wedge angles were found only with test-pieces whose {112} planes were slightly asymmetric with regard to the direction of the stress. The reply is clear. We have not been concerned with the explanation of the deformation of the crystal. All we attempted to do was to discover, when a certain deformation had been produced, what was the nature of the atomic displacement in the final wedge. That asymmetry of crystal is necessary for the production of a blunt wedge is merely an experimental fact which has no bearing on our analysis of the deformation when it had actually been effected.

We would point out again that our letter offered a reasonable explanation and, incidentally, the only comprehensive one yet suggested, of all the experimental results which Dr. Goucher has obtained in his most excellent experimental work. Until, therefore, something more satisfactory is offered it must take precedence over an explanation which, as a result as it seems to us of a perfectly arbitrary assumption, is capable of explaining half the results only, leaving the remainder as inexplicable anomalies.

May we in conclusion point out that in the formula in our original letter a misprint occurs, and that $2/\phi$ should be $\phi/2$?

Manchester, August 24.

The Ionisation Potential of O II.

PROF. A. FOWLER has worked out (*Proc. Roy. Soc.*, **110**, 476, 1926) with much elaboration the main spectral characteristics of O II, but has not been able to obtain the fundamental levels because the jumps to them produced lines which were below 700 Å.U. With our high resolution hot-spark spectroscopy for the extreme ultra-violet and assisted by the new methods of identification of multiplet structure recently worked out by Russell, Hund, Heisenberg, and Pauli, and applied by R. H. Fowler and D. R. Hartree (*Proc. Roy. Soc.*) to the classification of Fowler's O II terms, we have succeeded in accurately fixing these fundamental levels as is shown in the accompanying table. Russell assisted us in this search by placing at our disposal his unpublished identification of the quartet p'' level, which should replace the x_3 level in Fowler and Hartree's classification.

The knowledge of this ionisation potential of O II should be useful in fixing the temperatures of certain stars.

I. S. BOWEN.
R. A. MILLIKAN.

California Institute of Technology, Pasadena.

TABLE I.

Series Lines of O II.

Int.	λ I.A.Vac.	ν	Δν	
		Quartet System.		
1	429·97	232574·4		$as - p''$
3	539·067	185505·7	157·1	$as - ap_3$
2	539·524	185348·6	107·5	$as - ap_2$
1	539·837	185241·1		$as - ap_1$
		Doublet System.		
0	440·51	227010·		$x - bp''$
1	441·97	226260·		$x - cd'$
2	481·56	207658·		$x - bd'$
2	484·00	206612·		$x - ap''$
2	485·56	205948·		$x - f$
4	616·325	162252·	185·	$x - 2p_2$
4D	617·030	162067·		$x - 2p_1$

Term Values.

$x(p'$ or $d) = 256202·$

Assuming $ap_3 = 97100·$[1]

$as = 282605·9$

This corresponds to the ionisation potential 34·88 *volts.*

To the foregoing interesting communication, I think it may be usefully added that the designations and values of all but one of the doublet terms, apart from x, are those given in the paper by myself to which reference is made, namely:

$$\begin{cases} ap_2'' = 49590·80 \\ ap_1'' = 49476·81 \end{cases} \quad \begin{cases} bd_2' & 48618·42 \\ bd_3' & 48565·45 \end{cases} \quad \begin{cases} 2p_1 = 94132·52 \\ 2p_2 \ \ 93952·53 \end{cases}$$

$$\begin{cases} bp_1'' = 29231·39 \\ bp_2'' = 29229·03 \end{cases} \quad \begin{cases} cd_2' = 29974·67 \\ cd_3' = 29972·55 \end{cases}$$

The f term (= 50273·5) was afterwards provisionally identified as such by Fowler and Hartree from lines which I had somewhat doubtfully indicated as involving a term xd_2'. The writers of the letter appear to have overlooked the fact that Fowler and Hartree had already identified my x_3 term as the unresolved first p'' term of the quartet system.

While the value indicated for the as term is probably not much in error, it should be understood that the value of ap_3, on which it depends, remains somewhat uncertain. A Rydberg formula for ap_3 and bp_3 gives $ap_3 = 98850$, but this can only be regarded as an approximation, since only the first two terms of the sequence are known. A more trustworthy value would result if intercombinations between the doublet and quartet systems could be traced.

A. FOWLER.

[1] A. Fowler assumes $ap_3 = 100,000$. We have changed to the foregoing value in order to bring the Ritz formula for the sequence of ap and bp terms into better agreement with that for the corresponding terms of N I.

The Earliest Human Knowledge of Copper.

THE first discovery of metals by man is usually described as having resulted from the association of the necessary materials in the construction of a primitive hearth on some chance occasion. At best, this explanation does not contradict our accumulated knowledge about the habits and conditions of early human life.

There seems to me to be quite another possibility, not necessarily antagonistic to the earlier one, which is the outcome of a recent communication from Sir Flinders Petrie (*Ancient Egypt*, June 1926) on the Egyptian Paradise. He directs attention to the remarkable similarity of the place-names, the geography, and the " lakes of fire . . . in the midst of the paradise of cultivation " in the " Book of the Dead," with those of a definite region in the Caucasus —that along the rivers of the Iora and Kura. Then, following the normal lines of archæological argument, Sir Flinders suggests the possibility of the earliest Egyptian immigrants having come from that region.

It is known that some later arrivals, the earliest dynastic peoples, suddenly appeared in Egypt, equipped with a written language and with a knowledge of the working of metals, and of agriculture. If these constituted a later wave of wanderers from the same locality—just as there were several eruptions of tribes out of Arabia—they would bring with them knowledge naturally obtained from their home surroundings.

Copper occurs widespread throughout the Caucasian area. So also does petroleum ; and the very locality in which Sir Flinders Petrie locates two lakes of fire and " a place of purification, probably by fire " from indications in the " Book of the Dead," is to-day occupied by an area of considerable richness in petroleum.

At one spot in a recent map (" Handbuch der regionalen Geologie," vol. v. pt. 5, heft 25, " Kaukasus," by v. Stahl, 1923) copper and petroleum are shown as being to-day in close proximity. But there must be and must have been innumerable seepages of oil over the whole area, so that many other points of intimate contact between copper and petroleum must have existed since remote times.

This being so, when a petroleum spring or lake became ignited, as is known occasionally to have happened, there is the greatest likelihood of the adjacent copper being reduced by the high temperature of the reducing flame to the metal itself, to be discovered by man at some later date.

This suggestion is supported by the fact that copper was in use very early in the history of the country that is now known as Iraq ; this is also a petroliferous region, as is shown by the presence and use of bitumen from the earliest times.

It would be interesting to speculate on local results when other minerals were smelted in the same natural fashion, including the effect of the liberation of large quantities of arsenic or arsenic oxide over the surrounding country. PERCY E. SPIELMANN.

The Athenæum, August 19.

The Zoological Names *Simia*, *S. satyrus*, and *Pithecus* and their Possible Suppression.

UNDER the above heading in NATURE of July 10, p. 49, Dr. C. W. Stiles gives a summary of the argument in support of a proposition to re-open the case of *Simia* before the International Commission on Zoological Nomenclature. Although in agreement with most of the general principles enumerated in his summary, we dissent from the view that the names *Simia*, *S. satyrus*, and *Pithecus* are ambiguous and " so confused in zoological literature as to preclude hope of reasonable uniformity in their use in zoological, bacteriological, serological and public health work."

With regard to *Simia* for the orang, the name is supported by the many mammalogists who signed the list of " Nomina Conservanda " published in the *Proc. Zool. Soc.*, London, 1924, p. 345. It is consistently used by naturalists in general. To suppose that bacteriological and medical writers (at all events those on this side of the Atlantic) would accept and use such a completely unknown name as '*Pongo*' for the orang is to show ignorance of the mentality and prejudices of the very workers for whose benefit the argument is professedly framed. For such writers, past, present, or future, *Simia satyrus* is the name of the orang, free from all ambiguity whatsoever, and with that widely signed " Nomina Conservanda " list to support them they would certainly regard '*Pongo*' as 'Jazz'—and go their old way.

The fact that Dr. Elliot, in his bulky work on Primates, has used another name, would seem to have unduly influenced those who framed the argument outlined by Dr. Stiles ; but unfortunately that work is so full of errors that as a standard of nomenclature it is repudiated by systematists in general.

The same has to be said about *Pithecus*, which is the technically correct name of the langurs, but has been wrongly used in another sense—for the macaques by Dr. Elliot alone among mammalogists. This wrong use has received no acceptance whatever, and cannot be said to render the name *Pithecus* ambiguous or unsuitable for acceptance by medical and other writers.

We would therefore reiterate our opinion that *Simia satyrus* for the orang, and *Pithecus* for the langurs fulfil the demand for names which are " thoroughly unambiguous and suitable."

Moreover *Macaca*, for which, according to the letter of Dr. Stiles, *Pithecus* would be abolished as the name of the macaques, should be, and is, used for these very animals, side by side with *Pithecus* for the langurs.

Arguments in favour of *Simia* for the orang are to be found in the Fiat lists above referred to, and for *Pithecus* in a paper by Thomas in the *Ann. Mag. N. H.* (8) xvii. p. 179, 1916. OLDFIELD THOMAS.

Lead Hydrogen Arsenate as a Mineral.

A SPECIMEN from the Tsumeb mines in the Otavi district, South-West Africa, recently acquired for the Mineral Collection of the British Museum, shows colourless transparent crystal plates with brilliant lustre, which had been labelled 'lanarkite.' The largest of these are 1 cm. across with a thickness of 1 mm. They rest on a crust of bayldonite pseudomorphous after mimetite (chloro-arsenate of lead), chessylite, and large crystals of anglesite ($PbSO_4$). The crystals are monoclinic ($a:b:c = 0{\cdot}8643:1:0{\cdot}7181$, $\beta = 84^\circ\ 36'$) and show a development of sixteen crystal-forms. These forms have been listed to show the angles from each to the three axial planes ; and it is believed that such a method of tabulation may effect a compromise between the method of giving interfacial angles in zones and that of longitude and latitude (ϕ and ρ) angles employed in two-circle goniometry. The crystals are optically positive, and the optic axial plane is perpendicular to the plane of symmetry and direction of good cleavage. The

refraction ($n_\gamma = 1 \cdot 9765$ for sodium-light), birefringence, and dispersion are all high.

A chemical analysis made by Mr. E. D. Mountain on a quarter of a gram of carefully selected crystal fragments agrees closely with the formula $PbHAsO_4$. It was then found that the crystallographic data agree with those previously determined for artificial crystals of this substance. A copy of E. S. Fedorov's "Tables for Crystallo-chemical Analysis" not being available, it was not possible to identify the substance from the crystallographic data alone. Artificial crystals of lead hydrogen arsenate had been prepared and completely determined crystallographically by the late Baron A. de Schulten (a political refugee from Finland, who worked in the chemical laboratories of the Sorbonne in Paris) in 1904. He also prepared a series of other compounds isomorphous with the mineral monetite ($CaHPO_4$), with strontium, barium, or lead in place of calcium, and arsenic in place of phosphorus. Of these only $CaHPO_4$ has been hitherto known to occur in nature. For the compound $PbHAsO_4$ occurring as natural monoclinic crystals the mineral name *schultenite* is suggested. The "lead arsenate" of commerce is the same substance. This is used as an insecticide, especially in America in sprays for fruit-trees; and being practically insoluble in water it is no doubt responsible for the retention of arsenic in apples.

A detailed account of the new mineral, so far as this can be completed from the single specimen, will be given in the December issue of the *Mineralogical Magazine*. There are no doubt other specimens of this mineral in collections amongst the rich series of crystallised material that has come from the Tsumeb mines. L. J. SPENCER.

British Museum (Natural History), South Kensington.

The Anomalous Flocculation of Clay.

IN a letter to NATURE of May 1, 1926, Dr. Joseph and Mr. Oakley allude to some experiments which have convinced them that the alleged anomalous flocculation of clay does not exist. The anomalous flocculation of clay is said by them to be the accelerating influence of hydroxyl ions on flocculation by calcium salts when compared with the retarding effect of hydroxyl ions on flocculation by sodium salts. I should like to submit, however, that the behaviour of calcium ions in alkaline medium is not regarded as anomalous by comparison with the behaviour of sodium ions in alkaline medium. Flocculation of clay by calcium salts is anomalous when considered in the light of prevalent theories, and not necessarily when compared with the behaviour of other ions. As I understand the anomalous flocculation of clay, the most that could be claimed by Dr. Joseph and Mr. Oakley is that the sodium flocculation of clay is also anomalous.

One realises, of course, that within the limits of a letter a description of experimental detail is not possible, but it is crucially important to know what precisely is meant by a "highly purified clay." The significance of the results in question is entirely dependent upon the complete removal of both adventitious and absorbed calcium in the clay. A highly purified clay suspension would ordinarily be taken to mean a suspension of clay in which there was no appreciable amount of the coarser particles, but such a clay suspension would still contain absorbed calcium, and on the addition of sodium salts that calcium would come into solution. Soils containing absorbed calcium can ordinarily be flocculated by the addition of a sufficient amount of alkali, but according to some incidental observations made on soil suspensions in these laboratories by S. J. Saint (*Proc. 2nd Comm. Intern. Soc. of Soil Science*), when the absorbed calcium has been completely replaced by sodium, no amount of sodium hydroxide will bring about a flocculating effect. N. M. COMBER.

Persistent Solar Prominences.

IN NATURE for July 24, page 131, reference is made to a large prominence formation on the sun's north-western limb on July 16. Apart from the interest in this display as to grandeur, consideration is enhanced by the fact of the many repeated appearances of this particular display. My records, which cover 71 observing dates since June 1, show that the first appearance of this exceptional formation was on June 18, in the north-west quadrant, in the north-east quadrant on July 2 and 3, again in the north-west on July 16, in the north-east again on July 29 and 30, once more in the north-west on August 12, and, although reduced somewhat, once again in the north-east on August 25 and 26.

We have thus 2½ complete synodic revolutions of the sun, during which this formation was preserved practically to the full extent for two complete synodic rotations, the display being easily recognisable, not only by its large extent, but also by the particular form which the various constituents retained, mostly magnificent tree forms, with bright trunks spreading into an elaborate tracery of interlacing branches. On the last appearance the trunks only seemed to be left, although faint overhead festoons and filaments were still visible. ALBERT ALFRED BUSS.

Lee-Observatory, Chorlton-cum-Hardy, Manchester, August 27, 1926.

Spraying Crops from Aeroplanes.

IN NATURE for August 14, p. 239, it is recorded that the first attempt in Great Britain to utilise the aeroplane for spraying operations took place in Lincolnshire in August 1926. It is to correct an error that the present communication is made. The first record of powder spraying by aeroplane in Britain is made in the *Fruitgrower*, June 29, 1922, and of which no reference can be found in NATURE of that year.

The experiment took place at Portobello Farm, Kingsdown, near Sevenoaks, owned by Major R. F. Bartlett, on an eighteen-acre cherry orchard badly infested by caterpillars. The material used was a proprietary dust ('Belummite') manufactured and supplied by Messrs. W. J. Craven and Co., Evesham. The lessons learnt at this initial experiment are published in the *Fruitgrower*, July 13, 1922.

It should be placed on record that Major Bartlett was the first in Great Britain to use the aeroplane for the control of orchard pests, although the recorded facts of the efficiency of the method leave much to be desired. G. FOX WILSON.

International Code of Zoological Nomenclature.

DURING this year I have so often been asked how this Code could be obtained that I hasten, with your permission, to announce that the Washington Biological Society has just published a reprint at the price of one dollar. Prof. C. W. Stiles, secretary to the Commission, says: "I would suggest that, if your colleagues wish copies, it would expedite matters to order a number at once." The address of the Society is at the Bureau of Entomology, Washington, D.C., U.S.A. F. A. BATHER.

Seven Decades of Botany.[1]

By Prof. F. O. BOWER, F.R.S.

"The future of Biology lies not in generalisation but in closer and closer analysis."—BATESON (Birkbeck Lecture, 1924).

DEATH sudden and wholly unforeseen has stepped between Section K (Botany) and the president of its choice. Dr. Bateson had presided over the whole Association at its meeting in Australia, and partly on that account he had been specially selected for the chair of this Section in Oxford. From him we might have expected a broad outlook upon biological science. His address would have been instinct with wide experience in both of the branches of living things, the interests of which interweave in enthralling and often most perplexing ways. We should have heard a fearless statement of his mature views. Something constructive would certainly have justified the congratulations with which some of us had already welcomed his nomination. A great figure has been taken from the arena of biological science. A career still full of the promise of further achievement has closed prematurely.

This is not the time or the place for any comprehensive obituary of Bateson. I will only allude briefly to four leading events in his scientific career. He felt in early life the lack of facts bearing on variation, and sought to extend their area in his great work "Materials for the Study of Variation," published in 1894. This was the year when the British Association last met in Oxford. I do not remember that its contents came into the discussions in Section D, though the book centred upon the vital question of continuity and discontinuity. The second event was the publication in 1902 of "Mendel's Principles of Heredity," in which, though essentially a controversial statement, Bateson perceived latent in the rediscovered writings an expanding vista of advance. "Each conception of life," he says, "in which heredity bears a part must change before the coming rush of facts." In a third stage of his work Bateson expanded this theme into a fuller statement under the same title, and it was published in 1909. Passing from this period of high hopes to the fourth phase of 1924, we see in his address at the Birkbeck Centenary a chastened attitude. He there remarks: "We must frankly admit that modern discoveries have given little aid with the problem of adaptation," and that, much as Mendelian analysis has done, "it has not given us the origin of species." But that analysis having "led to the discovery of transferable characters, we now know upon what to concentrate. . . . Henceforth the study of evolution is in the hands of the cytologist acting in conjunction with the experimental breeder. Every appeal must ultimately be to the mechanics of cell-division. The cell is a vortex of chemical and molecular change. . . . The study of these vortices is biology, and the place at which we must look for our answer is cell-division." I would ask you to mark that last word. It is cell-division, not nuclear division; and earlier in his address we find the pregnant sentences: "As to what the rest of the cell is doing, apart from the chromosomes, we know little. Perhaps the true specific characters belong to the cytoplasm, but these are only idle speculations." Such extracts from Bateson's latest public pronouncement may suggest to you what the Section has lost by his death. They show the mind still elastic and perceptive: still both constructive and critical.

Any address that follows such a tragedy of disappointment as the Section has suffered can only fall short of what we had hoped to hear. Instead of attempting to fill the broad biological rôle that naturally fell to Bateson, I propose to centre my remarks upon three dates when the Association has met in Oxford, namely, 1860, 1894, and 1926. It happens that these dates mark approximately periods of transition in the progress of biological science, and particularly in botany.

1860.

I need scarcely recall that the meeting in Oxford of 1860, the year after the publication of the "Origin of Species," witnessed the clash between the new view and the opposition it was certain to arouse. The story has been often told of the aggressive attack and the crushing retort. But it is not sufficiently recognised that, though Huxley bore the first brunt of the fight, a large part in the contest was taken by Hooker. The meeting closed after he had spoken, and in his own words he was "congratulated and thanked by the blackest coats and the whitest stocks in Oxford."

Two generations have passed since the Oxford meeting of 1860: and still the "Origin of Species" holds its place as a great philosophical pronouncement. As the methods of research passed into greater detail, the area of fact has been extended through the labours of an ever-growing army of inquirers, and naturally divergences of view have arisen. Some authors appear to demand that for all time the "Origin" must cover every new aspect of biological inquiry, or else the whole theory crumbles. That is to demand a prophetic vision for its author. We need not for the moment follow these or other criticisms, but rather recognise that the theory rested essentially on facts of heritable variation, without defining their magnitude, limitations, or origin; and that it explained a means of their summation so as to produce progressive morphological results.

Before we leave the historical aspect of evolution a moral may be drawn from the lives of its four protagonists of 1860. Darwin, Wallace, Hooker, and Huxley were all equipped for the battle from the armoury of personal experience in the great world. The theory of evolution was born and bred of foreign travel, and upon foreign travel quite as much as upon quiet work at home its future still depends. We should not for a moment minimise the great developments of laboratory study and of breeding experiment in recent years that bear upon its progress. But it is not thence alone that the fullest achievement can be anticipated. The cytologist and the breeder, just as much as the abstract theorist, should know Nature

[1] From the presidential address to Section K (Botany) of the British Association, entitled "1860—1894—1926," delivered at Oxford on August 5.

face to face, not merely through a glass darkly. To those who believe in the close relation between environment and variation, which is to me the very core of evolution, this seems essential to any well-balanced view. The open forest, the sea-coast, steppe, and mountain-side should be regarded as the natural complement to the laboratory and the breeding-station. No one, morphologist or physiologist, should hold himself equipped for research or fully qualified to teach unless he have at least some experience of travel through wild Nature. This can best be acquired in the tropics.

What, however, do we find? In 1886 a committee of the British Association was appointed to assist the visits of botanists to Ceylon for study. Several well-known botanists availed themselves of its aid; but after a few years the scheme flickered out through inanition. In 1909 I visited the Cinchona Station in Jamaica, and again a scheme for continued use of the station by British botanists was initiated; but it has since died out for want of consistent support. Why did these efforts fail? We may set these failures down to under-valuation of the importance of foreign, and particularly of tropical, study; and the lack of full perception that open Nature is the greatest laboratory of all. Our future botany seems in danger of becoming myopic by reason of study being concentrated at too short focus. To correct this, young aspirants should travel early, as free lances, hazarding the fortune of the wild, as Darwin and his fellows did.

HOMOPLASY.

I have already alluded to the tempestuous meeting of 1860 in Oxford. Shortly after it an undergraduate came up to Christ Church who, before he was of standing to take his M.A. degree, had himself made a real contribution to the philosophy of evolution. It was Ray Lankester, who in 1870 published a short paper "On the Use of the term Homology in Modern Zoology, and the distinction between Homogenetic and Homoplastic Agreements." Its author was only twenty-three years of age, and its date barely a decade after the publication of the 'Origin.' This short paper went far to clear up the vague ideas surrounding the term 'homology' in the minds of early evolutionists. Lankester introduced the idea of 'homogeny,' substituting in a more strict sense the word 'homogen' for 'homologue.' He also suggested, to avoid confusion, the use of another new term, namely, 'homoplasy.' He defined homogeny as simply the inheritance of a common part, while homoplasy depends upon the common action of evoking causes or of a moulding environment upon homogonous parts, *or* upon parts which for other reasons offer a likeness of material to begin with.

This definition was at once adopted in the morphological study of animals, but Lankester did not himself apply it at the time to the morphology of plants. In point of fact the conception of homoplasy and the use of this clarifying term made its way but slowly into botanical literature. There is reason to believe that we are as yet only beginning to recognise in the evolution of the plastic plant-body how far-reaching has been the influence of homoplasy, not only upon external form, but also in the internal evolution of tissues. We are only now beginning to realise how far-reaching have been its results in plants as we see them. On the other hand, such realisation when well assured cannot fail to react upon our estimates of affinity of the organisms in which homoplasy appears. It may be going too far to trace all such results as consequences of the meeting of 1860; but the initiative was certainly given by Lankester in the years that followed.

1894.

Passing from the stormy period of 1860, when the whole outlook of biological science was being transformed by the advent of evolution, to 1894, we see that the atmosphere had cleared. One result was that the evidence of descent tended to become too definite in the minds of some enthusiasts, and there was even a disposition to argue deductively from the accepted position, a tendency that is much too prevalent to-day.

The outstanding feature of the Oxford meeting of 1894 was Strasburger's generalisation on the periodic reduction of chromosomes. This shed a new light on the vexed question of alternation, which, based on the brilliant results of Hofmeister, by this time held the field not only as an objective fact but also as an evolutionary problem. The effect of Strasburger's communication was to establish the chromosome-cycle as general for plants that show sexuality. It provoked comparison with a similar cycle in animals. The recognition of both cycles took its origin in the discovery by van Beneden in 1883 that in sexual fusion the number of chromosomes is the same in both of the conjugating nuclei. Later observers have confirmed this in a multitude of instances, and disclosed the correlative reduction, or meiosis. The existence of a nuclear cycle alike in animals and in plants cannot, however, be held as establishing any homogenetic unity of the two kingdoms. Comparison of the simpler forms of each indicates that the divergence of the kingdoms, if they ever had a common origin, was very early indeed, and probably antedated sexuality in either. Such similarities as they show in propagative detail, and particularly in the nuclear cycle, would be homoplastic, not homogenetic. If this be so for the two kingdoms of living things, may it not be equally true for the several phyla of plants that show sexuality; for we are not justified in assuming that sexuality arose but once in plants?

Historically this generalisation of Strasburger fell like a bomb-shell into the midst of the old controversy between the rival theories of alternation, styled in the words of Celakovsky 'homologous' and 'antithetic.' But it must be remembered that at the moment there was no complete demonstration of a cytological alternation in any one Alga, though the facts soon followed for Fucus and for Dictyota. We need not recite again the arguments for and against that old discussion. It soon lost its intensity in face of the obvious deficiency of crucial facts, which alone could lead to some final conclusion. Loose comparisons between organisms not closely allied are but the long-range artillery of morphology. Comparisons between organisms closely related are its small arms. The discussions of the 'nineties of last century on alternation were all engagements at long range, which could not be decisive

without the use of close comparison. As the necessary facts were not then in our hands, those premature engagements might be held as drawn; and it was open to both parties still to entertain their own opinions.

Before discussing the relation of somatic development to that cycle, it will be well to revise the terminology then in use. It would be well to drop those old terms, which are neither exact nor explicit, and to support a more general use of the words 'interpolation theory' in place of 'antithetic' and 'transformation theory' in place of 'homologous.' These words accord better with current views, and are explicit.

1926

From the time that the periodic reduction of chromosomes was recognised as general in organisms showing sexuality, the nuclear cycle has formed a natural foundation for the comparison of the life-histories of plants. The normal cycle may be figured to the mind as a closed circular thread with two knots upon it, syngamy and reduction. Between those knots beads may be strung, one or more than one, or none. These represent somatic developments, which are normally diploid between syngamy and reduction, haploid between reduction and a fresh act of syngamy. They follow in alternate succession in any normal cycle, but either may be repeated indefinitely by vegetative propagation.

Certain questions arise with regard to the evolution of these somata as we see them. The first is, how far are the diploid and haploid somata of the same cycle comparable one with another? The reply will turn upon the constancy of the events of syngamy and reduction throughout descent. If they were constant, then it appears a necessary consequence that the alternating diploid and haploid somata must have been distinct throughout their history; and any similarity which they may show, as in Dictyota or Polysiphonia, would be homoplastic. It would indeed appear natural that they should be alike in Algæ, since they are parts of the same organic life and live in identical circumstances. It has, however, been suggested that reduction may not be a fixed but a movable event in the individual life: liable to be deferred or carried over to a later phase, in which case a diploid generation might arise by transformation from an already existent haploid phase. The monospores of the Nemalionales have been cited as possibly convertible in other red seaweeds into tetraspores, by some sudden deferring of the act of reduction.

I am not aware that this has been advanced by close comparison beyond the position of tentative suggestion, though the existence of a diploid gametophyte and of a haploid sporophyte in certain abnormal ferns would indicate the possibility of the suggestion being true. Pending the advance of a closely reasoned argument it is best to keep an open mind. Meanwhile the weight of facts hitherto known from plants at large may be held to support the stability of the events of syngamy and reduction during normal descent. The two generations of the same life-cycle would, in the absence of a carry-over of reduction, be homoplastic, not homogenetic.

No one has yet made out a closely reasoned case for the descent of the Archegoniatæ from the green, the brown, or the red algæ. The old view that they originated from the green algæ has never recovered from the blow delivered by Dr. Allen, when he showed that the reduction in Coleochæte takes place in the first divisions of the zygote, and that the presumed primitive sporophyte is really haploid, and not cytologically a sporophyte at all. It is a perfectly tenable position to hold that the Archegoniatæ sprang directly from none of these groups, as we know them. In the absence of definite comparative evidence, the field appears to be open to an origin of alternation in the Archegoniatæ by interpolation of a sporophyte *de novo*, developed not in water but in relation to a land-habit.

DEVONIAN FOSSILS AND A LAND FLORA.

Palæobotanical discovery has been greatly advanced within the period under review. The features of the vegetation of Mesozoic time are becoming clearer than ever before under the hands of Prof. Seward. The Carboniferous flora has been richly presented to us by Williamson, Scott, Oliver, and Kidston in Britain, and by continental workers such as Renault, Zeiller, Bertrand, Nathorst, and Solms-Laubach. We are now able to substitute something positive in place of vague surmisings. Not only do the new facts illuminate our knowledge of plants now living, but they also apply a check upon theories as to their origin.

Latterly a vision is becoming ever more and more real of a Devonian flora, revealed by Kidston and Lang in Britain, and by other workers in Scandinavia, in Germany, and in America. Given more extended collecting, an improving technique, and the fortune of finding more material as well preserved as that at Rhynie, who knows but what the coming decades may see the land of the Devonian period clothed before our eyes by a flora no less stimulating and even more suggestive than that of the coal? But though Devonian lands are the earliest yet known to have supported a sub-aerial flora, the highly advanced structure of such a fossil as *Palæopitys Milleri* suggests that we are still far from visualising the actual beginnings of land vegetation. Moreover, the mixture in the Rhynie Chert of algal types with vascular land-plants presents at the moment a problem as perplexing as it is ecologically strange.

It is always difficult to estimate justly the times in which we live; but we may well believe that the future historian of botany will note the present period as one specially marked by successful study of the floras of past ages, and by the increasing cogency of their comparison with the vegetation of the present day.

THE *ANNALS OF BOTANY* AS AN HISTORICAL DOCUMENT.

Perhaps too much time has been claimed for morphological questions, which are closely related to the dates of the three meetings of the British Association in Oxford. The brief space that remains may be devoted to a more general survey of the period which these dates cover. In this we could not do better than to take as an index the pages of the *Annals of Botany*, for the existence of which we owe a deep debt to the Oxford Press. In 1860 there was no organised laboratory

teaching of botany in any university in Britain; and as yet there was no journal of the nature of the *Annals*. But the revival of close observational study in botany under Huxley and Thiselton-Dyer at South Kensington in the early 'seventies, recorded last year by various writers in the *New Phytologist*, was beginning to take effect in 1881, when the British Association met in York. There the outstanding feature was the address of Hooker on geographical distribution. This and the papers by Bayley Balfour on Socotra and by Baker on Madagascar were all that really mattered botanically, and almost all the contributions were systematic or regional in subject. The revival of the laboratories had not yet fructified.

At this time all the work that was done in laboratories was called 'physiology,' as distinct from systematic botany, which was conducted on dry specimens in the herbarium. In 1887, six years after the York meeting, the *Annals of Botany* was founded through the activity of the late Sir Isaac Bayley Balfour, and a small committee of guarantors whose personal security induced the Clarendon Press to make the venture. From the start that journal has paid its way. The forty stately volumes form a record, between the pages of which may be read the history of botanical progress in Britain, and in some degree also in the United States, for American botanists have always been with us in its pages.

In the first issues of the *Annals*, morphology and systematic botany preponderated, and from the proceedings of the meeting of the British Association in Oxford in 1894 we see that this was still so. That meeting witnessed a crisis in the affairs of botany in Britain. A newly established Section I of Physiology assumed that the functional activities of plants would be swept, together with those of animals, into its hands. Up to this time Section D had been the undivided section of Biology. An irregular cleavage of interests was set up by this claim, for the zoologists were mostly willing to give up their physiology, but the botanists were not. Their refusal to accept divorce of form from function contributed to, or at least coincided with, the foundation of a separate Section K of Botany, and has dictated the policy of British botany ever since.

As we pass from 1894 to the current period we perceive a marked shifting of the interest of botanists from the study of form to that of the intimate constitution and functional activity of plants. Whole fields of colloidal chemistry and physics, of quantitative physiology, of cytology and genetics, of ecology, of fungology and bacteriology, have been opened up. The present century has been specially marked by the extension of opportunities for physiological research, by better equipment of departments in the universities, and by the foundation of independent establishments carrying on experimental inquiry in its broadest application. This is rapidly bringing the science into closer relation with Imperial and social aims.

It is needless to specify, but the effect of it all is plainly written in the pages of the *Annals*. Experimental results have gradually taken the preponderant place over description and comparison, as is amply shown in the last January number. 'For better, for worse,' the pendulum has definitely swung over from the extreme systematic position of half a century ago, through a phase of prevalent morphology (or perhaps we should better say of organography), to an extreme physiological position at the present time. Some may even have felt that this address is in itself an anachronism, in that it has not touched upon the moving physiological questions of the day. While I may claim none the less to sympathise with physiological aspirations, I do not assent to any ultra-physiological aspect of botany that would degrade or minimise the comparative study of form. *Medio tutissimus ibis* is still a true maxim. The laboratory physiologist, dealing with the things of the moment, cannot safely detach himself from the things of the past as recorded in heritable form. He should not allow himself to be immersed in statistics and neglect history. The pendulum has gone full swing, within a period of about half a century; but we may confidently anticipate a return towards some middle position.

Power Alcohol and other Petrol Substitutes.

ALTHOUGH opinions differ concerning the extent of the world's petroleum reserves, it is generally agreed that if the consumption of petrol continues to increase at its present rate, available supplies will soon become inadequate. Thirty years ago, it is said, there were but four motor cars in the United States; to-day there are nearly twenty million, and the consumption of petrol in that country has risen to about 900 million gallons a month. The demand for aviation shows every sign of expanding, and when we consider that petroleum is very unequally distributed in the earth's crust, and that economic independence is still a watchword in international politics, we can readily understand the vigorous efforts that are being made to produce liquid fuels by artificial means.

So far as we can see to-day, there are not many possible alternatives to petrol. There are, indeed, immense supplies of liquid fuel lying dormant in the oil-shales that are so abundantly distributed over the earth, but until methods of extraction and purification are devised that are both technically and economically successful, we shall continue to look to other fossil fuel, coal or peat, to vegetable matter, and to the mixture of carbon monoxide and hydrogen known as 'water-gas,' to supplement our present supplies of petrol, and to replace them when the day of extinction draws nigh.

Benzol is an excellent motor-fuel, but its production is comparatively small; and it is required for other purposes: for example, for dyes and explosives. Acetone is the ideal liquid for mixing with other motor-fuels, but at present it is too costly to compete with them, although its commercial production through the acetic acid made by fermenting cellulose may be achieved at an early date, and so bring it into the foreground. Alcohol is of especial significance, because the raw materials of its manufacture, cellulose and sugar, are renewed incessantly by a bountiful Nature, and also because its value as a motor-fuel, particularly in admixture, has been proved beyond a doubt. Hydrocarbon

oils of low boiling-point, such as are produced by 'hydrogenating' coal and peat, or by passing water-gas over heated catalysts, are among the most likely substitutes for petrol; from the technical standpoint the elaboration of such processes will be comparatively easy; the whole issue lies in their economy. Though the raw materials—coal, peat, air, water—are cheap, heavy capital expenditure upon plant appears to be unavoidable, and in some instances a considerable amount of energy has to be expended in promoting the chemical reactions concerned.

Of a different order are the processes for producing alcohols (and acetic acid) from cellulose or sugar by fermentation, for they require neither a high temperature nor a high pressure. Here again the problem is essentially an economic one. The raw material may be very cheap, especially if it grows wild, but it may cost a great deal to collect and transport. A few years ago there was much talk of utilising the Indian mahua flower as a source of power alcohol, but the proposition was soon found to be uneconomic, mainly on account of the cost of collecting the flowers. Cultivated sugar-cane and sugar-beet are necessarily more costly than wild vegetation, and they cannot be grown everywhere. Moreover, they contain an essential foodstuff, and the world-price of sugar rules them out as sources of power alcohol unless their production is subsidised by the State. Molasses, being a by-product, is in a different category. Although it is produced in considerable quantity (constituting about 30 per cent. of the weight of raw sugar manufactured), supplies of it would not cover more than a fraction of the world's requirement of light motor-fuel in the event of a petrol famine; its production is confined to sugar-growing countries, and it is in great demand by manufacturers of rum and cattle-cake. The production of fuel-alcohol from molasses is now being undertaken on a large scale in Queensland, Australia, states Dr. W. R. Ormandy (*Journ. Soc. Chem. Ind.*, Aug. 13, 1926), where, with the aid of the Queensland Government, a plant is being erected to produce two million gallons of alcohol per annum, and three additional plants are projected. This enterprise will be assisted by the existence of a thriving sugar industry, and by the total absence of petroleum deposits in Australia.

Among post-War developments the initiation of a State-subsidised beet-sugar industry in Great Britain is one of the most interesting. A flourishing industry of this kind would have far-reaching effects, especially upon agriculture; and the view being held in certain quarters that agriculture would benefit more if beets were grown for the distillery than for the beet-sugar factory, the Government appointed a small committee, consisting of two chemists and one physicist, to inquire into certain economic aspects of the question. The report,[1] which was issued in July, is a short document of a few thousand words. In reply to the questions put to it, the Committee estimates the cost of raw material per gallon of alcohol (taken throughout as 95 per cent. by volume) to be 5 per cent. of the price per ton of beet, due allowance being made for the value of residual products. Cost of conversion or manufacturing cost is given as 9*d*. per gallon of alcohol, so that, excluding other charges (*v.i.*), the cost per gallon net naked at works would be 1*s*. 9*d*. or 2*s*. 9*d*., according as the price of sugar-beet is taken at 1*l*. or 2*l*. per ton. The yield of alcohol from one cwt. of sucrose is 8 gallons theoretically, 6·8 gallons in practice. With the aid of these figures, and taking 28*s*. per cwt. as the commercial price of sugar and 1*s*. 6*d*. or 2*s*. per gallon as the probable price of power alcohol, the Committee calculates that with the same rate of subsidy in both cases (19*s*. 6*d*. per cwt. for sugar and 2*s*. 10½*d*. per gallon for alcohol), the subsidy would amount to 70 per cent. of the commercial price of sugar, and 191 or 144 per cent. of the commercial price of alcohol.

The economic case against subsidising the sugar-beet industry for producing power alcohol is really stronger than these figures suggest. The Committee ignores (wittingly) charges for denaturing, packing, transporting, and selling. Assuming a wide distribution, these charges would amount to about 1*s*. per gallon; hence the subsidy would really represent 258 or 221 per cent. of the commercial price of the alcohol. Furthermore, it must not be overlooked that the present rate of subsidy is very high and will diminish as time goes on. Last season the price paid to English growers was about 56*s*. per ton of beet, and the subsidy per ton was about equal to the price received by Dutch growers for their produce; in other words, the English beet-sugar manufacturers practically obtained their raw material for nothing.

The Committee was also asked to report upon the prospects of producing power-alcohol by synthetic processes. Its reply is to the effect that the present position of such processes is obscure, and that reliable statements of costs will not be available for some time. Nevertheless, a useful appendix is inserted containing remarks on the chief processes that are potentially important for making alcohol and other liquid fuels from sugar, cellulose, coal, and water-gas.

Preparation through ethylene appears unlikely to provide alcohol in quantity, and synthesis from calcium carbide is regarded as improbable in view of the abandonment of carbide manufacture in this country owing to economic considerations. The use of water-gas for making liquid fuels, whether alcohols or hydrocarbons, is held to be promising, although but little has been done in this direction in Great Britain. Processes involving the use of high pressures, like those of Patart and Fischer, are referred to, but no specific mention is made of Fischer's work on producing hydrocarbon liquid fuel from water-gas without employing high pressures. In some quarters this development is regarded as a great advance, but it should not be overlooked that the saving effected by dispensing with the costly high-pressure plant is quite counterbalanced by the cost of the very much larger plant required for working with gases at ordinary pressure. A few reasons are given for and against the use of methyl-alcohol as a motor-fuel, but the Committee issues no verdict on this head. Actually methyl-alcohol is a very inferior fuel, not only because it has a low calorific power, but because it causes serious 'pinking' in the engine. The Committee thinks well of the possibilities of the improved Classen and Prodor processes for converting the cellulose of wood, or waste-wood, into

[1] Power Alcohol Production, being a report to the Minister of Agriculture and Fisheries of the Departmental Committee appointed by him in connexion with the Manufacture of Alcohol for Power Purposes from Sugar Beet. (London: H.M. Stationery Office, 1926.) 6*d*. net.

sugar and alcohol, especially in countries where wood is abundant. There is, however, little prospect for making alcohol from waste sulphite-liquors in Great Britain, whilst production by fermenting cellulose is more likely to be developed in the overseas dominions than in our own country.

The outlook for producing motor-fuel from coal is considered to be favourable, but not by the low-temperature carbonisation process, which, the Committee states, cannot yet be worked on a large scale at a profit, and when it can be so worked it would not provide more than a fraction of our requirements in heavy and light fuel-oil. The Bergius process (for the investigation of which the Government has recently granted the sum of 25,000*l.*) is stated to be the only one which could satisfy our requirements, but in view of the difficulty in constructing plant, some years must elapse before really commercial data concerning it can become available. In its remarks upon this process the Committee gives some quantitative data which are not up-to-date. The statement that at least one ton of coal must be burnt for every ton put through the process should read "one ton of coal is burnt as fuel for every *two* tons put through the process"; and the yield of light fuel is not 15 gallons but from 20 to 25 gallons per ton, according to the quality of the coal treated. Further, the remark that "65 per cent. of the weight of the coal may be converted into a kind of oil," would be more accurate in the form: "85-93 per cent. of the coal substance is converted into oil."

In its summary of this interesting section of the report, the Committee states that of all the processes not involving the distillation of fermented foodstuffs, the most likely to be adopted in Great Britain are those based upon the use of water-gas as raw material, and those by which fermentable sugars are obtained in high yield from wood. It is, however, strongly open to doubt whether the latter processes could be worked economically in Britain, where wood is scarce and expensive, and where wood-waste can only be collected and transported at prohibitive cost.

Discoveries in the Gobi Desert by the American Museum Expeditions.[1]

By Prof. HENRY FAIRFIELD OSBORN, For. Mem. R.S.

IN 1799, William Smith, then a young man of thirty, who was born at Churchill in Oxfordshire, dictated his now classic document, "The Order of the Strata," including a map showing the successive and characteristic fossils of southern Britain and the Oxford clay underlying this great University, with its Jurassic deinosaur Cetiosaurus. In the century and a quarter which has intervened before the present meeting of the British Association in Oxford, the twin sciences of geology and palæontology have reached a degree of precision which enables us, after our relatively brief and intensive surveys of the past four years, to declare 'the order of the strata' of Mongolia. Included in the Gobi Desert is a stratum equivalent in age to the Oxford clay of William Smith, containing the giant sauropod Asiatosaurus, a first cousin of the Oxford Cetiosaurus.

Meanwhile, physicists have extended the life-history period of the earth from the momentary 5000 years of Usher to the 1,000,000,000 years of Rutherford. This allows a comfortable margin of 400,000,000 years' time for the wonderful procession of evolutionary advance recorded in the twenty-four chapters of Mongolian prehistory, beginning with the equivalent of the Purbeck and Oxford formations of Upper Jurassic time, continuing with the appearance of man in the Old Stone Age, ending practically with the dominance of Ghenghis Khan, and followed by the decline of Mongolia to its present desert and relatively uninhabited state.

In the meantime, this now arid 'roof of the world' has been the scene of a whole succession of animal dynasties, fertile, productive, with a relatively temperate and invigorating climate, sometimes arid, sometimes pluvial, from first to last the homeland of waves of migrating land reptiles and mammals, which successively spread into every other continent (Fig. 1). It is a singular fact that this first and greatest of all life-centres (7) of prehistory was the last to be discovered, following by a half to three-quarters of a century the discoveries of great life-centres in Australia, in North and South America, in northern Africa, and in southern Asia. Although each of these great centres contributed its quota to the prehistory of the earth, none played a part at all comparable to that of central Asia.

With this introduction we may proceed to show by means of photography the contrast between the present geography of Mongolia and its palæogeography as recently revealed, and exhibit a new palæogeographic map of the world (Fig. 1) prepared especially for this discourse, showing that by placing North America on the east, Asia in the centre, and Europe on the west of an equal-area projection, we have a complete solution of all the animal migratory routes from Upper Jurassic time to the six great waves of human migration which swept over northern Asia into North America in late Pleistocene time.

PRESENT GEOGRAPHY OF MONGOLIA.

The position of Mongolia in Asia as shown in the map of Perthes may be projected areally on a map of the United States along lines of the 40th parallel; and there at once appears the remarkable similarity between the Mongolian fauna and that of the Rocky Mountain region throughout the entire period from Jurassic to recent times, the parallelism varying in closeness from epoch to epoch, at times Europe being closer than the United States. To the north of the hypothetical 'Gobia' lies 'Angara,' to the south the 'Gondwana' of Suess.

[1] From an evening discourse delivered to the British Association at Oxford on August 9. For further information regarding these expeditions reference should be made to "Methods and Results of the American Museum Expeditions in the Gobi Desert, 1922-25" (NATURE, August 7, 1926, pp. 198, 199), a lecture delivered to the Geological Society of London, June 23, 1926.

PERSONNEL AND TRANSPORTATION.

It has been estimated in the United States Geological Survey that as much was accomplished in three years by the American Museum survey as had been accomplished in the first fifty years of discovery in the corresponding Rocky Mountain region, namely, from 1850 until 1900. This was due to prolonged palæontological experience in America and to the combination of slow camel transport and rapid automobile transport, under the guidance of ten Mongols, ten Chinese, and an equal number of Americans trained in the western desert region. These rapid modern methods were rendered possible by the approval of the Mongol Government, but neither aeroplanes nor radio were allowed admission. Over the great level stretches now traversed by wild asses and gazelles, the camels advanced fifteen miles a day, the automobiles a hundred and fifty miles a day, or ten times as rapidly.

The routes and discoveries of three seasons (1922–1925) may be summarised as follows:

(a) Peking, Kalgan, Pang Kiang, Irden Manha, Houldjin, Iren Dabasu, Tuerin, Urga (the main and only telegraph line in Mongolia).

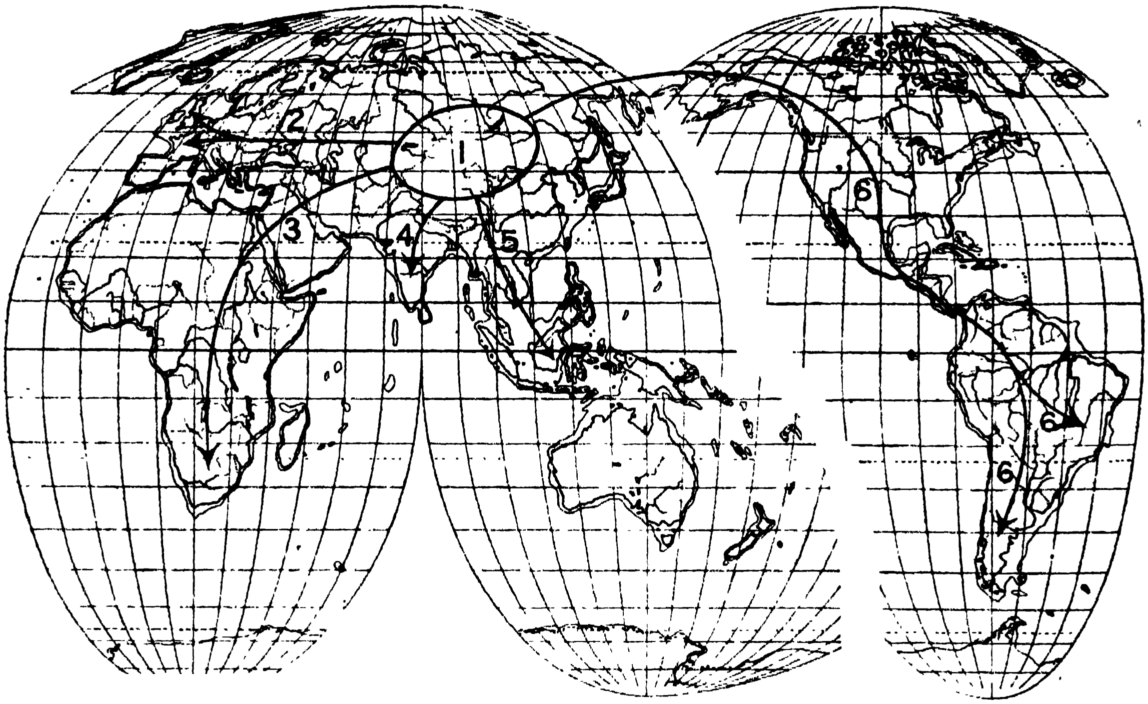
(b) North-west Uliassutai route: Shara Murun, Ardyn Obo, Sair Usu.

(c) Altai route, travelling southward to Kolobolchi, Ondai Sair, Oshih (Ashile), Djadokhta, Gashato, Golobol'n Ola.

(d) Northward on the main route to Urga through Irden Manha, Houldjin, to Iren Dabasu.

Excepting Peking and Kalgan, all these localities yielded fossils, often in enormous quantities. At Houldjin we found the very spot where Obruchev discovered the single rhinoceros tooth, hitherto the only fossil vertebrate found in all Mongolia. At Iren Dabasu Andrews pointed out to me distant fossil beds of the Wealden age on the horizon, a rich Lower Cretaceous level. Each of the watering stations mentioned in the above routes, where wells are sunk for the camels, now gives its name to a more or less great geological horizon or formation contemporaneous with the great horizons of western Europe or of the United States.

Nothing could exceed the fidelity and ability of the Mongols and of the Chinese; the former were found to be true to their word on every occasion, and the latter were not only faithful but also became extremely expert in the discovery of fossils; and many of them are now engaged in working the fossils out of the rock in our Peking laboratory.



[J. Bartholomew and Son, Ltd

New Central Asiatic continent 26: Migration lines of the great reptilian Sauropoda—to Europe (2), to South Africa (3), to India (4), to Malaysia (5), to North and South America (6).

THE UPPER JURASSIC CONTINENT AND FIVE LIFE-ZONES OF UPPER MESOZOIC TIME.

It is an interesting coincidence at the present meeting of the British Association that the oldest horizons, known as Ondai Sair and Oshih (Ashile), are of sub-Wealden age and at present appear to be close to the Purbeckian and Oxfordian horizons of England. They contain primitive short-headed iguanodonts. Above them lies the Iren Dabasu, probably of Wealden age, containing large iguanodonts, ostrich deinosaurs, and megalosaurs. Still more recent are the famous Flaming Cliffs of the Djadokhta, which have no terrestrial equivalent in England; here were found the skulls of five small Cretaceous mammals and a host of deinosaurs, herbivorous and carnivorous, including the

now famous Protoceratops with its supposed enemy, the Oviraptor or egg-snatching deinosaur. From the lower Ashile level the giant sauropods, Asiatosaurus, may have wandered to all the great continents except Australia. The fascination and the perils of fossil hunting among the Flaming Cliffs of Djadokhta for the eggs and skeletons of deinosaurs were recorded by instantaneous photography.

Successive Life Phases of the Age of Mammals.

Even closer and more continuous is the remarkable succession of Gobi formations starting with the basal Eocene Gashato, of the same age as the Thanet sands of England and rising through beds of the age of the London clay to the Hordwell and Headon of the Isle of Wight, where England's terrestrial formations are interrupted, presenting a series of extraordinarily close parallels with the great Rocky Mountain succession from basal Eocene to Miocene time. In the creodonts, uintatheres, and titanotheres of the Gobi region we discover close generic and almost specific affinities to their distant American cousins. But the giant Baluchitherium, which had ancestors in Upper Eocene time and attained its gigantic size in Upper Oligocene time, seems to have had a monopoly of the central and south Asiatic region, because it has never been found elsewhere. In the Miocene and Pliocene phases of the Gobi there are some breaks which will doubtless be filled by future discovery, but in the Middle Miocene, and again in the Upper Pliocene, we discover close kinship to Western Europe and North Africa, especially in the arrival of the proboscideans or mastodonts of remote African ancestry. Thus the high plateau region of central Asia, including, doubtless, Chinese Turkestan, Tibet, and Mongolia, is firmly established as the previously missing area of origin not only of the terrestrial life of the entire northern hemisphere, but also of life which wandered into the extremities of Africa and of South America as well.

Scientific truth is far stranger than scientific fiction: Gobia takes the place of the mythical Atlantis and other imagined continents as the source of most of the animal civilisations and probably also of most of the vegetal civilisations of the northern hemisphere.

Discovery of the Old Stone Age in 1925.

At least four periods in the Old Stone Age of man were recognised in the campaign of 1925, namely, in descending order, Azilian-Campignian, (?) Mousterian, Acheulean (much more doubtful), and (?) Eolithic. Directly opposite the Flaming Cliffs of Djadokhta was discovered a great human culture level believed to be of late Palæolithic, Campignian, and Azilian age, with thousands of implements, to the north-east of the Mousterian horizon discovered by Licent at Ordos in north China. Above this closing Old Stone Age level occurred, in order, traces of Neolithic, of Bronze, and of Iron ages, ending in traces of pre-Mongol peoples which are succeeded by burial-places of the Mongol race that ended with the warrior race of Ghenghis Khan and the conquest of all southern Asia by Kubla Khan.

Thus are written twenty-four new chapters in the prehistory of the earth by the expansion and elaboration of methods of research first introduced to the world of science by William Smith of Oxford in his chart showing the companionship of geology and palæontology, and in the most unexpected manner connecting Mongolia with England and, especially, with Oxfordshire.

Observations with the Spectrohelioscope.

By Dr. George E. Hale, For. Mem. R.S.

The spectrohelioscope described in my article on "Some New Possibilities in Solar Research" (Nature, July 3, 1926) has been provided with new oscillating slits and driving mechanism and an improved parallel-plate line shifter and micrometer for setting various parts of the $H\alpha$ line on the second slit during observations, with divided arc indicating the exact wave-length employed. In this form the spectrohelioscope not only discloses the most delicate details of structure shown on the best Mount Wilson spectroheliograms, but has also served for the detection and measurement of some new and interesting phenomena.

Three cases observed on August 15 may be mentioned, all in the hydrogen vortices associated with the large spot group which on that day was near the central meridian of the sun. The first two were noticed south of the following spot of the pair. By rocking the parallel glass plate back and forth, thus showing the change in form with wave-length of two slender curved flocculi, their dark heads were seen to advance toward the spot as the $H\alpha$ line was moved across the second slit from its centre toward the red. At a slit position about 1·3 angstroms from the centre of the line, the curved flocculi had disappeared, but their point-like extremities were still visible, projected against the outer boundary line of the penumbra. If we assume this effect to be caused by the rapid descent of the hydrogen in the vortex above the spot, the radial velocity was about 65 km. per second. Another slender flocculus south of the preceding spot behaved in the same way. A similar observation on August 16 gave a maximum radial velocity of 56 km. per second for the descending point. These velocities are of the same order as those of knots in prominences moving toward spots, measured by Slocum and Pettit on photographs of the sun's limb made with the Rumford spectroheliograph, and observed visually by myself with the spectrohelioscope.

Although I confirmed the new results on August 17, the day I left Pasadena for a month's absence, I wish to check them more completely before expressing a final opinion as to their interpretation. It now seems probable, however, that the spectrohelioscope can be used for a more complete analysis than has previously been possible of the hydrogen vortices surrounding sunspots. These vortices involve the prominences as well as the chromosphere, and a means of measuring the velocities of the hydrogen, seen in projection against

the disc as well as in cross-section at the limb, should prove of great service.

If we may interpret another group of observations in the same way, the parallel plate micrometer will also make it easy to distinguish eruptive jets, rising near spots and descending at some distance after following a long-arched trajectory, from the true vortex structure with which they are likely to be confused on spectroheliograms. At their source these apparent jets often appear as bright flocculi, seen on the violet side of Hα, which seem to become dark absorbing streams at a higher level and finally descend at a velocity sufficient to produce a marked displacement to the red, beyond the normal boundary of the Hα line.

Bright hydrogen flocculi include those of the quiescent or slowly changing type and those of short life, which change rapidly in form and intensity. These short-lived bright flocculi are themselves of two kinds: eruptions, shown by the spectrohelioscope, when near the centre of the sun, to give a displacement of the bright Hα line to the violet; and bright flocculi which are receding or stationary in the line of sight. From my recent visual observations, it appears probable that the short-lived stationary or receding bright flocculi are often due to the descent of comparatively cool hydrogen, which appears dark at high levels but turns bright as it falls. The distinction is important, as terrestrial magnetic storms and auroras will probably be found to result from the presence near the middle of the sun of bright flocculi of the eruptive type, which emit charged particles at velocities sufficient to carry them to the earth.

Spectrohelioscopes capable of distinguishing such eruptions, if they could be built at small cost and used systematically at a sufficient number of stations well distributed in longitude, should aid materially in determining the exact relationship between these solar and terrestrial phenomena. After considering several possible designs, and making a variety of preliminary tests, I am now building a solar telescope and spectrohelioscope which promise to be both inexpensive and powerful. From tests already completed, I find that a single plano-convex lens of 3 inches aperture and 18 feet focal length, used with a simple heliostat or cœlostat just large enough to fill it with light, will serve very well for the necessary solar telescope. In the spectrohelioscope a single prism, twice traversed by the sunlight, will take the place of a grating. Its dispersion will be adequate with a focal length of 13 feet, or by the use of additional prisms the focal length can be reduced. For general use, fixed monochromatic telescopes of the above type will be less expensive and probably more satisfactory than those carried by an equatorial mounting. Moreover, I have designed a spectrohelioscope for attachment to equatorial telescopes, but have not yet found opportunity to build and test it.

Continued use of the spectrohelioscope has strengthened my hope that in the hands of amateur astronomers it may contribute materially to our knowledge of the solar atmosphere. As another indication of its service, I may add that on June 26 last I observed a phenomenon recorded but once, and then incompletely, in the entire collection of Hα spectroheliograms obtained on Mount Wilson since the beginning of such records in 1908. This unique case was the sudden engulfment, on June 3, 1908, of a large dark flocculus (prominence) by the vortex associated with a sunspot, illustrated and described in "Solar Vortices," *Astrophysical Journal*, vol. 27, September 1908. The phenomenon of June 26 was very similar in appearance, and although the parallel plate micrometer was not then completed, I was able to see its final stage, which was necessarily missed in the earlier record. This was the appearance of a black dot, after the large dark flocculus had been sucked into the vortex, exactly upon the outer (preceding) boundary line of the penumbra, as in the observations of August 15 and 16. This could be seen only when the second slit was on the red side of Hα, indicating the rapid recession of the hydrogen. The detailed observations will be given later. The point to be made here is that many interesting and unfamiliar phenomena of the solar atmosphere, including cases of this kind, can be observed by any one who cares to equip himself with the simple and inexpensive apparatus required. A full description of the instruments now under construction will be published soon after the final tests have been completed.

News and Views.

THERE have just been placed on exhibition in the Geological Department of the British Museum (Natural History) the remains of a Stegosaur or armoured deinosaur, obtained by the late W. E. Cutler from the Belly River sandstone of the Red Deer River, Alberta. Baron Nopcsa, who will soon publish a description of the specimen, believes that it represents a new genus; but in any case it is closely allied to Panoplosaurus (Lambe) and Ankylosaurus (Barnum Brown) from the same beds, and is not very unlike Polacanthus (Owen) from the Wealden of the Isle of Wight. The chief interest of the specimen lies in the preservation of the plated skin still in position over the greater part of the skeleton. The bony plates range from large broad-based spikes, presumably covered with horn in life, to minute specks in the wrinkled skin of the neck. The skin of the under surface has left no trace and was no doubt relatively thin. The vertebræ of the back lie in a straight line, and the ribs were probably fused to them, as in Ankylosaurus. The sacral vertebræ are fused to one another. The vertebræ of the neck and tail were movable. The limb-girdles are clearly shown, and the large bones of the left fore-limb clearly retain their natural position, indicating a squat posture with a bend at the elbow, so that the height at the shoulder was only about three feet. The left hind-limb has been bent over the belly, and is almost complete. The skull is missing. The length of the fossil is 15 feet, and its breadth 6 feet. In the absence of jaws and teeth, the feeding habits must be inferred from those parts in allied forms. Baron Nopcsa holds the view that the creature roamed a sandy desert and lived on occasional swarms of

locusts, the museum labels adopt the more usual interpretation of the Stegosaur teeth as adapted for vegetable food.

THE Trustees of the British Museum have recently placed in the Central Hall of the Natural History Museum a case illustrating the tragic effect on sea-birds of the waste oil which is allowed to escape from ships or is pumped out with bilge-water. The scene shows a portion of a beach on the south coast shortly after the turn of the tide, the sand in the foreground being still wet from the sea. At the high tide level lie six dead birds just as they have been washed up by the waves, together with the usual flotsam, while a little higher a guillemot, with glazing eye and panting breath, is evidently on the point of death. The feathers of the living and dead are heavily befouled with the thick dark liquid. A realistic touch is added by the two large flies which have already scented the dead bodies. Guillemot, razorbill, and red throated diver are the three diving birds represented. The scene reproduces with exact fidelity an actual group of dead birds which were washed up on the Isle of Wight. Such sights are, however, by no means confined to the shores of the English Channel, and may be seen in crowded waters all over the world where oil-burning vessels congregate. The prevention of the oil nuisance was considered at an international conference held at Washington this summer, and it is hoped that as the result stricter regulations will be enforced by the several maritime nations which will lead to an abatement of the nuisance. What precisely is the action of the oil on the birds which leads to their destruction is uncertain.

THE town council of Swindon has decided to purchase for the sum of 2150*l.* the small farmhouse and land adjoining the Marlborough road at Coate, about one and a half miles from the town, which was the birthplace of Richard Jefferies. Jefferies died in 1887, and, since his death, his name, which meant so little to his neighbours during his lifetime, has attained to a certain immortality in the big railway town The small house in Victoria Street, in which the early days of his married life were spent, is marked with a tablet recording that fact. There is a 'Jefferies Club' amongst the young people of the secondary schools, and the Field and Camera Club, as well as the flourishing branch of the Workers' Educational Association, regard him more or less as their patron saint. But as with so many others, so too with Richard Jefferies: he was no prophet to his neighbours whilst he lived, and only became one when he died. In truth, to country people the "common objects of the country" are so common that they do not appeal to them, as they do to the dwellers in towns. The study of natural history has its strongholds in the large towns and not in the country districts; and this is probably even more the case now than it was fifty years ago. But the influence of Richard Jefferies, for all that, lives to-day. It was he who for tens of thousands of town dwellers discovered the beauty of the Downs and the hanging wood of the chalk escarpment, which are the characteristic features of the country that he loved so well. He was not a scientific naturalist. He troubled himself not at all as to the minute points of distinction between sub-species and varieties, so beloved by many specialists of the present day; but he was a great observer, and what he saw he set down on paper and taught others to see too, and so may rightly claim to have been one of the chief founders of that 'Nature Study' which is now regarded as a necessary means of education.

A NOTEWORTHY event of the seventy-second meeting of the American Chemical Society, held on September 6-10 in Philadelphia, was the great pilgrimage of chemists to the grave and former home of Joseph Priestley at Northumberland, Pa. It was there, on the pleasant banks of the Susquehanna River, that Priestley, in 1794, then aged 61 years, joined his sons after religious persecution had made his life intolerable in England; and it was there that he spent the remaining ten years of his life engaged mainly in the study of theology and philosophy. He never became naturalised, saying that "as he had been born and lived an Englishman, he would die one, let what might be the consequence." The house which was built by Priestley at Northumberland in 1796 has acquired additional fame from the fact that it was the meeting place of a band of American chemists who assembled there in 1874 to celebrate the centenary of the discovery of oxygen, and to found an association which two years later developed into the American Chemical Society, now the largest chemical society in the world. In 1920 the house was in a sad state of decay, having been used during the War as a boarding-house for immigrant labour, but owing to the enterprise of the G. G. Pond Memorial Association it was purchased at public auction, thoroughly renovated, and a museum was erected on the lawn, which still bears two pine trees planted by Priestley himself.

THE ceremonies held at Northumberland on September 5 comprised a visit to the grave where Priestley, his wife, and seventeen descendants lie buried, an inspection of the house and of the museum containing original apparatus and other personal effects of Priestley; and a short meeting on the lawn at which addresses were delivered, by Dr. W. H. Walker on the history of the house, and by Dr C. A Browne, of the U.S. Bureau of Chemistry, on the life of the famous 'pneumatic' chemist, whose great-granddaughter, Mrs. Frances Priestley Forsythe, took part in the proceedings. Although England lost what America gained when Priestley emigrated to Pennsylvania, English chemists will always be grateful to their American colleagues for the way in which they have honoured and preserved his memory. Not all of them, however, will endorse the official reference to Priestley as "the founder of modern chemistry," great as his experimental achievements undoubtedly were. The number of famous chemists in different lands who have been awarded the title of 'founder' or 'father' of the science tends to become embarrassing, and it almost seems time to invoke the

Code Napoléon and put a ban on any further "recherche de la paternité."

IN a recent paper before the American Chemical Society, Dr. W. Blum, electro-chemist to the U.S. Bureau of Standards, stated that the manufacture of metal tubes and sheets by electrolytic means is fast becoming a reality. Although no details are given in the announcement before us, Dr. Blum is reported to have said that the possibility of continued manufacture on a commercial scale was not yet proven. In the past large sums of money have been spent on working out such a process, but the results have hitherto been disappointing, largely owing to the difficulties experienced in obtaining impervious deposits and uniform distribution of metal of the required structure and quality. These obstacles are now stated to have been overcome. Advantages claimed for the new process are ease in making complicated forms, and, unlike the rolling and drawing processes, thin-walled tubes are cheaper to manufacture than heavy ones.

THE future of petroleum supply is a problem that is interesting many countries to-day, and none more than the United States, which has been the chief producer and consumer since the industry began, and, it is said, is likely to be the first to have the wolf at the garage door Nineteen years has of late been the accepted probable life of the known petroleum deposits in that country, but a more pessimistic view was expressed by Dr. A. C. Fieldner, chief chemist to the Pittsburgh Department of the U.S. Bureau of Mines, in a recent address to the American Chemical Society at Philadelphia. According to this authority, the United States owns five-sixths of all the motor cars and trucks in the world, and consumes 80 per cent of all the motor-fuel, mainly petrol The oil-wells of proved extent are estimated to contain 5 billion barrels of readily available petroleum, a quantity which, at the present rate of consumption, would last only until 1936; the amount left in the oil-sands, which may be recovered when ordinary pumping is finished, is about 26 billion barrels. Supplies of proved extent could be made to last until 1943 if the yield of petrol from 'cracked' oils were increased from the 35 per cent. obtained in 1925 to 55 per cent., which is regarded as a likely figure; and they could also be conserved by using engines with a higher compression-ratio than that now in vogue in the United States (about 4 : 1). Looking to the future, Dr. Fieldner foresees the use of alcohol, derived from vegetation or obtained by synthesis, for mixing with petrol, but ultimately, he thinks that oil-shale, soft coal, and lignite will be the main sources of motor-fuel. Failing these, we may have to use a light electric storage-battery, or revert to Diesel's original idea and use coal-dust in our motor-engines.

PROF. SCHWARZ, in an undated volume, "The Kalahari or Thirstland Redemption," proposed an ingenious scheme for the development of the Kalahari Desert by flooding depressions to the west and east of Lake Ngami by dams across the Cunene River and the Chobi River above its confluence with the Zambezi. The southern Kalahari was expected to benefit by two overflow channels from the projected lake near Ngami to the Orange River, and the whole climate of South Africa to be improved by the moistening of the atmosphere by evaporation from the large water surfaces. To test this project the South African Government last year sent out an expedition under Dr. Du Toit, whose opinion will carry much weight. His report, of which an abstract was published by the *Times* of September 10, declares Prof. Schwarz's scheme impracticable, and emphatically rejects its axioms that there has been a progressive desiccation of South Africa within the last century, and that the reduction in the size of Lake Ngami was the result of that change. The new report concludes that the climate has not altered appreciably within historic times. Owing to heavy rains Lake Ngami, according to recent reports, is as large as it has been ever known.

THE Commission concludes that owing to the high rate of evaporation the water supplies on which Prof. Schwarz relies would be inadequate, and that for the establishment of any extensive permanent lakes the main flow of the Zambezi would have to be diverted by the erection of a dam 60 ft. high across the Zambezi at Katombora, which would submerge 4,600 sq. miles. A rejoinder by Prof. Schwarz severely criticises the report on the unconvincing grounds that the expedition did not go near the Kalahari and was not led by an engineer He declares that damming the Zambezi is "not practical politics," as the submergence of half Barotsiland and some native towns would be opposed to the Colonial Office insistence that there must be no interference with native rights. Considering, however, what has been submerged by the Nile dams, the transference of native settlements would not be a serious objection to any scheme for the better utilisation of the waters of South Africa, especially as due compensation to the natives, apart from the improved value of the rest of their land, would no doubt satisfy the Colonial Office stipulations as to native rights. The report of Dr. Du Toit, as one of the leading geologists and geographers in South Africa, will doubtless receive careful consideration.

IN the *Wireless World* for September 1, Col. Crawley gives a survey of the overseas radio services in Great Britain. He proves that, so far as radio communication is concerned, the position is satisfactory. We are now on the eve of a complete system of Imperial radio communication. The control of all the overseas commercial messages is in the hands of the Government and the Marconi Company, but the military messages are controlled by the three fighting services. The Post Office services are operated from the London General Post Office, on the roof of which eight receiving aerials are installed. To obviate the effects of local electrical interference, however, this receiving station will shortly be transferred to St. Albans. The messages

received are relayed to the recording machines in the same building. These machines are placed alongside the transmitting machines which actuate the sets at Rugby, Oxford, Northolt, Stonehaven, Dollis Hill, and Caister. When the St. Albans station is ready the received signals will be relayed to the General Post Office.

THE Rugby station, with a frequency of 16 kilocycles, transmits messages to stations and ships all over the world. It is hoped also to inaugurate shortly long-range radio telephone services. The station at Leafield, near Oxford, communicates with Halifax and Cairo, both by an electric arc (24·21 kilocycles) and by a valve set (6000 kilocycles). The station at Cairo is operated by the British Post Office and communicates with Oxford, Germany, France, Italy, and Basra. At Northolt there are two aerial systems, one a valve set and the other an arc set. This station communicates with Czecho-Slovakia, Italy, and Hungary. Stonehaven communicates with Germany, Norway, Iceland, Poland, and Esthonia. Caister communicates with Holland when the cable service is interrupted, but it is normally closed. Dollis Hill is the Government experimental station. Last year the Post Office point-to-point services dealt with over ten million words of paid traffic. The Marconi Company operate an alternator station at Carnarvon and a group of valve stations at Ongar. They have a large receiving station at Brentwood. Considerable extensions are in progress. They erect the beam sending and receiving stations for the Post Office; the transmitting station at Bodmin and the receiving station at Bridgwater are practically completed.

THE Royal English Arboricultural Society held its summer meeting recently at Newcastle, with Mr. Leslie S. Wood as president and Mr. Gerald W. E. Loder, vice-president. The secretary, Mr. Edward Davidson of Haydon Bridge, had arranged a programme of excursions to Middleton Hall, Chopwell, and Healey. The woodlands were evidence of the energy of those responsible—Messrs. Gerard F. T. Leather, A. D. Hopkinson, and W. St. A. Warde-Aldam. Outdoor discussions were shared by foresters, estate agents, timber merchants, nurserymen, and university lecturers. South country visitors were surprised to see little planting of ash, elm, sycamore, though these with birch and mountain ash come by natural regeneration. The timber merchants' control demands conifers for pit props, especially larch. Sitka, Douglas, Corsican, Japanese larch are being tested by the acre. Pre-War plantations are thriving. Even in war-time some planting was achieved. Post-War planting has struggled against increase of rabbits and a legacy of forst weeds, gorse, bracken, and bramble. Gorse has been twice cut, and the trees may now outgrow it. Bracken has grown apace this year, cutting seems necessary. The blackberry-picking problem is accentuated when the forest is on the edge of an unemployed mining village. One estate was remarkable for continuity of management —only three foresters in a century; another for the high qualifications of its officers although their reigns have been short; a third for the skilfully arranged economies of an estate railway, sawmill and woodwork shops, the engine fed by gas generated from scrap and sawdust.

A REMARKABLE find of Mycenæan treasure is described by Mr. A. J. B. Wace in the *Times* of September 10. The Swedish Archæological Expedition to Greece, in excavating a beehive tomb near the village of Dendra, which lies at the foot of the acropolis of the Homeric Midea in the neighbourhood of Nauplia, has discovered four grave-pits, two of which are undisturbed. This is the only untouched burial hitherto found in a beehive tomb, excepting that at Vaphio from which the famous Vaphio cups were obtained. In one of the undisturbed pits lay two extended skeletons, one male, the other female. In the second was a female skeleton. The 'king' was covered almost from head to foot with gold, silver, and other riches. On his breast was a magnificent golden cup, 18 cm. in diameter, cunningly chased with what is described as "almost . . . a submarine seascape," the figures including argonauts, dolphins, and four octopuses. Artistically and technically the cup is a masterpiece. In the cup were the king's seals, and on or by his body were bronze swords with hilts of gold, or ornamented in gold, silver vases, a gold cup sheeted with silver, a bronze vessel, knives and spearheads. With the 'queen' lay a splendid gold cup sheeted outside with silver inlaid in gold, bronze, and black silver Other treasures were a necklace of 61 gold beads, a lamp of steatite and a vase of ostrich-egg with applied ornament in gold, silver, and bronze. The 'princess' was less richly supplied, but had a gold ring, a necklace of 38 gold beads of rosette form, and the remains of a girdle. All the finds, excepting the 'king's cup,' are of a comparatively late date, on the ceramic evidence scarcely earlier then 1350 B.C. The older cup, it is suggested, may be an instance of the burial of an heirloom or antique, in which case, Mr. Wace points out, it indicates caution in accepting theories recently put forward that the beehive tombs should be dated much earlier than they usually are.

PROF. V. H. BLACKMAN, Prof. F. G. Donnan, and Prof. F. A. Lindemann, have been appointed by Order of Council dated August 20, 1926, to be members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research, in succession to members who have retired on the completion of their terms of office

THE ninth International Congress of Zoology, held at Monaco in March 1913, decided that the tenth Congress should take place in 1916 at Budapest, with Dr. G. Horváth, Hungarian National Museum, Budapest, as president. The War rendered the meeting impossible. The international situation, however, has now so much improved that the Congress need no longer be postponed. After due consultation with members of the permanent committee of the international congresses of zoology,

Dr. Horváth is able to announce that the tenth Congress will meet at Budapest on September 4-9, 1927, and he cordially invites all zoologists and friends of zoology to attend. The detailed programme of the Congress will shortly be issued and sent to all who are interested.

A SERIES of Sunday afternoon addresses under the general title of "The Contribution of Science to Human Life" is to be given during the autumn at the Guildhouse, Eccleston Square, London, W. The lectures are free, and no tickets are required. The lecturers and their subjects are as follows: Oct. 3, Sir Richard Gregory, the worth of science; Oct. 10, Dr. Bernard Hollander, sound and unsound mind; Oct. 17, Sir Sefton Brancker, the scientific problems of commercial aviation; Oct. 24, Dr. W. A. Bone, the economic aspects of coal; Oct. 31, Prof. H. H. Turner, the fight against fear; Nov. 7, Dr. W. H. Eccles, the influence of wireless on modern life; Nov. 14, Dr. E. E. Fournier d'Albe, eyes and ears of the future; Nov. 21, Dr. G. C. Simpson, meteorology in the service of man; Nov. 28, The Right Hon. Viscount Haldane, the wider meaning of relativity; and Dec. 5, Sir George Newman, the contribution of medical science to human life.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant in the anatomy department of the University of Aberdeen—The Secretary (September 27). A head master for the Eye Grammar School, graduate, science preferred (with agricultural bias)—W. E. Watkins, Hon. Clerk to the Governors, County Hall, Ipswich (September 29). A joint keeper of archæology in the National Museum of Wales and lecturer in archæology in the University College of South Wales and Monmouthshire—The Director, National Museum of Wales, Cardiff (October 16). A senior lecturer in zoology and physiology at Huguenot University College, Wellington, Cape Province, South Africa—The High Commissioner for South Africa, Trafalgar Square, W.C.2. A laboratory attendant for histology in the anatomy department, University College, London—Prof. J. P. Hill, Anatomy Department, University College, Gower Street, W.C.1.

Our Astronomical Column.

THE METEORIC PHENOMENA OF SEPTEMBER 6.—Mr. W. F. Denning writes that a large number of observations have been received of apparently two large fireballs which illuminated the sky in many parts of England on the evening of September 6 at about $20^h\ 30^m$ and exactly at $20^h\ 45^m$ G.M.T. respectively. The data collected have not yet been thoroughly discussed and will necessarily take some time. The first meteor appears to have travelled from a southern radiant northwards and was observed at places so distant as Wanstead, near London, Durham, the south-west of England, and Sunderland. It gave a considerable light and some persons mistook it for lightning, but its motion to north dispelled the idea.

The second meteor made its apparition about 10 or 15 minutes later, and was no doubt the most brilliant object of the pair. Its path was also to the northwards, and it terminated its career by a series of loud detonations when it was some miles south of York. This meteor appears to have given several flashes of dazzling brilliancy; for some observers compared its light with that of the sun. For a moment or two it illuminated the landscape as it is at noonday. Some fragments of this object may possibly have fallen to the ground unobserved in the north-east region of Yorkshire, but no evidence of actual stonefalls has been received. In the district of Selby, and Goole, Yorkshire, the height of the fireball was about 26 miles, and it was decreasing.

The first object seen on September 6 appears to have been of very unusual size and aspect. Did it represent anything of similar nature to the auroral beam which passed over England on November 17, 1882?

THE UNIFORMITY OF THE EARTH'S ROTATION.—M. Bigourdan, of the Paris Observatory, contributes an article to *Comptes rendus de l'Académie des Sciences* for August 30, in which he points out that the comparison of the clocks of a large number of observatories by the aid of wireless time-signals distributed from Bordeaux-Lafayette, Saïgon, Honolulu, and Washington, should afford a very delicate test of the uniformity of the rotational movement. It is not even necessary for this purpose to await the determination of the errors of the different clocks, provided that their daily rates are uniform to 0·01 sec. or thereabouts. Comparison of 100 such clocks will permit the testing of the uniformity of rotation to the order of 0·001 sec. The present time is particularly appropriate, as the International Astronomical Union has arranged for a general series of wireless longitude determinations to be made between October 1 and November 30 next.

A very large number of signals will be recorded at each observatory, but a small number will suffice for M. Bigourdan's purpose, and he asks that observers will communicate to him the Bordeaux-Lafayette signals Nos. 113-122 and 235-244, that is, those just preceding $20^h\ 3^m\ 0^s$ and $20^h\ 5^m\ 0^s$ of Universal Time. The uncorrected clock times of reception of the signals will suffice, and they need only be sent for the period of 30 days, commencing on October 15. It will be remembered that many astronomers, including Prof. E. Brown, now attribute the unexplained irregularities in the moon's motion to changes in the earth's rate of rotation. The inequalities that M. Bigourdan wishes to examine are of much shorter period than these, but analogy leads one to expect that if inequalities are present at all they may have many different periods.

MR. WILK'S COMET ANNOUNCEMENT.—It has now been confirmed that a motion among the stars of a degree in 4 minutes of time was the correct interpretation of the telegram from Cracow Observatory referred to last week, p. 388. Since no further observations have been received, it is evident that the material is insufficient to pronounce definitely in favour of the cometary nature of the object. It may have been a patch of aurora or the trail of a meteor in the upper atmosphere.

Prof. Perrine and his assistants observed a somewhat similar object at Cordoba in May 1916. In that case also its nature remained doubtful, but Miss Glancy showed that, if a comet, it must have approached very near to the earth (even closer than the moon).

Research Items.

THE MAGLEMOSE CULTURE. — Some interesting observations on the genesis of the Maglemose culture were made by the Abbé Breuil in a communication to the Institut Français d'Anthropologie, and are now published in *l'Anthropologie*, T. 36, Nos. 3-4, *à propos* of a characteristic harpoon from Béthune, dated 1840, now in the British Museum. Similar harpoons from the Béthune marshes and from Isbergues near by are recorded. Deer's antlers, pierced and ornamented, from the Somme and Paris described by Acy afford further incontestable evidence of Maglemose influence. Several examples of Maglemosian harpoons have come from Belgium; but in the Musée d'Histoire Naturelle of Brussels are a number of unpublished harpoons found by M. Lequeux in mixed Tardenoisian-Maglemosian sites, and quite recently investigations still going on have brought to light harpoons in which the barbs are made of Tardenoisian triangular implements. A harpoon ornamented in Maglemosian style has also been found at the proto-Tardenoisian level of the Remonchamps site. The opinion already expressed, though not accepted by Scandinavian archæologists, that while Maglemose is related to the Magdalenian, but not directly descended from it, being rather a result of a combination of Magdalenian and eastern elements coming from the direction of the Urals, has received support from the discovery at Wercholensk, near Irkutsk, of an Upper Palæolithic site with harpoons. While the harpoon is a link between Magdalenian and Maglemose, the difference in the decorative art precludes close connexion Even the style of the harpoons found on the peripheral Magdalenian sites of Central and Eastern Europe, like the decorative art, have distinctive characters indicating important ethnic differences. A composite origin for Maglemose is therefore suggested, including provincial Magdalenian of Central Europe, oriental (decorative motives and Campignian forms), a Southern or Mediterranean influence (Tardenoisian), and possibly a late Palæolithic from Scandinavia when Norway was free from ice during the latest oscillations.

PHYSICAL ANTHROPOLOGY OF THE JAPANESE.—A study of the cephalic index and the stature of the Japanese, by Akira Matsumura, is published by the Imperial University of Tokyo as Vol. 1, Pt. 1 of Section 5, Anthropology, of the *Journal of the Faculty of Science*. The chief point that this study serves to emphasise is the marked differences in head form and stature which are to be found among the population. The Japanese, both men and women, are brachycephalic, the men slightly less so than the women, but the mean values of the cephalic index according to locality differ from province to province. The variability in head measurements also differs from province to province. On the whole, the south-western district, which has received the benefits of culture from ancient times, is more variable than other parts where civilisation arrived later. In head-length, head-breadth, and cephalic index, the Japanese differ from the Ainu and Koreans. They appear to resemble closely the people of eastern Siberia and south China. As regards variation, however, the Japanese are less variable than the Koreans in head measurement; but sensibly more so than the Ainu. The stature of men and women has shown a tendency to increase slowly during the last ten years. The variation in stature as between provinces is marked, but not so much as is the cephalic index. The relation of stature to cephalic index is also different for each province. As in the case of head-form, the Japanese in stature resemble the peoples of eastern Siberia, south China, and Indo-China, and not the Koreans or the Ainu. By combining the stature and cephalic index, grouped according to the significance of the differences between means, it is found that the Japanese fall into nine different local groups.

THE EFFECT OF THE GROUP ON MENTAL WORK.—In the *Indian Journal of Psychology* (vol. i. No. 2) N. N. Sen Gupta and C. P. N. Sinha report an interesting piece of research on mental work done in isolation and in the group. Five subjects took part in the experiments and the test employed was the well-known cancellation. The same column taken from a number of copies of a daily paper was given to each subject and he was asked to cancel all the 'a's' and 'e's' for a period of three minutes. Each subject did the test several times alone and also as a member of the group. The writers exercised the frequently neglected precaution of securing that adequate practice had taken place beforehand. The results show a significant difference in favour of working in the group. The reasons for this result cannot yet be given. It would be necessary to know whether other subjects gave the same result, how long such group stimulation could operate, whether different types of people reacted differently. It is a commonplace in industrial occupations that some people prefer to work alone while others dislike it. From the statistical point of view, we would suggest to the writers that the standard deviation or probable errors should be inserted. In this case all the details are given and the reader can work them out, but with larger numbers that would not be possible.

TERTIARY MOLLUSCAN FOSSILS FROM KOREA.—Comparatively little is known concerning the Tertiary invertebrate fauna of Korea, but Jirô Makiyama is now able (*Mem. Coll. Sci. Kyoto Imp. Univ.*, Ser. B, vol. 2) to add somewhat to our knowledge regarding the mollusca. His specimens came from beds in the neighbourhood of Meisen, North Kankyô-dô, which have been divided by the Japanese geologists into two groups: a lower, or Ryûdô group, which contains a rich flora of the so-called 'Arctic Miocene,' and an upper or Meisen group. This last is further subdivided into three members: in ascending order, the Heirokudô, the Kanchindô, and the Mankodô. These J. Makiyama, from their fossil molluscan contents, is lead to infer belong respectively to the Upper Eocene, the Oligocene, and the Lower Miocene. The author comments on the fact that some of the Korean forms recall corresponding ones from Europe, from Nigeria, and California, but none resembles those from the Eocene of either India or Java. The main part of the paper contains the descriptions of the sixteen new species, which form the bulk of the material, and are figured on two well-executed photo-litho. plates.

LAND MOLLUSCA OF PANAMA AND COSTA RICA.—Considerable interest attaches to the land molluscan fauna of southern Central America on account of the light its study should yield as to the region where the typical North American assemblage gives way to that of South America. Dr. H. A. Pilsbry (*Proc. Acad. Nat. Sci.*, Philad., vol. 78) describes and gives a catalogue of all the Panamic land mollusca, including that of the Canal Zone. Seventy-seven species and three subspecies, including nine new species and five new subspecies, referable to thirty-one genera are now

known from this area. Their geographical relations are set forth in a table with indications of the northern and southern limits of the genera and species. It results that thirty-four species have been found only in Panama and the Canal Zone; twenty-four also occur northward; thirteen both north and south; and six species only southward. From these and other statistics it appears that while the transition between the South American and tropical North American faunas is gradual, some genera of each region penetrating far within the other, the change is most rapid in a comparatively short section of the isthmus at and immediately east of the Canal Zone. Some modification, however, may be expected with further research, which may even double the present number of species. Appended are notes on the classification of snails from Mexico to Columbia, referred by authors to Microphysa and Thysanophora. Four new genera, six new subgenera, and three new species result from this investigation. The foregoing is followed by descriptions by the same author of Costa Rica land shells collected by A. A. Olsson. It is a short communication, but yields one new genus, four new species, and one new subspecies. Excellent figures throughout the text and on three plates illustrate the two papers.

A SMALL ULTRA-VIOLET SPECTROSCOPE.—For the convenience of those using ultra-violet light, Messrs. R. and J. Beck have introduced a small quartz prism spectroscope which can be held in the hand and requires no source of light other than that to be observed. The spectrum is formed on a fluorescent screen so that the lines are visible. The scale is in Ångström units and extends from 2000 to 4500, each 100 units being marked.

INTERMITTENCY IN PHOTOGRAPHIC EXPOSURES.—Mr. Raymond Davis, photographic technologist in the Bureau of Standards, Washington, finds that if the exposure is intermittent, such as is produced by the rotation of a sector wheel in the incident light, an equivalent exposure, as compared with the effect on development of a continuous exposure, may give either a gain or a loss (or an intervening zero effect) in the resulting density, according to the intensity of the illumination. That a more intense light gives a gain "has not been heretofore brought out." As an explanation of this result he suggests that the action of light on the silver haloid is not a single step or simple conversion into the developable image, but that there are two actions going on simultaneously which produce respectively a lessening and an increasing of the recipient exposure effect, the more intense light favouring the increase and the feebler light the decrease, during the intervals of nonexposure of an intermittent exposure. These results vary with the nature of the emulsion and the illumination, as well as with the number and duration of the intervening nonexposure periods. The experiments suggest that with illumination intensities higher than 4-candle metres, the growth of the exposure effect during the intervals would probably exceed the fading in all cases.

GASEOUS COMBUSTION AT MEDIUM PRESSURES.—Experiments by R. W. Fenning on air-fuel explosions in closed vessels have been in progress at the National Physical Laboratory during the last five years, and the results relating to carbon monoxide and methane have been published in No. 998 of the Aeronautical Research Committee's reports and memoranda. Two investigations are described, the first deals with the effect of hydrogen-air mixtures and water vapour on carbon monoxide-air explosions in a closed vessel, and the second relates to explosions of methane and air over a range of temperatures and pressures. The report includes tables of explosion temperatures and pressures, and the results are illustrated by reproductions of indicator diagrams under various conditions.

COPPER HYDRIDE AND ITS CRYSTAL STRUCTURE.—The *Journal of the Chemical Society* for July 1926 contains an interesting paper by H. Müller and A. J. Bradley on copper hydride and its crystal structure. *Cuprous* hydride was prepared by a method similar to that of Wurtz, namely the interaction of hypophosphorous acid and copper sulphate. The ratio of copper to hydrogen was determined by combustion, or by a method analogous to the Schiff nitrogen estimation, and was found to agree with the formula CuH. X-ray diagrams were obtained by the Debye powder method and the crystal structure was shown to be hexagonal close-packed with an axial ratio of 1·59-1·60. The X-ray spectrum of the substance obtained by the reduction of copper oxide with hydrogen, or the action of hypophosphorous acid on copper sulphate and copper oxide, which was considered to be *cupric* hydride, corresponded exactly with the spectrum of a mixture of copper and copper oxide. In conjunction with other evidence, the results of these experiments cast considerable doubt on the existence of *cupric* hydride.

THE CATALYTIC DECOMPOSITION OF NITRIC OXIDE.—When exposed to heated platinum wire at temperatures from 1000°-1500°, nitric oxide decomposes into nitrogen and oxygen; and if the products are allowed to cool before the reaction is complete, nitrogen peroxide is formed from the unchanged nitric oxide. This involves a diminution in volume, and the maximum contraction occurs when the oxygen produced is sufficient to combine with all the residual nitric oxide. A paper in the July issue of the *Journal of the Chemical Society* describes the temperature and pressure measurements made by T. E. Green and C. N. Hinshelwood, which prove that the order of the reaction $2NO = N_2 + O_2$ is unimolecular with respect to nitric oxide. It is uninfluenced by nitrogen but retarded by oxygen. Jellinek has shown that the ordinary thermal decomposition is bimolecular; this is, therefore, an example of a reaction which is bimolecular in the gas phase becoming unimolecular at the surface of the catalyst.

ACTIVE NITROGEN.—There are two views as to the nature of the active modification of nitrogen which is produced when an electrical discharge is passed through the gas at low pressures: that it consists either of atoms or of metastable molecules in an excited form. E. J. B. Willey and E. K. Rideal conclude from their experiments on the heat of formation of active nitrogen, which are fully described in the *Journal of the Chemical Society* for July 1926, that metastable molecules are the cause of the activity. The heat of formation was calculated by measuring the rise in temperature in a calorimeter, first when active nitrogen reacted with nitric oxide and secondly when the gas underwent catalytic decay in the presence of the air. By means of a calibrated heating coil in the calorimeter, the temperature changes observed in these experiments were reproduced and the heat equivalent of the reactions obtained. The mean value for the energy content of the active nitrogen was found to be 42,500 cals. per g.-mol.

Patent Office Statistics.

THOSE who are interested in the industrial applications of science will find much that is worthy of their attention in the recently published report of the Comptroller-General of the Patent Office for the year 1925. The report consists entirely of statistics, so that, in the absence of any official commentary, an attempt to analyse some of the figures and to compare them with those given elsewhere may perhaps be of value, for the relation between invention and industrial prosperity is an intimate one. Further, it is of interest to assess the quality of the services rendered to the State by the Patent Office, not only because this is essentially a scientific department, but also because it has been felt for some time past that the Patents Acts cannot be left where they are: and the question whether the desired improvements are practicable is one which depends in great measure on the degree of efficiency with which the existing system is being administered.

The number of applications for British patents filed during 1925, namely, 33,003, exceeded the numbers filed during 1923 and 1924 by 1·1 per cent. and 5·2 per cent. respectively, the corresponding excesses in the case of the United States being 4·3 per cent. and 4·2 per cent. respectively. Too much importance should not be attached to these figures, however, for fairly wide fluctuations are common even in normal times. In fact, when averaged over several years, the annual input of patent applications appears to depend, for countries having comparable patent and industrial systems, mainly on the population of the countries considered: thus, the number of applications per 10,000 of the population is, under normal conditions, roughly 7·5 in Great Britain, 7·3 in the United States, 7·2 in Germany, and 8·7 in Switzerland. In France, however, which is more extensively agricultural and has a backward patent system, the corresponding figure is only 4·8. It is contended by the United States Commissioner of Patents that fluctuations in the input of patent applications are in some sort an index of fluctuations in national prosperity: and though his contention would require considerable qualification before it could be generally accepted, the upward trend of inventive enterprise in Great Britain is satisfactory so far as it goes. The number of patents actually sealed in 1925 was about 52 per cent. of the number of applications filed, and 88 per cent. of the number of complete specifications filed. These figures indicate the extent to which worthless patents are weeded out by the official examination and various other causes, but no figures are given which would enable us to judge the effect of the official examination on the drafting of the specifications finally issued; nor is any information given as to what the United States Commissioner calls the 'gain in dates.' In the United States, the average time which an applicant had to wait for the first official action was reduced in the course of the year from 4·5 to 2·6 months, and the delay in dealing with amendments from 3 or 4 to 2·3 months. Promptness in the issue of patents is of such importance that it would be of interest to the public to know how far the British office has been able to make good the ground lost during the War. It is to be noted that the examining staff has been reduced in strength from 260 in 1913 to 241 in 1925: such economies are desirable in themselves, but the 'gain in dates' is of greater importance, and the public might with advantage be allowed to know how this matter stands.

As regards the nationality of applicants for British patents, it is to be noted that the percentage of these residing in Great Britain fell from 75 per cent. in 1923 to 69·8 per cent. in 1924 and 68·1 per cent. in 1925: at the same time the percentage residing in the United States rose from 8·2 per cent. to 8·9 per cent. and then to 9·6 per cent. Further, it must be remembered that only the best of the foreign inventions will be considered worth patenting outside their country of origin, and consequently the great majority of applications coming from abroad lead to the actual grant of patents. Thus in 1923 (the latest year for which complete data are available) 16 per cent. of the patents actually granted (as distinct from mere applications) were granted to persons residing in the United States, and only 57 per cent. to persons residing in Great Britain: for the previous year the corresponding figures were 15·5 per cent. and 59 per cent. respectively. Of the patents issued by Germany in 1923, 80 per cent. were granted to Germans, 2·1 per cent. to Britons, and 2·8 per cent. to Americans, while Germans took 6·5 per cent. of the British patents and 2 per cent. of the United States patents. These figures are not likely to change greatly, in the absence of unforeseen causes, for they must be ascribed mainly to differences in population between the countries concerned: thus, in the year 1923, while 3 out of every 100,000 Britons took United States patents and 2·3 took German patents, 2·5 out of every 100,000 Americans took British patents and 1·2 took German patents, and 1·6 out of every 100,000 Germans took British patents and 2·4 took United States patents. Out of every 100,000 Frenchmen, 2·5 took British patents.

For the year in question, 6615 or 43 per cent. of the British patents were taken by foreigners, while the corresponding figures for the United States were 4465 or 12 per cent., and for Germany 9127 or 20 per cent. The German patent is thus the most popular among foreigners, as judged by the absolute figures, and its popularity is not due to abnormal economic causes. In 1912, for example, when Germany issued fewer patents than now, 4251 or 32 per cent. of these were granted to foreigners. (The German '*gebrauchsmuster*' are excluded from the preceding figures.) But when we consider *percentages* we find that not much less than half of the monopolies which Great Britain grants for the manufacture and sale of goods within her borders are granted to persons residing outside the country: and we find that this state of things, depending as it does on differences of population, is likely to continue. It is to the advantage or the disadvantage of British industry according as the monopolies granted will be used for the purpose of developing new industries in Britain, or for the purpose of obstructing British manufacture in favour of imports. Examples can be cited in which each of these effects has been produced, but no general statistics are available for ascertaining the balance of good or ill which at present results from the grant of patents to foreigners. The Acts provide that where a patent is being obstructively used, an interested party may apply to the Comptroller-General for the compulsory grant of a licence to work the patent, or for its revocation: but in 1925 *only two such applications were made, and one of these was withdrawn.* It may be mentioned in passing that of the patents granted by Canada, about 70 per cent. are held by persons residing in the United States.

While the Patent Office is not empowered to make an exhaustive investigation into the validity of the patents which it grants, it does make an investigation of limited scope which is relevant to validity: and the Comptroller-General has powers which constitute

him a court of first instance for the trial of certain legal issues. It is of interest, therefore, to see with what degree of efficiency the Patent Office discharges its legal functions. The report before us shows that in 1925 the Comptroller-General, or rather three senior members of the corps of examiners who appear to have acted for him, gave decisions in over 2000 'hearings' under various sections of the Patents Acts, and in 84 'oppositions' brought by interested parties against patents provisionally granted. The quality of the work done in these cases can best be gauged by reference to the decisions of the Law Officers of the Crown, to whom a cheap appeal lies from the findings of the Patent Office. It appears that 27 appeals against the 'opposition' decisions of 1924 and 1925 were disposed of during the year, the official decision being vindicated in 20 cases (including 4 cases of withdrawal), varied in 2 cases, and reversed in 5. The appeals against 'hearing' decisions which were disposed of during the year numbered 42: the official decision was vindicated in 34 cases (including 3 cases of withdrawal) and reversed in 8. Actual figures for the number of hearings held during the year are given for only three sections of the Acts: the number of hearings under these sections was 2088, of which 0·33 per cent. gave rise to successful and 0·86 per cent. to unsuccessful appeals As regards the work of the corps of examiners as a whole, it is to be remarked that while 19,434 complete specifications were examined and 17,199 patents sealed during 1925, the official actions taken have now been accepted by all concerned except in the case of 11 successful and 5 outstanding appeals, unless any further question should arise upon them in the High Court.

In the financial section of the Comptroller-General's report the tables of receipts and expenditure are fairly complete, and take account of such items as depreciation of buildings, the estimated value of pension rights, and the upkeep of the public library; but a more precise statement of the distribution of the staff would be of interest when it is desired to estimate the cost of changes in the patent system. Of the revenue 82 per cent. is derived from Patents fees, 2·4 per cent. from Designs fees, and 9·9 per cent. from Trade Marks fees. The total of Patents fees, namely, 391,677*l.*, is made up of items which may be divided into three groups. The first group comprises items which are likely to give a fairly constant yield in future years, namely, the initial filing and sealing fees (28 per cent. of the whole), renewal fees for the 5th, 6th, and 7th years (24 per cent.), and miscellaneous fines and fees (9 per cent.). The total of these, accounting for 61 per cent. of the yield of patents fees, may be regarded as normal. Renewals for the 8th to the 11th year (of war-time patents) are affected by the War, and their total (18 per cent.), being abnormally low, will improve during the next few years. Renewals for longer periods (21 per cent.) do not yet show the effect of the War, and their yield will therefore fall off for a few years to come. On the whole, therefore, revenue is likely to be stationary, and in the absence of new expenditure the inventor will continue to pay large sums in relief of general taxation. The surplus was 75,203*l.* in 1924 and 88,540*l.* in 1925, after accounting for all imaginable charges and meeting the deficit on publications and the upkeep of the library, which represents a service to the general public. The United States Treasury, on the other hand, subsidised the American Patent Office to the extent of 81,720*l.* in 1924 and 68,150*l.* in 1925, so that the United States subsidises invention to nearly the same extent that Great Britain taxes it.

The financial section of the report is also relevant to the degree of efficiency with which the Patent Office is administered, for under the prevailing conditions the most rigid economy is incumbent, as a patriotic duty, upon public departments. It is extremely difficult to find a standard by means of which administrative economy may be measured, but we can obtain some idea as to how far an economic spirit prevails at the Patent Office by comparing its present scale of staffing with that which obtained before the War, with that which obtains in the United States, and with that which obtains in other comparable Government Departments in Great Britain. We find that whereas the number of patent applications per annum has increased by 10 per cent. as compared with 1913, the strength of the corps of examiners has decreased by about 8 per cent., so that each member is on the average dealing with 20 per cent. more applications now than before the War. The salary bill for this section of the staff is not distinctly shown, but if we estimate the cost-of-living bonus from the average salary and then assume that (in accordance with the Ministry of Labour index) 1*l.* in 1925 was equivalent to 0·57*l.* in 1913, the 'real' or purchasing value of the salary bill appears to have decreased by 6 per cent. As regards the auxiliary staff, there is no sign of any increase in strength or cost disproportionate to the increase in work done, the 'real' salary bill for the whole office being 2 per cent. more than that for 1913. The staffing is roughly on the same scale as that of the United States Patent Office. In each case there are 130 to 140 patent applications per annum per member of the corps of examiners, and the duties in the two cases, though not identical, are probably comparable. Our third comparison may conveniently take the form of a table, the contents of which have been compiled from the Estimates (Class II.) for 1926–7:

Department.	Total staff.	Number of posts with salaries rising to a maximum of		Total of higher posts.	Percentage of higher posts.
		1000*l.* to 1800*l.*	2000*l.* and more.		
Treasury	331	21	11	32	9·7
Foreign Office	830	25	3	28	3·3
Ministry of Transport	524	11	2	13	2·5
Board of Trade (Head Office)	667	8	5	13	1·9
Ministry of Agriculture	1207	14	3	17	1·4
Patent Office, with Trade Marks and Designs Branches	685	4	0	4	0·38

From the point of view of economy, attention may also be directed to the large amount of judicial work performed by the Hearing Officers, as set out above. For men who doubtless have other important duties to perform, the record of 2172 hearings and oppositions is a remarkable one.

The outstanding inferences to be drawn from the Comptroller-General's figures appear, then, to be that an enormous proportion of British patents is held by foreigners, while manufacturers take no advantage of the existing facilities for the grant of compulsory licences; that the legal work of the Patent Office is admirably performed; that the Office is administered in a spirit of economy which deserves particular attention; and that a large annual surplus is available for the improvement of the patent system when this step is considered desirable.

The Royal Photographic Society's Exhibition.

THE Royal Photographic Society's Annual Exhibition is now open at the Society's House, 35 Russell Square, London, admission being free; and it closes on October 9. In the Scientific and Technical Section the items that seem to be the most novel or the least often seen are some results obtained by a combination of the cinematograph and microscope, and a photograph of the ultra-violet spectrum of silicon by Prof. A. Fowler, of the Imperial College. This is done in sections, from wave-length 2820-2420 Å.U. on ordinary plates, from 2250-1840 Å.U. on plates smeared with a fluorescent oil, and from 2150-1250 Å.U. on Schumann plates using a vacuum grating spectograph.

Cinematography is more fully represented than it has been before. Dr. S. Bayne-Jones shows the life-history of the Penicillium, taking the pictures at the rate of two per minute by means of an automatic mechanism which also turns on the light. Dr. S. E. Sheppard and Dr. R. H. Lambert, of the Kodak Research Laboratory, have photographed the electrophoresis of rubber latex particles, the film showing the Brownian movement of the particles and their movements in an electric field. Mr Loyd A. Jones, also of the Kodak Research Laboratory, has studied the growth of crystals using elliptically polarised light and the 'Kodachrome' process, and he contributes films of six different substances in very realistic colours. There are several other films of the more usual type and also a collection of historic films, including the famous train film of Lumière Bros., which was the first ever exhibited to a paying audience (in 1895). Photo-micrography is associated with colour processes in the four autochromes of Dr. C. F. Elam, of the Royal School of Mines, which show at a magnification of × 100 various crystalline forms of silver nitrate taken between crossed Nicols. Dr. L. F. E. Johnson, besides two slides taken in a similar way, has two illustrations of fabrics as they appear under the microscope when illuminated by Rheinberg's differential colour stop, which shows the warp red and the weft blue.

Of the numerous photo-micrographs taken in the usual manner we would direct attention to Dr. G. H. Rodman's series of 24 which illustrate the various forms of hairs occurring on plants which are recognised as liable to produce mischief (sting, etc.) in those who come in contact with them; Mr. J. H. Pledge's 9 photographs (× 10) of an Indian mistletoe that has no leaves; cultural types of meningococci and gonococci from the Lister Institute of Preventive Medicine; and a series of the rabbit embryo in utero and rabbit placenta, each showing various stages in its development, by Mr. G. S. Sansom. There are many others of considerable merit and interest, and a large collection that shows the present results of metallography obtained in numerous laboratories where it is practised, including the National Physical Laboratory. Viewing the photo-micrographs as a whole, the difficulty of getting good results at certain rather low magnifications seems to have been entirely overcome, and they indicate that no more detail is obtained by increasing the magnification above about × 2000.

Radiography and photographic printing in colours are as well represented as ever. The structure of emulsions, and the changes produced in the silver bromide grains, are shown by Mr. L. F. Davidson and the British Photographic Research Association, and Mr. L. E. Jewell shows the advantage of what he calls 'relief illumination' in photo-micrography, that is, the mirror in the vertical illuminator is considerably decentred so that there is a mixture, in regulatable proportions, of oblique specular and diffused light. The General Motors Corporation of Michigan, U.S.A., contributes prints of its Midgley Optical Gas Engine Indicator, which records as curves the character of the combustion in automotive engines. Of the various trade exhibits, those that impressed us most were Messrs Ross's rapid speed photographs of the last test match taken with a 40-inch *f*/8 Teleros lens from outside the ground, and Messrs. Ilford's illustrations of the method of making and testing their light filters

Smoke Abatement Conference.

A CONFERENCE on smoke abatement was held in Birmingham last week, organised by the Smoke Abatement League of Great Britain, in connexion with an exhibition of apparatus and methods bearing upon fuel economy and the abolition of smoke. The conference was divided into two main sections, one of which dealt with the industrial, and the other with the domestic, smoke problem. On the morning of September 7, Mr. J. Robson read a paper dealing with smoke in Bengal, describing the action taken to prevent undue emission. A special smoke commission was appointed, and it was stated that, since 1906, 90·8 per cent. of the smoke from factory chimneys had been abolished—a remarkable achievement. In an evening address on the same day Sir John Robertson, Medical Officer of Health of Birmingham, emphasised the injury done by smoke in obstructing the sun's rays, more particularly the ultra-violet. This affects children especially, and results in a failure to deposit lime salts in the bones and teeth, thus causing rickets and dental decay. It was stated that the exposure of rickety children to sunlight is an almost certain cure if the disease has not progressed too far.

In the conference Dr. Fishenden gave a general summary of the position relative to the low temperature carbonisation problem, and the general trend of the discussion showed that the real difficulties in producing a low temperature coke, suitable for domestic use, are financial and economic rather than technical. Nothing new or of outstanding interest was brought forward in connexion with the industrial side of the smoke problem, but there was a general agreement that the real reason why industrial smoke still remains a serious evil in Great Britain is not any technical impossibility in preventing it, but rather the absence of any special effort to do so on the part of many manufacturers.

On the domestic and housing side of the conference there were several interesting papers—one by Mr. E. D. Simon and Miss Marion Fitzgerald. This gave valuable statistics of the steps taken in different places in connexion with new housing schemes. The Ministry of Health was criticised somewhat severely for "totally ignoring" the recommendation in the Interim Report of the Departmental Committee on Smoke Abatement that "the central housing authority should decline to sanction any housing scheme submitted by a local authority or public utility society unless specific provision is made in the plans for the adoption of smokeless methods for supplying the required heat." This criticism was afterwards replied to by Mr. Poynton-Taylor, chief assistant architect of the Ministry of

Health, who endeavoured to show that they had done as much as they could.

A paper by Messrs. R. Unwin and Poynton-Taylor, chief and chief assistant architects respectively of the Ministry of Health, dealt with the problem of the domestic fire and set out the methods at present available. In the discussion on this there was an expression of opinion against the 'all-electric' house as a possible solution of the smoke problem, owing to the high cost of electricity and the absence of the ventilating effect with electric heaters. Messrs. Unwin and Taylor described the theory of 'zoning,' whereby the factories in a new town should be located outside the town, and on that side where the prevailing wind would blow the smoke away from the living quarters. Dr. Owens criticised the soundness of this principle, suggesting that it is the light anti-cyclonic, rather than the strong turbulent south-west, prevailing wind which should govern the position of factories; concentration and low drift of smoke are characteristic of the former, while dilution—owing to high velocity and turbulence—with the latter makes smoke of less consequence. He therefore suggested that factories should be so situated that the light easterly anti-cyclonic wind does not blow smoke over the living quarters.

Dr. Leonard Hill gave to the conference a paper on ventilation and heating, in which he stated that the most healthful form of heating is by a bright, visible source. He said, "We want, then, an elastic system of heating, not plenum or stove heating with windows all sealed up, but a fire which can be made up or let down, and an open window." Radiant heat and cold air are his ideals of healthful heating

The chief interest in the conference centred round the domestic heating problem and the need for a cheap, smokeless, solid fuel which, apart from ordinary gas coke, is not available in sufficient quantity at present to help materially. Probably the most valuable effect of the conference was to keep before the public the importance of smoke abatement rather than any specific contribution towards the solution of the problem

University and Educational Intelligence.

CAMBRIDGE.—The commemoration of the tercentenary of the death of Francis Bacon will take place on October 5. The University is conferring honorary degrees upon Sir Ernest Rutherford and Prof. William Holdsworth. A reception at Trinity College will be followed by a lecture upon Bacon, by Dr. C. D. Broad. In the evening, Trinity College will entertain a number of guests to dinner.

AN interesting programme of lectures has been arranged by the British Institute of Philosophical Studies for the forthcoming session, beginning October 4. In the Michaelmas term the Hon. Bertrand Russell will give two courses of lectures: (1) on the problems of philosophy, (2) on mind and matter. Dr. T. W. Mitchell will deliver ten lectures on medical psychology. Prof. G. Dawes Hicks will deliver ten lectures on the development of philosophy since Kant. A course on general psychology, by Prof. C. W. Valentine, should appeal to a wide audience. In the Lent term Dr. C. Delisle Burns will lecture on the philosophy of social life, and Prof. J. S. Mackenzie on social values. The Very Rev. Dean Inge, Dean of St. Paul's, has promised to give a course of six lectures on the philosophy of religion, in the Summer term. A full syllabus of lectures can be obtained on application to the director of the Institute, 88 Kingsway, W.C.2.

Contemporary Birthdays.

September 21, 1867. Rt. Hon. Lord Bledisloe, K.B.E.
September 23, 1850. Prof. W. Mitchinson Hicks, F.R.S.
September 23, 1863. Mr. William Lutley Sclater.
September 23, 1850. Prof. Richard von Hertwig.
September 25, 1843. Dr. Thomas C. Chamberlin.
September 25, 1866. Prof. Thomas H. Morgan, For. Mem. R.S.

Lord BLEDISLOE was educated at Sherborne and Eton, graduating at University College, Oxford. Until lately he was chairman of the Lawes Agricultural Trust Managing Committee. In 1922, at the Hull meeting of the British Association, he was president of Section M (Agriculture), delivering an informing, if pessimistic, address on efficient organisation in agriculture and the means of its development. Lord Bledisloe is now Parliamentary Secretary to the Ministry of Agriculture and Deputy Minister of Fisheries.

Prof. HICKS, born at Launceston, was educated at Devonport, graduating 7th wrangler at St. John's College, Cambridge. He was principal of and professor of physics in the University of Sheffield from 1883 until 1905. At the Ipswich meeting of the British Association in 1895 he was president of Section A (Mathematics and Physics). The Royal Society awarded a Royal medal to Prof. Hicks in 1912 for his contributions to hydrodynamics and those on vortex motion. He is Hon. D.Sc., Victoria.

Mr. SCLATER, bearer of a name much honoured in the scientific annals of a past generation, was educated at Winchester and Keble College, Oxford. He was a science master at Eton College, 1891–95; afterwards director of the South African Museum, Cape Town, from 1896 until 1906.

Prof. RICHARD VON HERTWIG, distinguished as a zoologist, emeritus professor of zoology and comparative anatomy in the University of Munich, and director of the Zoological Institute, was born at Friedberg, Hesse. He has specially studied the Radiolaria and the Rhizopoda, whilst he contributed two monographs on the Actiniaria to the reports of the *Challenger* Expedition. Prof. Hertwig is Hon. Sc.D., Cambridge, and a foreign member of the Linnean Society.

Dr. CHAMBERLIN, the veteran geologist, was born at Mattoon, Illinois, U.S.A. He graduated at the University of Michigan. Professor of natural science in the State Normal School, Whitewater, Wisconsin, 1867–1872, he held afterwards the chair of geology in Beloit College from 1873 until 1882, transferring then to a similar chair in the University of Chicago, retiring in 1919. Dr. Chamberlin has rendered valuable geological service to the State of Wisconsin. He acted as geologist in the Peary Relief Expedition of 1894. He is a foreign member of the Geological Society.

Prof. T. H. MORGAN, occupant, since 1904, of the chair of experimental zoology in Columbia University, N.Y., was born at Lexington, Kentucky. He was educated at the State College of Kentucky and Johns Hopkins University. Prof. Morgan is a foreign member of the Royal Society. In 1924 the Society awarded him its Darwin medal for his researches in biological evolution, variation, and inheritance. He is the author of "The Mechanism of Mendelian Heredity" (1915) and "The Physical Basis of Heredity" (1919).

provision should at the same time be made for the scientific study of all those factors on which good administration and material development depend."

After these assurances it is disappointing to find that the Committee, out of the total of 10,000,000*l.*, recommends the allocation of 8,949,536*l.* for railways, ports, roads, and waterways, and allocates only 39,000*l.* for research: namely, 4000*l.* for the Amani Institute, 5000*l.* for the Geological Survey in Tanganyika, and 30,000*l.* for a Northern Rhodesia Research Station at Mazabuka. Applications were submitted for larger sums, including 100,000*l.* by the Government of Kenya Colony for research in native welfare, 50,000*l.* by the same colony for a Veterinary Institute at Kabete, near Nairobi, 5000*l.* for the continuance of the Veterinary Laboratory at Mpapwa, and by the Uganda Government for a grant, amount unspecified, for a Sleeping Sickness Station at Entebbe. These research schemes are either so nebulous or so likely to overlap with other work that the Loan Committee is unable to recommend them without fuller information.

The Committee suggests that 1,000,000*l.* out of the loan should be allotted to roads, waterways, and research; and as out of that amount 547,872*l.* is not yet allocated, the balance appears to offer adequate funds if suitable definite research work is proposed. How much is likely to be used for research is doubtful. Of the 452,000*l.* of which the allocation has already been recommended by the Committee, only 8·6 per cent. is for research; and as the Committee has not included in its recommendations anything for road construction in Kenya, Uganda, or Nyasaland, and has invited alternative proposals for the large grant applied for under this head by Kenya Colony, the expenditure on research under this loan may be quite inadequate.

In regard to the Amani Institute for agricultural research, Sir George Schuster's committee proposes a policy which the Secretary of State states definitely in the preface that " he does not accept." Apparently he intends to appoint a Director and trust him to develop a plan for the work, organisation, and relation of the Institute to the technical departments in the East African territories. The Committee doubts the wisdom of this policy, which is certainly speculative, as its success depends entirely on the selection of a suitable man for an ill-defined post. The Committee recommends that a small commission of the best scientific experts available should determine the scope of the work to be undertaken there. If it should then be found impossible to provide the Institute with the necessary funds, the Committee considers that " it would be better to face the facts and close the institute altogether rather than to attempt to run it with an inadequate and second-class staff."

Either the closing of the Amani Institute or its second-rate maintenance would be a national disgrace as well as a calamity to East Africa. The Institute was established when the locality was in German East Africa; it was planned on magnificent lines, was well equipped, and had in progress work of primary importance. Sir Frederick Lugard's appreciation of the former merits of Amani doubtless inspired his excellent suggestion during the recent discussion at the British Association on African race problems, that it would be an appropriate gesture in the development of Tanganyika Territory to re-appoint some of the former staff. Sir George Schuster's Committee doubts whether a first-rate scientific expert would be willing to accept the directorship of Amani until the future of the Institute be assured. Men considering the appointment might fear the fate of the former Geological Survey of Tanganyika Territory, where the Director would not agree to the Governor setting aside the method of work which had been agreed to when he accepted the appointment. It would appear difficult to select the right man for the post until the scope of the work to be undertaken at Amani has been defined. An appointment on the lines at present contemplated might follow the too common precedent of selecting as director a man of administrative experience and engaging scientific experts to work under him.

That scientific research should develop on economic and sound lines, the Committee recommends the establishment of a sub-committee under the Committee of Civil Research to consider the foundation of " an Imperial organisation of scientific research, with the object of securing the best possible co-ordination of effort throughout the Empire and of deriving full value from all existing organisations." Any scheme for the extension and better co-ordination of research throughout the British Empire is to be welcomed; but the sub-committee proposed would not serve the urgent needs of British East Africa and would not render unnecessary a special organisation for these territories. The duty proposed for the new sub-committee would, moreover, so far as concerns the scientific development of the economic resources of the Empire overseas, overlap with the Imperial Institute, which was established for that purpose. If that Institute is unable to fulfil its functions, it should be made able: it has a large building and a considerable endowment, and there seems no reason to expect a sub-committee of the Civil Research Committee to be more successful. The insistence by Sir George Schuster's committee that the different British East African territories should co-operate, and that each should specialise in the work for which it has the best

opportunities, is unquestionably sound: and it is not the fault of that committee that it has only been able to recommend for research the meagre pittance of less than 0·4 per cent. of the loan. The proposals received were too indefinite. A sub-committee of the Civil Research Committee appears to be the most easily constituted authority to secure a prompt decision as to the research needs of East Africa; and if the sub-committee were successful with those territories, its efforts to secure co-operation and prevent duplication of work might secure for it the wider function with which the Loan Committee would overburden it at the start.

The Theory of the Gene.

The Theory of the Gene. By Prof. Thomas Hunt Morgan. (Yale University: Mrs. Hepsa Ely Silliman Memorial Lectures.) Pp. xvi + 343. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1926.) 18*s.* net.

IN this volume is published the series of lectures on the Silliman Foundation recently given by Prof. Morgan. We are not told when the lectures were delivered, but as the book appeared only during the present year, we may take it as representing the latest pronouncement of the American school of geneticists on these matters. In the first chapter is given a formal statement of the theory of the gene, and in view of the fact that some misconception of what it implies is not infrequently to be found among biologists who have not specially studied genetics, it may be as well to reproduce it here.

"The theory states that the characters of the individual are referable to paired elements (genes) in the germinal material that are held together in a definite number of linkage groups; it states that the members of each pair of genes separate when the germ-cells mature in accordance with Mendel's first law, and in consequence each germ-cell comes to contain one set only; it states that the members belonging to different linkage groups assort independently in accordance with Mendel's second law; it states that an orderly interchange—crossing-over—also takes place, at times, between the elements in corresponding linkage groups; and it states that the frequency of crossing-over furnishes evidence of the linear order of the elements in each linkage group and of the relative position of the elements with respect to each other."

It will be noticed that nothing is stated about the chromosomes; though if the linear order of the elements in each linkage group be accepted, and it is clearly the simplest explanation of the facts as they stand, then the interpretation in terms of chromosomes follows almost as a matter of course. Still, the omission is significant, conveying as it does the recognition of the fact that even if the chromosomal interpretation were ultimately to be rejected, the phenomena of segregation and of linkage, the foundations of the theory of the gene, would remain unaltered. At present, however, there are few signs of weakness in the chromosomal interpretation, and in his chapter on "Chromosomes and Genes" Morgan brings forward fresh evidence from Drosophila in demonstration of its strength.

As might be expected, the fruit fly is much to the fore in this volume, though less so than in Morgan's earlier books on "The Mechanism of Mendelian Heredity" and "The Physical Basis of Heredity." Nevertheless, in the chapters on the "Origins of Mutant Characters," on "Chromosomes and Genes," and on "Genes in Related Species," it figures prominently, owing to the unrivalled material which it offers for discussion. The brief chapter giving a comparative account of the operation and arrangement of the genes in several closely allied species of Drosophila is one of the most interesting in the book, and might well have been expanded. Geneticists will look forward with keen interest to the progress of this work, offering as it does one of the most fruitful lines of attack on the problem of species.

Another chapter of much interest is that in which the author discusses the well-known "Presence and Absence" hypothesis. This generalised view of the relation between dominant and recessive characters has never found favour with the American school, and Morgan devotes many pages and much ingenuity in arguing against it. Some of his cases will certainly not bear the strain he puts upon them. For example, the argument that the 'albino' guinea pig cannot be due to absence of the pigment producing gene, because it often has a few coloured hairs on the feet and toes, at once falls to the ground when it is realised that such animals are not true albinos at all, but very slightly pigmented forms analogous to the Himalayan rabbit. So too the objection that the recessive black rabbit actually has more pigment than the dominant wild grey type at once loses its force when it is understood that the question at issue is not of the grade of pigmentation but of a definite inhibitor for pigment. That this is the proper way of looking at it is clear from Onslow's striking research on the chemical nature of this very case. Again, Morgan argues that since there is a dominant white in poultry, there must, on the Presence and Absence hypothesis, exist an inhibitor for this white factor in the wild jungle fowl. The argument supposes that all domestic breeds are descended from *Gallus bankiva*, but in the light of recent work this is almost certainly not true. As a matter of fact, Morgan admits that it is very difficult

to present any clear-cut evidence against the Presence and Absence hypothesis in contradistinction to the existence of positive recessive genes. In the end he falls back upon the familiar argument from multiple allelomorphs, and here we need not follow him; for if the reader will turn to Bateson's paper on "Segregation," which was recently published in the *Journal of Genetics*, he will realise that this group of phenomena, so often adduced against the Presence and Absence hypothesis, may quite well be regarded as one of its chief supports.

Still, the implications involved in the Presence and Absence hypothesis are of such fundamental importance to the science of genetics, and the difficulty of obtaining decisive evidence between the rival hypotheses is so great, that we may be pardoned for commenting upon a case which seems to provide the best evidence of the kind yet obtained. This is the interesting case of the 'bar-eye' in Drosophila to which Morgan has devoted several pages of his book (pp. 86-91). Experiment has shown that when females homozygous for the dominant bar gene (B) are crossed with the recessive normal male, they produce occasional normal sons. Sturtevant demonstrated that this is due to the fact that in the homozygous barred female an irregular process of crossing-over occasionally occurs which results in one of the X chromosomes carrying both of the bar genes while its mate is left without one. The occasional normal male alluded to above is produced when the gamete carrying the X chromosome that has lost its B is fertilised by the Y chromosome gamete of the male. Now since the X chromosome lacking B has been brought to this state through crossing-over with one that also contains B, it cannot contain that positive recessive gene for normal eye postulated by the American school. In other words, it can contain *nothing* from the bar locus. Yet in association with a Y chromosome which also contains *nothing* it gives rise to the normal eye. Hence the appearance of the normal eye must be due to the *absence* of B, and not to a positive recessive gene corresponding to bar. This is surely as good a demonstration of the validity of the Presence and Absence hypothesis as we can hope to obtain.

Nearly one-third of the book is devoted to an account of forms in which the chromosomes depart from the normal diploid arrangement, whether through the loss of a set as in haploids, or through duplication as in triploids, tetraploids, and polyploids, or else through loss or addition of individual chromosomes as in heteroploids. The author has made use of the interesting material that has recently accumulated in wheats and other plants, and especially in Datura through the remarkable researches of Blakeslee and Belling, and has produced an account which will be at once useful and stimulating to the student. There is rather a lack of synthetical grip in the account, but perhaps this is hardly to be expected when dealing with a branch of study where most of the facts are the outcome of the past few years only, and into which they are so rapidly pouring.

Another third of the book is devoted to the subject of sex considered in its relation to the chromosomes. The outstanding problem here is still the relation between the two groups into which diœcious animals fall, namely, that in which it is the male sex that is heterogametic (the XX-XY type) and that in which it is the female sex that is so constituted (the WZ-ZZ type). Seeing that both types may occur in the same class of animals, as for example in vertebrates, and also in insects, it is difficult to suppose that they will not eventually be harmonised under some common scheme. Morgan inclines to the view that the chromosomes involved in the two types are not homologous, but that the two types have arisen independently through some change in balance. It is not very clear how such a change might be supposed to have come about, and we could have welcomed more discussion on this most important point.

In this portion of the book devoted to sex the reader will find some account of intersexes and of sex-reversal, upon which so much interesting work has been done in recent years. The facts are often accompanied by shrewd bits of criticism which will be of great value to the student, but here again one has the feeling that the author tends to lose grip as he proceeds. The impression conveyed is that of a collection of facts, of the highest interest and fairly set forth, but insufficiently digested, inadequately related to one another. The book as a whole lacks that unity found in Prof. Morgan's other books dealing with heredity—the unity that comes from a thorough assimilation of the facts. We cannot help the suspicion that the author's hand was forced by his appointment as Silliman lecturer, and that if he had had his own way he would have preferred to wait a little longer before writing it. In making such a criticism we do not wish to imply any condemnation of the book. Every geneticist should read it and be grateful to Prof. Morgan. But, judged by the high standard that we have become accustomed to expect from him, we are naturally rather disappointed when he tends to fall below it.

In conclusion, we would direct attention to some errors in the hope that they may be set right when a further edition is called for. On p. 113 a drawing is described as "a periclinal chimaera, S. lycopersicum." It is true that it represents *S. lycopersicum*, but *S.*

lycopersicum is *not* a periclinal chimæra. On p. 175, last line but one, "Fig. 12" should surely read "Fig. 33." On p. 247 the figure of the embryo calves has been so drawn as to omit the direct vascular connexion which was the main point of Lillie's original picture. In the note on p. 265, Crew is quoted as having fertilised the eggs of a hermaphrodite frog with its own sperm. Reference to the original will show that this hermaphrodite only functioned as a male in fertilising the eggs of a normal female. The 'common' cabbage butterfly is a Pieris, not a Colias as given on p. 293. In Figs. 11 and 12 the rules should be arranged as in Fig. 13. In neither case does the male shown on the second line belong to the F_1 generation, nor does the third line represent an F_2 generation as indicated.

One further point may be mentioned in connexion with the bibliography at the end of the book. This runs to some 26 pages and contains numbers of titles to which no reference is made in the text. Yet in the text some 40 papers are quoted for which no reference is given in the bibliography. It is extremely aggravating to the student to find a reference to a paper that he does not know, and to turn to the bibliography to find that it has been omitted; nor is there any consolation in finding the titles of a hundred other papers with which he is already familiar.

R. C. PUNNETT.

Optics—Pure and Applied.

Pp. 737-906. (Berlin und Wien: Urban und Schwarzenberg, 1926.) 7·50 gold marks.

(1) A CERTAIN philosopher once said, "Learn the past, so that you may know the future"; but history appeals very differently to different minds; one sees in it a subject satisfying in itself, while to another the past is dead save in so far as it yields lessons for present and coming days. Prof. Ernst Mach's "Principles of Physical Optics" is bound to make a wide appeal to the many who cannot find much time to go back to the original authors of optical theory and practice, though it must be noted that the matters treated do not extend to the more contentious topics of the present day, such as the nature of light, the problem of the ether, the quantum theory, and so on; they are confined to those older parts of the subject which are adequately treated on the basis of the undulatory theory of light.

It is a common experience that first-hand reference to original books and papers is invaluable. The early investigator was treading a new path, and the subject was developing in his mind in a spontaneous and natural manner. His very mistakes are instructive. The modern text-book, on the other hand, is apt to be written by a much less ingenuous author, who returns to the elementary parts of the theory with a subconscious contempt for, and lack of appreciation of, the difficulties which beset the path of the beginner. Then, again, there are the writers who fail dismally through never having thoroughly mastered the elementary principles of their subjects. On the other hand, an adequate acquaintance with even the works of the main optical writers, Newton, Huygens, Young, Fresnel, and the rest, is a matter for years. Hence the appearance of the book under review will be welcomed, because from its perusal it is possible to obtain a clear idea of the historical development of the subject and of the contributions of the various early thinkers.

It is not a book for the beginner. For such, nothing can take the place of a careful systematic treatment adapted to develop the philosophical sense which is demanded of the reader of the present volume. From its very nature, an historical treatment must deal with matters with which a beginner need not concern himself, such as Newton's "theory of fits." Then, again, the standard of knowledge demanded of the reader of Chapter ii. (on the rectilinear propagation of light) is certainly higher than that of a novice; and the same applies to the several later parts of the book. Nevertheless, it is a valuable book for a teacher or for a student who wishes to get a little beneath the surface of the subject.

The translators have performed their task well, although there are a few places in which the meaning is obscure. The text is full of interest, and the admirable range of portraits gives a human touch to all.

It seems to the writer that one or two references to recent work might well have been added by the translators. For example, the following passage occurs in the description of the Michelson interferometer: "If it is desired to study an interposed substance which is non-homogenous, and upon which the eye must thus accommodate, parallel light cannot be used for this purpose, and the substance may not be traversed *twice* by the rays." Such a statement, although perhaps applicable to the case in

 N 1

question, should not have been passed without a reference to Twyman's modification of the instrument, in which the interposed substances *are* traversed twice by the 'parallel' rays. There is still an unfortunate gap between the optics of the laboratory and the workshop, and there are several places where this is instanced in the present work.

Prof. Mach occasionally manifests an amusing touch of dogmatism. His introductory letter speaks of "the only possible form of immortality." Has he, then, explored the possibilities of life so thoroughly? Dogmatism emerges, too, in the discussion of colour vision. The conclusive nature of the introspective analysis of a series of sensations is taken for granted, and Thomas Young is accused of introducing confusion into the subject! It is to be hoped that this statement may challenge some to go back to Young's own discussion. In another case where a psychological question is involved, namely, the question of light quantities, the book is vague and unsatisfactory. The coming of physical photometry is foreshadowed in terms which give no hint of the many and serious difficulties which have been encountered since 1913, when the German edition of the book was published. Indeed, the statements on p. 20 would lead the unsuspecting to conclude that a physical measurement of the gross energy of "the *illuminating* rays" (whatever that may mean) is an adequate means of finding the "quantity of light emitted from a light source in unit time." We conclude with regret that the 'philosophy' of the book is lamentably lacking where it might be most helpful. This is yet another instance of a clear call for the insertion of a translator's note directing attention to more recent developments. It is not forgotten that the book deals with physical optics, but every text-book ought to indicate the vital points of connexion between its own subject and allied branches of knowledge.

A feature of the book which deserves especial praise is its treatment of polarisation and double refraction. For several years past, the present writer has encouraged optics students to begin the study of these subjects with the simplest apparatus and natural crystals, such as were available to the early workers. In this way they obtain a thorough acquaintance with the main features of the subject; after a day or two of making retardation plates of mica, and using natural crystals of quartz, they are ready to appreciate the quartz wedge; the natural rhomb of spar affords an introduction to the Nicol prism and its modifications. Thus by easy stages the properties of uniaxial crystals become familiar; and how many students are *really* ready to pass beyond this stage in the limited time of college courses? The book adopts a similar method of approach, and, in addition, describes many beautiful experiments which will be new to the majority of readers.

This book, then, may be commended to all teachers who have occasion, in the midst of the multiplicity of subjects comprised in present-day 'physics,' to give some little attention to 'light.'

(2) This volume is a part only of one of the series of 'Handbooks' with which German scientific literature is so extensively equipped. The present section has articles dealing with (*a*) interference refractometers for gases and liquids, by Paul Hirsch; (*b*) ultra-microscopy, by Marie Anna Schirmann; (*c*) refractometry, by Heinrich Kessler. The object of the whole handbook is to explain to biologists the various physical, chemical, psychological, and other experimental methods employed in biological practice; the discussion of the physical instruments is very elementary and non-mathematical; almost unnecessarily so, in fact. Nevertheless, the practical details are well described, such as the determination of the constituents of serum by the use of the interferometer for liquids. The portable gas-interferometer, which has found a use in detecting fire-damp in coal mines, is described.

The section on ultra-microscopy begins with an exposition of the Abbe theory of microscopic resolution, where the author apparently gets mixed with her two equations, then passes on to a good description of the different methods of 'dark-ground' work, and the methods of Siedentopf and Zsigmondy. The fault of these handbooks is that they are apt to give an undue confidence in their completeness. No mention is made of recent British dark-ground condensers of the focussing type. Nothing becomes out-of-date quite so rapidly as the highly technical handbook.

The section on refractometry appears to be reasonably complete so far as German apparatus and methods go, and there is an abundance of practical detail likely to be of use to the chemist or biologist. The differential method of Hallwachs is described by way of conclusion.

L. C. MARTIN.

Direct Realism.

A Theory of Direct Realism: and the Relation of Realism to Idealism. By Dr. J. E. Turner. (Library of Philosophy.) Pp. 324. (London: George Allen and Unwin, Ltd.; New York: The Macmillan Co., 1925.) 12*s.* 6*d.* net.

THIS book is the outcome of a bold and engaging enterprise. It sets out to do two things; first (and chiefly) to cut a clean way through the tangled growth of modern epistemology by justifying the plain man's view that the perceiving mind is in immediate contact with the external world, "as this actually

exists," or that ordinary sense-perception, so far as it goes, "is, in principle, veridical"; secondly, to show that Hegelian idealism is entirely compatible with this supposedly antagonistic realist view.

The second aim is well fulfilled. The last four chapters of the book give a good and well-documented version of what idealism meant for Hegel, and on lines that are not now unfamiliar, pretty completely demolish the charge of subjectivism that for long lay at Hegel's door. But the first part of the book is less satisfactory. One can imagine the sigh of relief that would go up if Dr. Turner or any one else thoroughly established the position which he wants to hold. For 'phenomenalism,' as Dr. Turner sees, is a nuisance to scientific workers and to philosophers alike: and we should all be glad to be persuaded out of it. The trouble is that whenever one starts to reflect upon the process of perception, the extreme complexity of that process drives one obstinately to the conclusion that only by ignoring many plain facts and making some gallant but unverifiable assumptions, is it possible to hold that (to use the simplest terms) 'the-thing-as-it-is-perceived' is 'the-thing-as-it-really-is.' Yet that is what Dr. Turner aims at showing—in his own words, "the existential identity between sensed contents and physical entities" (p. 23).

Dr. Turner's main point is that most of the difficulties have arisen because modern analysis has started its work too far up. It begins with and remains within mature adult experience where the distinction between 'appearance' and 'reality' is already entrenched. If, however, we start at a more primitive and simple level of apprehension, we find it free from that embarrassment, since all sensed contents are there taken as '*inherently* existent.' Standing on this ground, therefore, and carrying forward from it, under the guidance of this realised unity, the analysis of perceptual processes, Dr. Turner concludes that it is possible to regard "the entire series of physical and physiological processes as determining, not the actual existence nor real character of the object of perception, but simply *perception itself* as being also a process, but of a higher order than these preliminary basal processes" (p. 160).

The result is disappointing. For even if one grants the validity of the argument by which this thesis is supported, it is hard to see why it should be held to dispose of all the difficulties which have led to phenomenalism, or to justify the desired conclusion that perception is in principle veridical. Yet it is proper to say that in some of the detail of his argument Dr. Turner breaks new ground in an interesting and hopeful way. His discussion of imagery, for example, is acute and good; and if his review of the "causational aspects of perception" will scarcely bear all the weight which he lays upon it, it is nevertheless fresh and valuable.

It must be added that the first section of the book is sadly ill-arranged. Dr. Turner has gone to enormous trouble to make himself acquainted with the views of all important recent writers on realist epistemology. Unhappily, the very fullness of his knowledge prevents his allowing his own story to tell itself. It has to be gathered largely from his criticism of others—often enough on points of no great material importance. It is a pity that Dr. Turner did not take down his scaffolding. He has written a good book, which might easily have been much better.

Our Bookshelf

(1) *Modern Views on Digestion and Gastric Disease.* By Prof. Hugh MacLean. (Modern Medical Monographs.) Pp. x + 170 + 20 plates. (London: Constable and Co., Ltd., 1925.) 12*s.* net.

(2) *Modern Methods of Feeding in Infancy and Childhood.* By Donald Paterson and J. Forest Smith. (Modern Medical Monographs.) Pp. ix + 106. (London: Constable and Co., Ltd., 1926.) 7*s.* 6*d.* net.

THE value of the "Modern Medical Monographs" edited by Prof. Hugh MacLean has already been indicated in these columns. We now welcome the appearance of two additions to the series.

(1) "Modern Views on Digestion and Gastric Disease" is the contribution of the editor of these monographs. Its object is to provide a general account of the physiology of digestion and to indicate the main principles in the treatment of gastric disorders. The early chapters summarise the process of digestion, and include references to the more recent methods of gastric investigation, such as the fractional test-meal. The author emphasises the importance of recognising as a normal feature of digestion the existence of regurgitation from duodenum to stomach, which until recently was looked upon as an abnormal occurrence. The greater part of the book is devoted to the consideration of the main gastric diseases and their diagnosis. Perhaps the most controversial section is that dealing with the etiology of gastric carcinoma. Prof. MacLean records considerable evidence to refute the teaching of many pathologists and surgeons that this condition is often preceded by ulcer. The observations on the great differences in duration of symptoms of gastric ulcer and gastric cancer suggest very strongly that malignancy arising in an ulcer is rare. The section on treatment indicates the importance of basing therapy on physiological knowledge. The book is well illustrated by radiograms, and will be of great assistance to student and physician in the study and treatment of gastric disease.

(2) "Modern Methods of Feeding in Infancy and Childhood." An understanding of this subject is as necessary to the general practitioner as a sound knowledge of digestive disturbance in adult life. Dr. Paterson and Dr. Forest Smith urge the importance of insisting on breast-feeding wherever possible. The difficulties which may arise in connexion with this are

discussed and various methods of artificial feeding are indicated. A number of diet tables are given, covering the period of childhood up to the age of five. If the physician will remember the authors' reiterated maxim that feeding must be varied to suit the individual, he will find this book a very useful guide in an important branch of his practice.

Surveying. By Dr. W. Norman Thomas. Second edition. Pp. viii + 548. (London: E. Arnold and Co., 1926.) 25*s.* net.

THIS second edition differs but little from its predecessor. A few more corrections, a revised section on air survey (or "aerial survey" as the author calls it), and an appendix on pivotal errors in theodolites constitute the changes. The book is written for students of civil engineering. Naturally, therefore, it is a text-book on engineering rather than on topographical surveying, and it lacks the practical hints, and models of computation, which should be included for the latter purpose. The civil engineer will, however, find in it a clear explanation of all the methods he is likely to employ. Unlike many authors of works on surveying, Mr. Norman Thomas is at pains to examine the precision of each method he describes. He does so with conspicuous success, and illustrates his mathematics by examples drawn, in the main, from surveys in Great Britain and in the Empire.

There are one or two odd points in the author's sequence. He refers to maps in the chapter on chain surveying, and none of those referred to save those published by the Ordnance Survey were made with the chain. Again, to most of us surveyors, triangulation is the usual preliminary and the most useful friend. It comes late in the book, and when it comes this chapter does not stress sufficiently the importance, in any type of survey, of the theodolite. British theodolite design is diminishing the lead which some continental manufacturers have been allowed to acquire. It is a pity, then, that in his note on "Recent Developments in the Construction of Surveying Instruments" (included in the appendix on pivotal "Errors in Theodolites") some mention of new theodolites has not been made. Nowadays, when labour and transport are so heavy an item, it is more than ever important to get the best of instruments and to economise in time and weight. These, however, are small points, and every surveyor will be well advised to get and study this volume.

An Introduction to Practical Biology: a Course of Work based chiefly upon the Plant and arranged for Use without Special Apparatus in either the Class-room or the Home. By Norman Walker. Pp. viii + 224. (London: Sir Isaac Pitman and Sons, Ltd., 1926.) 5*s.* net.

ONE of the hindrances to the more frequent introduction of science subjects into the schemes of study under the tutorial class movement has been the difficulty of arranging for the practical work necessary to supplement the theoretical side, if the subject is to be at all successfully taught. Dr. Walker, who has had a long experience of the tutorial class movement in the north of England and has a wide knowledge of the needs and difficulties of adult students of this kind, has outlined a series of practical exercises illustrating some of the elementary principles of biology which can be carried out in the class-room or the home, without any special or elaborate apparatus and at a comparatively trifling cost. The work is based chiefly on plants, but certain exercises involving the use of animals are included. The student is guided, in clear and simple language, through a series of experiments and observations on the structure, physiology, and chemistry of plants and animals, sexuality and fertilisation, inheritance and variation, while the implication of such knowledge on the problems of human society is not overlooked.

The book is admirably conceived and meets a distinct need. It is becoming increasingly necessary that some knowledge of biological principles should form part of the educational equipment of all men and women. Dr. Walker's book shows how this can be acquired in a simple and inexpensive manner, and points the way to a wide dissemination of such knowledge through the medium of tutorial classes for adult students.

A Monograph of the British Lichens: a Descriptive Catalogue of the Species in the Department of Botany, British Museum. Part 2. Second edition revised. By Annie Lorrain Smith. Pp. ix + 447 + 63 plates. (London: British Museum (Natural History), 1926.) 20*s.*

A SECOND edition of Part 2 of the well-known "Monograph of the British Lichens," published by the British Museum, has just appeared. Part 1 of the first edition was prepared by Crombie and published in 1894. Part 2, elaborated by Miss A. Lorrain Smith, was published in 1911. Miss Lorrain Smith then proceeded to the difficult but useful task of revising part 1 (1918): she has now laid lichenologists under a further debt of gratitude by revising and bringing up-to-date her own volume, part 2. She states in an introductory note that there are no fundamental changes in the new edition, though the addition of many species, some rearrangement of genera and species, and other alterations will be noted. Only those who have worked at the small saxicolous lichens can fully appreciate the time, care, and patience which are required in describing and naming this group of organisms. British lichenologists are singularly fortunate in having a flora thoroughly up-to-date, and by an authority such as the author, provided in the excellent series of monographs published by the British Museum.

Hydrology and Ground Water: a Practical Text-Book for the Use of Civil Engineers, Surveyors, Students, and all those who deal with the Control of Water. By J. M. Lacey. Pp. viii + 159. (London: Crosby Lockwood and Son, 1926.) 12*s.* 6*d.* net.

WITHIN about a hundred and fifty pages the author has attempted to condense a treatment of the various phenomena associated with rainfall and ground water. Naturally the treatment is summary in places. The earlier chapters on rainfall, especially the sections on cycles of rainfall, are least satisfactory, and would require to be expanded if the volume were to be of general value. But it is planned chiefly to meet the needs of the water engineer, and for this purpose it is certainly well arranged, clear, and useful. The chapters on wells and water storage are of particular value.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

On the Oxygen Spectral Line $\lambda = 5577{\cdot}35$ Å.U.

A NUMBER of investigators, including Merton, Barratt, Johnson, Cameron and others, have shown that the spectrum of an element in the gaseous state can be profoundly modified if an electric discharge be passed through it when one or other of the rare gases helium, neon, argon is mixed in excess with it.

For example, Merton and Pilley showed that by this method it is possible to enhance greatly the arc spectrum of atomic nitrogen and even to isolate it completely from the spark spectrum of this element.

Again, it was shown a year ago by McLennan and Shrum that a line of weak intensity existed at λ 5577·35 Å.U. in the spectrum of oxygen, and that this line could be considerably strengthened when helium or neon were added in excess to oxygen excited by the passage of an electric discharge through it

As McLennan and Shrum put forward the view that this line in the spectrum of oxygen is identical with the famous "green line" λ 5577 Å.U. observed in the spectrum of the light from the night sky, and in the spectrum of the aurora, we were led to engage during the past year in a rather exhaustive study of the main characteristics of the line. The results of this investigation will be given in detail elsewhere, but in the meantime we think it well to state here a few results that are of special interest now.

(1) The spectral line λ 5577 Å.U. has been shown to be obtainable with pure oxygen and with intensity the strongest when the gas is at a pressure of two millimetres of mercury and the exciting electrical discharge is passed through a tube about one metre long and three centimetres in diameter.

(2) When currents varying in strength up to 160 milliamperes were used, the intensity of the line steadily increased with the strength of the exciting electrical current.

(3) A new series of measurements has shown that the wavelength of this spectral line is very close to λ 5577·35 Å.U.

(4) This spectral line, λ 5577·35 Å.U. has never been observed in our experiments in the spectrum of any electrical discharge in the absence of oxygen.

(5) When an electrical discharge was passed through oxygen at a pressure of 2 mm. of mercury mixed with helium, the line was obtained with strongest intensity when the partial pressure of the helium was about 20 mm. of mercury.

(6) A series of carefully executed experiments has shown that the power possessed by the rare gases of enhancing the oxygen line λ 5577·35 Å.U., assuming the strength of the line in oxygen alone to be 1, is as follows: helium 1·7, neon 4·6, argon 84·2.

(7) When argon in excess was mixed with oxygen the line λ 5577·35 Å.U. was obtained with an intensity greater than that of any known line in the spectrum of atomic oxygen having a wavelength shorter than λ 6000 Å.U.

(8) Observations with a powerful echelon spectrograph showed that the oxygen line λ 5577·35 Å.U. is simple and without any fine structure.

(9) In studying the Zeeman effect with the line λ 5577·35 Å.U. it was found that magnetic fields of weak to moderate intensity produced a symmetrical broadening of the line, the magnitude and the character of this broadening being of the order and of the nature respectively of that usually shown by spectral lines having an atomic origin.

(10) It would appear that this spectral line λ 5577·35 Å.U. originates in an electron transition between atomic levels for oxygen provided by one or other of two new singlet-triplet schemes that were based on Hund's theory and were recently put forward (*Proc. Roy. Soc.*, July 1926) by McLennan, Grayson Smith and McLay.

Interference and Corpuscular Light.

IN the new wave theory of matter (Einstein, L. de Broglie, Schrödinger), the material point is conceived as a singularity in a wave. More precisely, in the absence of any field of force, the wave phenomenon called 'material point' is represented by a sinusoïdal solution of the equation:

$$\Delta u - \frac{1}{c^2}\frac{\partial^2 u}{\partial t^2} = \frac{4\pi^2}{h^2} m_0{}^2 c^4 u, \quad . \quad . \quad (1)$$

where m_0 is a constant characteristic of the wave (proper mass of the material point). The function u has a uniformly moving singularity which *is* the material point. If the point at rest has a spherical symmetry, then the solution of (1) will be (the line of motion being chosen as z axis)

$$u = \frac{A}{\sqrt{x^2 + y^2 + \dfrac{(z - vt)^2}{1 - v^2/c^2}}} \sin 2\pi\nu\left[t - \frac{vz}{c^2}\right].$$

Further, the energy of the moving point is identical with the product $h\nu$.

In the special case of the light quant, we must suppose m_0 to be equal to an extremely small quantity if not to zero. Then the wave equation (1) reduces to the classical form:

$$\Delta u = \frac{1}{c^2}\frac{\partial^2 u}{\partial t^2}. \quad . \quad . \quad . \quad (1')$$

For each problem of interference or diffraction, classical optics tries to find a solution of the form:

$$u = a(x, y, z)e^{2\pi i\nu[t - \phi(x, y, z)]}, \quad . \quad . \quad (2)$$

satisfying the adapted limiting conditions. But, for the new mechanics, the motion of the light quants is given by a solution of (1′) of the form:

$$u = f(x, y, z, t)e^{2\pi i\nu[t - \phi(x, y, z)]}, \quad . \quad . \quad (3)$$

where the amplitude f has many moving singularities. The function ϕ is to be the same in (2) and (3), and the singularities, *i.e.* the light quants, must describe the curves normal to the surfaces ϕ = Constant.[1] In substituting (2) and (3) in (1′), we get the two following relations connecting the classical amplitude a and the 'granulated' amplitude f, respectively, with the phase-function ϕ:

$$\frac{2}{a}\frac{\partial a}{\partial n} - \frac{1}{a^2}\frac{\partial(a^2)}{\partial n} = -\frac{\Delta\phi}{\partial\phi/\partial n}, \quad . \quad . \quad (4)$$

$$\frac{\partial\phi}{\partial n}\cdot\frac{\partial f}{\partial n} + \tfrac{1}{2}f\Delta\phi = -\frac{1}{c^2}\frac{\partial f}{\partial t}, \quad (5)$$

dn being an element of trajectory.

[1] Of course it remains to prove the existence of such a solution of equation 1′ in each case.

Now, by analogy with the solution for the free spherical material point, we can suppose that the quantity $f/(df/dn)$ is zero at the points occupied by the light quants at a given instant. Then the velocity of a quant in passing by a point M will be, for example, 5:

$$v_M = \left(- \frac{\partial f/\partial t}{\partial f/\partial n} \right)_M = c^2 \frac{\partial \phi}{\partial n}. \quad . \quad . \quad (6)$$

The motion of the quants is permanent and $-c^2\phi$ plays the part of a velocity potential.

But, during the motion, the number of quants remains constant and along a very thin tube of trajectories, we must have:

$$\rho \sigma v = \text{constant}, \quad . \quad . \quad . \quad (7)$$

where ρ is the mean density of light quants in the wave and σ the section of the tube.

Hence, we conclude that:

$$\frac{1}{\rho}\frac{\partial \rho}{\partial n} + \frac{1}{v}\frac{\partial v}{\partial n} + \frac{1}{\sigma}\frac{\partial \sigma}{\partial n} \quad (8)$$

But infinitesimal geometry teaches us that the last term of the first member is equal to twice the mean curvature of the phase surface. Thus, equation (8) gives easily:

$$\frac{1}{\rho}\frac{\partial \rho}{\partial n} = - \frac{\Delta \phi}{\partial \phi/\partial n}, \quad . \quad . \quad . \quad (9)$$

and by comparing (9) and (4) we see that:

$$\rho = c \, . \, a^2. \quad . \quad . \quad . \quad . \quad (10)$$

The density of light quants is to be taken proportional to the classical intensity. In the dark fringes of the classical theory, the density of quants will be zero, but in a bright fringe a great number of quants will pass. Now, the motion being permanent, this explanation of the experimental facts will still be available if the light is very weak (Taylor's experiment), we have only to define the density of quants by a time average instead of a space average.

LOUIS DE BROGLIE.

Paris, August 27.

Science and Psychical Research.

I HAVE read the editorial note appended to the letters on this subject published in NATURE of September 11, and desiring to keep within the limits that you wish to be observed in this discussion, I have tried strictly to confine myself in the following remarks to replying to allegations against myself made by Sir Arthur Conan Doyle in that issue, as also to the specific points raised by Dr. Tillyard in his rejoinder to my letter on this subject published in NATURE of August 28.

Sir Arthur Conan Doyle states that my account of the incidents connected with the Combermere photograph, published in the issue of August 28 "is both inaccurate and misleading." It will, I think, be sufficient to direct attention to one only of Sir Arthur Conan Doyle's statements, to show whether he is, or I am, the more accurate person. After telling how I challenged him to publish, in the *Morning Post*, the ghost photograph alongside a photograph of the peer taken in life, Sir Arthur Conan Doyle goes on to say (italics are mine) —" I at once sent up my photograph *without any suggestion whatever that it would not reproduce*. That statement is a pure invention on the part of Mr. Campbell Swinton."

In reply to this, may I quote the opening sentence of Sir Arthur Conan Doyle's letter to the Editor of the *Morning Post*, published in that paper on April 23? It is as follows:

" I beg to enclose the Combermere photograph. I am advised that it will not reproduce, but you will be the best judge of that."

These two entirely contradictory statements, both from the pen of Sir Arthur Conan Doyle, show how little reliance can be placed upon the accuracy of what he writes, and I therefore do not propose to make any further reference to the remarks contained in his letter to NATURE except to say that they consist of a tissue of misrepresentation, together with a number of statements which are no more accurate than the one quoted above.

With regard to Dr. Tillyard's rejoinder, I should like, first of all, to say how much I appreciate the spirit in which he has accepted what may have seemed to him my somewhat provocative criticisms. I must, however, further criticise what he now says.

Dr. Tillyard complains that I do not distinguish between spiritualism and psychical research; but, so far as I can see, the only distinction between the two is that the second includes the first, while I may add that, though the heading under which it appeared was "Science and Psychical Research," Dr. Tillyard's article purported to be a review of a "History of Spiritualism."

Nowhere have I ever suggested that the medium is one of the experimenters, as Dr. Tillyard surmises. On the other hand, I cannot agree with him that the medium is a mere instrument, such as a microscope or spectroscope, for, quite apart from the question of free will, which is probably an illusion, due to the same portion of the brain being concerned in determining both our wishes and our actions, human beings have consciousness and motives, which are things possessed by no man-made instrument or mechanism.

Dr. Tillyard states, "If a medium is found to be fraudulent, then the genuine psychical researcher will not proceed with him, but will endeavour to find a more trustworthy one." But this, anyway, was not the method adopted by Crookes, who, I suppose Dr. Tillyard will agree, was one of the greatest of psychical researchers. If we are to believe the authorised life of Sir William Crookes, written by Dr. Fournier d'Albe, "Crookes does not seem to have taken up the medium (Miss Cook) seriously until after she had been exposed by a Mr. Volckman, who seized 'Katie King' (supposed to be a spirit) and found himself holding the medium (Miss Cook) dressed up."

Furthermore, Miss Cook, who had by then married and become Mrs. Corner, was again exposed by seizure, when masquerading as a spirit, by Sir George Sitwell, the well-known baronet. A detailed account of this exposure will be found under the heading "Capture of a Spirit" in the *Times* of Jan. 12, 1880, while in the *Times* for Jan. 15 following, there is a letter from the secretary of the British Association of Spiritualists (on whose premises the seance was held), on behalf of the council of that body, stating that Sir George Sitwell's account of what occurred was substantially correct. Sir George Sitwell quite recently told me that this complete exposure, which had wide publicity, made so great a sensation that it nearly wrecked the whole spiritualistic movement of that time; so Crookes must have known all about it. Yet, a few years later, as recorded in Sir Arthur Conan Doyle's history, we find Crookes giving an unqualified testimonial as to the bona fide mediumship of this twice-convicted impostor.

All scientific men hold Crookes in the highest veneration both as a physicist and as a chemist, but what can they think of his judgment in respect to spiritualistic matters, having regard to what is disclosed above?

Dr. Tillyard mentions the names of Crookes and of four other scientific men who studied spiritualistic

phenomena, and then asks me whether I can name a single one of these who did not become convinced of their genuineness. Surely this is a case of begging the question, as these are the particular five who did become convinced; but what about the others? What about Faraday, Tyndall, Sir David Brewster, and Dr. Carpenter, among those who are dead, and Prof. R. W. Wood of the U.S.A., Sir E. Ray Lankester, and Sir Bryan Donkin among those who are living? All these and many others have, I believe, made sufficiently serious investigations into the subject, though naturally, having come to the conclusion that there was nothing genuine in the phenomena warranting further research, they did not publish so much as other no more eminent, though perhaps more credulous investigators.

It may also be mentioned that, in 1908, a committee, including such eminent photographic experts as R. Child Bayley, F. J. Mortimer, and E. Sanger-Shepherd, though assisted by such a well-known spiritualist as Mr. A. P. Sinnett and others, failed to secure proof that spirit photography is possible.

Dr. Tillyard suggests that I should visit the National Laboratory for Psychical Research, but I must confess that I am not attracted by its name, which with its suggestion of parallelism with the National Physical Laboratory, seems to me to be *suggestio falsi*. I am informed that it is a purely private concern, with nothing national about it whatever. Apart from this, however, in my opinion thermographic phenomena in connexion with mediums are more a matter for a physiologist than for a physicist. That emotional disturbances affect the temperature of the body is, I think, fairly well known, and there does not seem to me to be any reason for dragging in such supernormal and incredible phenomena as the production of ectoplasm and such like in order to explain what are only commonplace matters. But then, all psychical researchers seem to delight in the maxim *omne ignotum pro magnifico*.

The Structure of the Continents.

As all the continental discussions of the observations of near earthquakes have been carried out by graphical methods, and as I could not satisfy myself as to the precision obtainable by these methods, I have recently carried out a rediscussion of the principal series of data by the method of least squares. These refer to the Kulpa valley earthquake of 1909, the Wurtemberg one of 1911, the Tauern earthquake of 1923, and the Oppau explosion. The results indicate very definitely that there is an upper layer that transmits compressional waves with a velocity of 5·6 km./sec. (though a velocity of 5·4 km./sec. would fit the Oppau explosion slightly better) and a lower one where the velocity is 7·8 km./sec. In addition, the Tauern earthquake gave rise to a wave with a velocity of 6·2 km./sec., which must have travelled in an intermediate layer. The probable error of all these velocities does not exceed 0·1 km./sec. The result for the upper layer corresponds to that found for granite by E. D. Williamson and L. H. Adams. The recent work of L. H. Adams and R. E. Gibson gives a velocity of 6·4 km./sec. in basaltic glass, and of 8·4 km./sec. in dunite, at ordinary temperatures and at pressures corresponding to depths of some tens of kilometres. If we allow for the higher temperatures within the crust, the basaltic layer below the granite may be in a glassy state, as Daly has suggested, and the lower layer may well be dunite. The evidence indicates that there is no further sudden change to a depth of about 1200 km.

The times of arrival of all the waves were linear functions of the epicentral distance; the consistency of the observations was great enough to give good determinations of the gradients of these functions, and hence of the velocities, but it was not enough to establish any departure from linearity. Hence there was no material for a determination of the depths of the foci or of the variation of velocity with depth in the various layers. By combining the results for near quakes with those for distant ones, however, it was possible to estimate the rate of increase of velocity with depth in the lower layer.

The observations permit a rough determination of the depths of the granitic and basaltic layers. The former may be about 12 km., the latter about 20 km., but both are subject to an accidental error of about 4 km. In addition there is a possibility of systematic error. Uncertainty as to the depth of focus may allow the thickness of the granitic layer to be doubled. On the other hand, the movement on the seismogram due to the indirect waves starts more gradually than that due to the direct one, and this may cause a slight delay in their measured time of arrival, especially as most of the observations seem to have been made on instruments recording on smoked paper. On this ground the depths determined may require some reduction.

I think, therefore, that determinations of the depths of the layers by means of near earthquakes are not more reliable than those based on the earth's thermal state, isostatic balance between continents and oceans, and the group-velocities of surface waves. All of these are affected by uncertainty concerning the thickness of the basaltic layer, but the uncertainties of the method based on the compressional waves from near earthquakes appear more serious. The results, taken as a whole, are as consistent as can be expected; a thickness of 10 to 15 km. for each layer would be within the range of uncertainty of every method.

Curved Path of Wireless Waves.

IN a recent number of the *Proceedings of the Royal Society* (Series A, vol. 111, N.S. 757) there appears under the title of "Discussion on the Electrical State of the Upper Air," a paper giving the views of several of the authorities who have contributed to the examination of this subject.

The discussion really turns on the question as to why wireless waves follow the curvature of the earth instead of spreading into space.

Heaviside supposed that this was due to a hypothetical conducting layer of the atmosphere existing at a great altitude above the earth's surface, which would act as a reflecting barrier and would compel the wave to remain within the envelope formed by it. Only one contributor to the discussion referred to refraction and diffraction as possible causes.

If it were assumed that the speed of long waves is the same as that of ordinary light, and depends in the same way on the density of the air, then refraction would account for, roughly, one-tenth of the observed deflection. I believe, however, that there are no direct measures of the velocity of long waves, and there is no sufficient knowledge of the nature of the 'ether' or of its relation to ponderable matter to allow of any certain, or even probable, theoretical deductions on this point.

As regards the velocity of visible light in air, the shorter the wave-length the less the velocity, but if it is true that X-rays are only shorter but otherwise similar waves, then since it is found that their refractive index for all substances through which they can pass is practically unity, there must be, at and after a certain shortness of wave-length is reached, a condition in which a decrease of wave-length is accompanied by an increase in velocity.

At the other end of the spectrum (where wireless wave-lengths are reckoned in miles) it seems not impossible that there may be a drop in velocity as the wave-length increases, although at present a physical explanation may be wanting.

A case of diminished velocity with increased period would occur in air if the waves were of such great length that the heat due to compression had time to diffuse. For such waves the velocity would tend to approach that given by Newton.

If it were found that for 'wireless' waves the velocity increased about one part in four thousand (the velocity of light is scarcely known to this degree of accuracy) per mile of height above the ground, the reason for such waves following the curvature of the earth would require no further explanation, and until experiment proves that there is no such change, it would be reasonable to impute the observed curvature of path to this kind of cause.

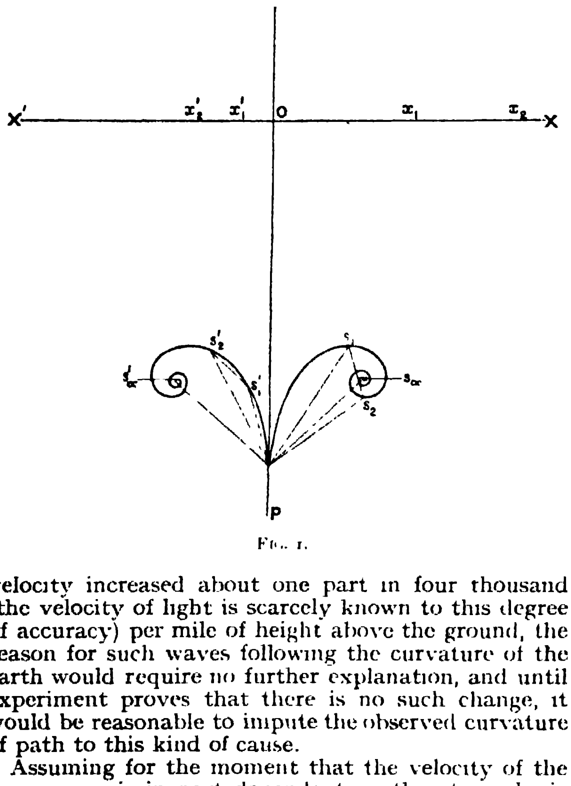

FIG. 1.

Assuming for the moment that the velocity of the long waves is in part dependent on the atmospheric conditions and increases with the elevation, it is certain that it will vary at different parts of the earth's surface, and this being so, the variation in the intensity and direction of trains of long waves would be only a leisurely analogue of the 'twinkling' of the stars.

Diffraction would have a slight effect in favour of increasing the audibility of signals when the observing station was within the 'shadow' of an obstruction, but this would only be noticeable for distances which were small fractions of the earth's radius. Diffraction would also cause variations of intensity at different levels above the boundary of the shadow, but it is unlikely that these 'bands' could be recognised without some instrumental aid in comparing intensities.

Nearly fifty years ago I gave [1] a graphical construction for determining diffraction effects, which as it was not published and is of very general application, I reproduce below.

Let it be required to know the intensity of the light at a given point in the normal to a wave surface.

For simplicity let the problem be one in two dimensions, and the wave surface be a line $X'OX$ (Fig. 1) emitting co-phasic waves confined to the plane of the paper. It is required to know the intensity at P due to all the partial waves emanating from $X'OX$.

Starting from P draw the curves S and S', such that the elements of arc at S and S' are proportional to the amplitude at P of the waves received from the elements dx and dx' at x and x', and also that the angle which the tangents at S and S' make with the normal OP, are the differences in phase in which the partial waves from x and x' reach P from the corresponding phase of the wave from O. Then the square of the chords PS and PS' are proportional to the intensity of the light which reaches P from either side of the normal between the limits x and x', and the total intensity at P is the square of the resultant of PS and PS' and the phase is given by the angle which the resultant makes with OP.

If x and x' are both infinite the intensity is given by $2PS^2_\alpha$, and the phase is the same as that which reaches P from O.

If $x = \alpha$ and $x' = 0$ the intensity is PS^2_α, and the phase differs from that of the wave from O by $\pi/4$. (This is the intensity at the edge of the geometrical shadow of O.)

If the source of illumination consists of disconnected portions of the line XOX', lying, say, between the limits x_1x_2, x_3x_4, etc., the resulting intensity at P due to each portion will be given by the squares of the chords s_1s_2. s_3s_4, etc., and the square of the resultant of these chords will give the total intensity.

The formal proof of this construction is simple and need not occupy space here.

I have recently been told that a somewhat similar construction was given by Cornu, but this I have not seen.

Schroedinger's Quantum Theory and the Stark Effect.

THE theory of atomic oscillations recently advanced by Schroedinger is of extraordinary importance since it throws a new light on the problems of atomic structure and, at the same time, offers a convenient practical method for calculating the Heisenberg-Born intensity matrices. It seemed desirable to apply it to as many special cases as possible. A complete theory of the Stark effect in hydrogen was, therefore, developed.

The first order effect (displacement of lines proportional to the first power of the electric field) turned out to be identical with that obtained by the writer on the basis of Bohr's theory (*Ann. d. Phys.*, 50, 489, 1916). The second order effect (displacement proportional to the square of the field) differs slightly from the expression found in the old theory by the writer (*Ann. d. Phys.*, 51, 184, 1916) and independently by Mr. Mosharrafa (*Phil. Mag.*, 46, 753, 1923). The dependence of this term on the three quantic numbers n_1, n_2, n_3 is expressed in the new theory by

$$-(n_1+n_2+n_3)^4\{17(n_1+n_2+n_3)^2-3(n_1-n_2)^2 -9n_3^2+18n_3+10\},$$

while in the old theory the terms $18n_3+10$ were

absent. Messrs. Takamine and Kokubu found a slight second order displacement of the central components of the H_γ line in a field of 130 kilovolts. Both formulæ give for this displacement practically the same value of 0·3 Å.U. in the right direction (while the absolute value of 0·3 Å.U. seems of the right order of magnitude, but somewhat smaller than the observed shift), so that the additional terms do not permit us to distinguish in favour of either theory.

Most interesting are the new intensity formulæ—comparatively simple closed expressions. It is known that in the old theory the correspondence principle was not sufficient to account for the intensities completely and that certain orbits ($n_3=0$) had to be eliminated by a special ruling prohibiting the electron from falling into the nucleus. Such a dualism is not necessary in the new theory; the state $n_3=0$ simply does not occur, and there is no need of any artificial restriction. So far, only the intensities of the *p*-components have been calculated. Comparing the calculated values with Stark's observations, the writer found the same situation which was stated by H. N. Russel in his work on intensities of multiplets (NATURE, 115, 835, 1925). The values estimated by observers agree, not with the calculated intensities, but with their square roots, *i.e.* with the absolute values of the amplitudes. Allowing for this, the agreement is fair, as appears from the following tables:

H_α line.			H_β line.		
Z.	Obs.	Calc. Ampl.	Z.	Obs.	Calc. Ampl.
2	1	0·8	0	1·4	0
3	1·1	1·1	2	1·2	1·8
4	1·2	1·3	6	4·8	4·8
			8	9·1	8·3
			10	11·5	9·9

H_δ line.			H_γ line.		
0	0	0	2	1·6	1·6
4	1	0·8	5	1·5	1·7
8	1·2	0·8	8	1	1
12	1·5	1·7	12	2·0	2·2
16	1·2	1·2	15	7·2	6·2
24	2·8	6·1	18	10·8	9·8
28	7·2	6·7			

We can say that the new theory based on Schroedinger's ideas accounts for the Stark effect at least as well as the old one.

Atomic Volumes of Carbon and Hydrogen.

PROF. INGOLD has introduced an important modification of Baeyer's strain theory, which brings the calculated ring strains into closer agreement with the thermal data of the cycloparaffins and with the general chemistry of the formation and decomposition of this series of saturated hydrocarbons (*Trans. Chem. Soc.*, 119, 305, 1921). He has pointed out that the carbon atoms in a cycloparaffin are secondary and, by assuming that the carbon atoms attached to the central one occupy more of the surrounding space than the two hydrogen atoms, has calculated the angle (115 3°) between the carbon to carbon valencies from the atomic volumes of carbon and hydrogen.

Objection may, however, be taken both to the method of calculation and to the values (Traube's) employed for the atomic volumes. In deducing the equation for the angle it is assumed that the two spheres representing the attached carbon atoms and the two spheres representing the hydrogen atoms are in mutual contact. This assumes either that the central carbon atom has a very much smaller volume than the carbon atoms united with it, or that the domains of the atoms are far from mutually exclusive. Neither of these assumptions appears to be in harmony with the main thesis that the value of the angle is determined by the volumes of the attached groups. It is possible, having determined the angle by this arrangement, to allow the small internal carbon sphere to assume its normal size without altering the angle, but, since the four attached spheres would then be moved through unequal distances, it is difficult to see how the arrangement then obtained depends directly on the volumes of the surrounding atoms.

Now the two spheres representing the attached carbon atoms and those representing two hydrogen atoms may be placed in contact with a sphere, representing the central carbon atom, in such a way that the inner tangents from the centre of the central sphere to each pair of adjacent spheres (in the plane through their centres) make equal angles. In such an arrangement allowance for the different atomic volumes of carbon and hydrogen is made directly, and, if the atomic volumes of carbon and hydrogen are taken as 4 : 1, it can be shown that the angle of the carbon to carbon valencies is 116° 34′. It would appear from recent investigations that the ratio 4 : 1 is a better measure of the atomic volumes which Prof. Ingold employed.

A Glaciated Ochreous Flint from Cromer.

DURING a recent visit to Cromer I found upon the foreshore site there, a flint of pyramidal form, and typical ochreous colouration. The more or less flat base of the pyramid is extensively glaciated (Fig 1),

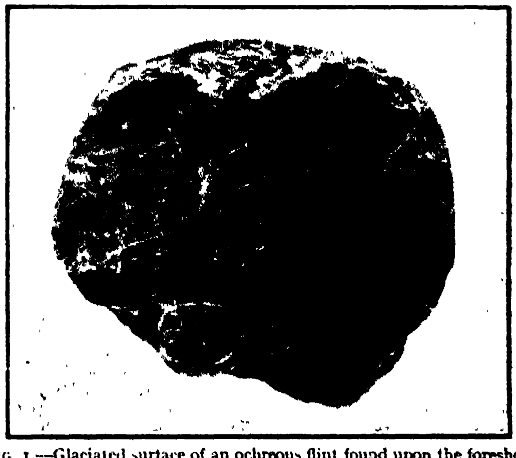

FIG. 1.—Glaciated surface of an ochreous flint found upon the foreshore site at Cromer. Half natural size.

and the striæ were obviously imposed after the flint was patinated. The ochreous specimens from Cromer are, as a rule, remarkably free from striation, but it is evident that this particular flint was exposed to the effects of moving ice—possibly of the second glacial epoch of East Anglia. In any case the specimen is, without doubt, glaciated, and its discovery affords final proof of the great antiquity of the ochreous flints found upon the Cromer foreshore.

Psychological Aspects of Our Penal System.[1]

By Dr. JAMES DREVER.

THE root idea in punishment as ordinarily understood is the infliction of some kind of disagreeableness, pain, or loss on an individual, because he has been guilty of some misdeed. There are thus two aspects—on one hand the infliction of hurt, on the other hand the relation of this to some wrongdoing or crime. Originally any end to be gained by such infliction was scarcely conscious, if it existed at all—any end, that is to say, beyond the satisfaction of the anger evoked by the misdeed itself. The psychological source is to be found in the anger caused by the wrong. From this primitive source to the modern conception the evolution of theories of punishment, conscious or unconscious, may be said to have passed through four stages or phases. These may be designated the vindictive, the retributive, the protective or deterrent, and the reformatory or curative.

To begin with, an individual who has suffered injury by the wrongdoing of another responds to the injury with the emotion and impulse of anger. This is satisfied by the infliction of some hurt on the wrongdoer. At the simplest and crudest stage of development—the stage where we have to deal with the mere instinctive impulse of the brute or the savage the hurt inflicted on the wrongdoer may have no direct relation, either in kind or in degree, to the injury done, but only to the intensity of the anger evoked. Of course this is not really punishment in any strict sense. Nevertheless it is unquestionably the psychological origin, and it therefore marks the first stage in the evolution of what became punishment in the strict sense. This is the vindictive stage or phase. In so far as punishment at any time reveals the same emotion and impulse it represents this primitive vindictive stage.

Even in a very primitive social life, however, some crude notion of justice must very early act as a determining influence on the hurt that may be inflicted on another for some injury done. So far as some notion of justice is a conscious determinant of the hurt inflicted on the wrongdoer by the injured individual, this hurt takes on the character of retribution, and punishment as such comes into being. This phase or stage in the evolution of punishment is the retributive phase or stage.

Another factor must have made its influence felt in a rudimentary way at a comparatively early stage. The notion of punishment must have involved a looking forward as well as backward, in the shape at least of a dim feeling that similar actions to that which has incurred it must be prevented in the future. There can be little doubt, that is to say, that at a comparatively early stage primitive society must have felt vaguely that punishment had a protective function, since by means of punishment of a culprit the individual and society were protecting themselves against the repetition of an injurious act.

The general line of evolution of our modern penal systems is thus clear. First of all we have purely vindictive action on the part of the injured individual. Then there is some sort of legalising—if we may use that word—of retributive action on the part of the injured, so long as this retributive action does not go beyond the limits of 'justice,' this being regulated by social law. Finally, recognising that punishment has a protective function as far as social life is concerned, society itself takes over the infliction of punishment, and a penal system is inaugurated. This stage or phase is the protective or deterrent stage or phase.

[1] From the presidential address to Section J (Psychology) of the British Association, delivered at Oxford on August 6.

EVOLUTION OF A PENAL SYSTEM.

To leave the matter thus, however, would be to obscure important aspects and phases of the actual course of events, and could not fail to produce a misleading impression of the facts. Stages in social evolution are never clear-cut. Thus the development of the retributive view of punishment by no means involved the discontinuance in practice of vindictive punishment. Still less did the realisation of protection as the primary social function of punishment alter the practice which had been founded on the older and more primitive conceptions. Practice lagged a long way behind theory in this, as in so many other cases.

The psychological explanation of the actual facts would appear to be that the crude emotion of anger remained the driving force behind punishment, though it was cloaked and obscured by other motives, and by various forms of rationalisation. After all, the reaction of anger is a natural reaction to an act which society agrees in reprobating. One leading authority on criminal law has indeed placed on record his conviction that it is "highly desirable that criminals should be hated, that the punishments inflicted upon them should be so contrived as to give expression to that hatred, and to justify it so far as the public provision of means for expressing and gratifying a healthy natural sentiment can justify and encourage it." I am afraid the learned author's thoughts have become somewhat mixed up in the latter portion of this statement. It sounds as if his rationalisation were not very satisfactory, even to himself.

However that may be, it is certain that the realisation by society in theory that the function of punishment from the point of view of society was primarily protective did not prevent an almost religious sanction continuing to be attached to the *lex talionis*. This remained, in fact, an assumption at the base of all penal systems which no one seriously challenged; and it is equally certain that the protective function of punishment was frequently made the excuse, as in the writer just quoted, for continuing the practice of vindictive punishment—'for deterrent purposes' was the usual rationalisation—even when it was quite evident that the psychological situation thus produced was often inimical to the ends sought. One need only instance the brutalising influence of capital punishment on society at large, and its inevitable tendency to increase the frequency of the crime of murder, during the period when it was the punishment also for less serious crimes, to show the kind of psychological situation which was created. Curiously enough the more humane—and indeed saner—attitude and practice of modern times in civilised countries were

due far less to recognition of the fact that vindictive punishment for deterrent purposes was frequently an entire failure, than to the fact that the infliction of pain and suffering on human beings became objectionable to the general sense of society.

The phase or stage of evolution at which we have now arrived is characterised, on one hand, by the discontinuance, or the radical limitation, of what was virtually the primitive vindictive punishment in disguise, and on the other hand by the recognition of social punishments as possibly possessing a reformatory or curative function. We may speak, therefore, of the present phase or stage as the reformatory phase or stage in the evolution of social punishment. The actual situation, however, is somewhat complex. Practically punishment still rests, in law and in popular thought, on the retributive basis—the *lex talionis*. Theoretically it is recognised that from the point of view of society punishment is protective, and this is its primary function, and also, I believe, that society is not directly concerned with the retributive aspect of punishment as such, but only indirectly because of the deterrent effect of retributive punishment. Moreover —and this is the mark of the phase of evolution at which we have arrived—it is realised that, so far as the individual is concerned, social punishment may be made reformatory, and that the reformatory function of punishment is worth keeping in view, if only because reformation of the individual means protection of society against the repetition of the injury so far as that individual is concerned, always provided that the attempt to reform the criminal does not involve the sacrifice of the primary aim.

PUNISHMENT OR REFORMATION?

The psychological problems of social punishment fall into two groups: on one hand those involved in the effects of punishment on the individual who is punished, and on the other hand those connected with the effects of punishment on the community itself. Of course there is a repercussion on society of the effects on the individual, so that the problems of punishment are ultimately in every case social problems. Nevertheless, we shall find it convenient to consider the two groups of problems separately in the meantime.

Consider first the problems arising in connexion with the effects of punishment on the individual who is punished. So long as the retributive aspect of punishment is placed in the foreground, the only psychological problems of serious import are those involved in the question of the responsibility of the offender. This question of responsibility is one over which medical and legal minds have long been at loggerheads. The source of this age-old controversy between lawyer and medical man lies primarily in the fact that the two use the word 'responsibility' in entirely different senses. For the lawyer 'responsibility' is purely a legal term, and the question of responsibility is to be determined on the basis of evidence germane to its legal meaning. For the medical man 'responsibility' is an ethical term, and the question of responsibility therefore raises much wider issues.

The psychological problems involved in the legal definition of responsibility are, more especially in so far as the question of control is raised, extremely difficult. I do not believe, however, that responsibility in this sense is a practical issue at all in connexion with any penal system. At least it does not arise in the form in which it is usually raised, or at the point at which it is usually raised, in a practical consideration of the problems of punishment as affecting the individual who has infringed social laws.

It is when we emphasise the protective and particularly the reformatory aspects of punishment that the vital psychological problems emerge. So far as we base our practice in social punishments upon these two functions, it is not too much to say that our whole practice must be guided primarily by the outcome of psychological inquiry. The two functions are not in conflict. We may aim at the protection of society by the reform of the delinquent. Treatment which is successful in eliminating a particular tendency to delinquency in an individual will *ipso facto* protect the community against the repetition of this delinquency by the same individual. Of course it will not necessarily protect society against the same form of delinquency in another individual. That is why we have to consider punishment, rather than reformation pure and simple, and that is why the silly and sickly sentimentality which regards the wrongdoer as a suffering victim rather than a criminal will always fail to appeal to any one, no matter how soft-hearted, who regards the whole situation frankly and sanely.

It is obvious also that the failure of reformatory measures must not be taken to imply the failure of society to protect itself. Other measures must be available, which are merely protective, and not at all, or only indirectly, reformatory. On the other hand, it is clear that reformation is, as a rule, the more economical way to secure protection for the community, provided there is reasonable hope of success, and so long as we restrict our attention to the individual delinquent. The reform of the delinquent is doubly a social gain. From being a minus quantity with respect to social efficiency he becomes a plus quantity. This point is especially important in the case of the juvenile delinquent.

Punishment exerts its influence through disagreeableness, or the fear of disagreeableness. The function normally performed by unpleasantness encountered in the activity of any living organism is to guide the activity so that unpleasantness may in future be avoided. The fear of unpleasantness again checks the immediacy of impulse, and so allows time for a new kind of behaviour to be substituted for the old kind which led to unpleasantness—the beginnings in the case of the human being, it is worth noting, of self-control. But it is only low down the scale of organic life that the phenomena are to be seen in their simplicity. As we pass up the scale the inner conditions which determine behaviour become more and more complex, and the actual results of any unpleasantness or fear become more and more difficult to foretell. With the human being the complexity of the inner situation has become enormous. The web of impulse and motive is so intricately and so subtly interwoven that the introduction of a new impulse and motive may come to have a result wholly unforeseen and entirely different from the result intended.

PRACTICAL DIFFICULTIES.

The most important source of practical difficulty is frequently our almost complete ignorance of the inner conditions which issue in any particular misdemeanour. This necessarily involves ignorance of the effect which our punishment is likely to produce. So far as the reformatory aspect of punishment is concerned, this is a very serious matter. We have to deal with an individual, and we must know the facts of that individual case. Any psychologist who has had experience of conflict cases among juvenile delinquents, can easily find illustrations from his experience. The usual form of misdemeanour that occurs is stealing, and frequently irrational and apparently motiveless stealing. Thus money, jewellery, and all kinds of things may be stolen and given away, or even thrown away. Until the inner conditions are understood and the causes of the trouble removed, no kind of treatment seems to be of any avail. Or sometimes, where punishment is apparently successful in eliminating the tendency to one particular kind of misdemeanour, there is a criminal outbreak in a totally different direction, the result of the punishment itself, which more than counterbalances any apparent success.

Cases of this kind tend to make one speak and think of treatment rather than punishment. It might be asked whether this is not the point of view from which all cases should be approached, not as a matter of ethics, but as a matter of practical expediency, punishment being merely a particular method of treatment. The proposition is arguable, but only so long as we confine attention to the individual delinquent, and that is only one side of the picture, as we shall see presently. Personally, I do not think the point of view will matter very much so long as we keep firmly in mind the essential fact that the action taken, whether we call it treatment or punishment, is primarily action taken by society for its own protection, the reform of the criminal being a means adopted to this end. There is undoubtedly a class of offender in whose case treatment, rather than punishment, is the appropriate notion and procedure. Other cases occur with fair frequency in which punishment as ordinarily understood is quite ineffective as regards the reform of the individual. The case of serious mental defect may be instanced.

The facts are such that we find the old problems of responsibility, so far as they were practical problems at all, cropping up in a new guise, and in new surroundings. It may be possible to determine beforehand, without waiting for the event, whether punishment will be effective for reform, and if so what kind of punishment, or whether the case is one demanding treatment, and not punishment at all, and if so what kind of treatment. The problems now, however, are neither legal nor ethical problems, but purely psychological problems.

The suggestion that in some cases punishment, as ordinarily understood, may be quite ineffective leads us on to the consideration of the measures society takes, and must take, for its own protection in certain instances. The most important method of protection that society utilises is the restraint of the offender in some appropriate institution—so far as the idea of punishment is concerned, some sort of prison. The restraint or imprisonment may be merely temporary, or it may be permanent. In the first case it is clear that the reformatory aspect of punishment ought still to be kept in view, so far as the psychological situation is taken into account. If it is not, it does not require much foresight to prophesy somewhat lamentable results. In particular, if the criminal is returned to social life, not only with his tendency to the original form of misdeed unaffected, but with other anti-social tendencies developed by his prison life, or by circumstances arising out of his prison life, our only possible verdict is that society is playing the fool. On the other hand, when the restraint is permanent, while reformatory measures must not be entirely excluded as intrinsically hopeless in every case, it is clear that the whole psychological situation and outlook are different. The prisoner will never be returned to civil life. For the protection of society he must be kept in restraint permanently. But he is a human being, and the moral sense of society will demand that he be treated as such, not merely negatively by the avoidance of inhuman conditions, but also positively by the provision of such amelioration of his lot as is possible without sacrificing essential principles.

Every one is agreed, I think, as regards these general matters. There will also be general agreement that the stigma of prison life means in itself the very serious modification of the psychological situation in the case of every individual who incurs it, so serious that no psychologist can regard short-term prison sentences with anything but dismay. It must be recognised that it is with respect to prison treatment especially that society, in protecting itself, or attempting to do so, runs the risk of making matters worse instead of better, and the gravest practical problems arise with regard to this type of punishment. Much has been done in recent years to remove acknowledged evils and defects of our prison system. Much may still be done. Nevertheless, I personally, and I imagine most psychologists, would look upon any further advance in the directions hitherto pursued with serious misgivings as to psychological results, until we have first attacked more fundamental problems, and reviewed our whole penal system in the light of the psychological knowledge of to-day.

NEED FOR PSYCHOLOGICAL DATA.

Let me try to indicate where, in my opinion, the crux of the whole matter lies. I think all will agree that the very first essential is that we should have the requisite knowledge and understanding of the psychological situation with which we are faced, and the psychological effects likely to be produced by the action taken. Society has to decide whether an individual delinquent is to be punished in this way or that way, whether he cannot be reformed but must be placed under restraint for life, or can be reformed during temporary restraint by appropriate treatment, or can be reformed without undergoing prison life, and in each case what can and ought to be aimed at. No general theories concerning the causation of crime, no systems of penal philosophy, not even the best intentions in the world, can take the place of a thorough knowledge and understanding of the individual case. This is precisely where our whole penal system is at present most defective. Moreover, the defect is one

that can be remedied without serious difficulty in the present state of development of modern science, medical and psychological, but no opportunity is afforded.

The first and essential step towards the further reform of our penal system lies in affording this opportunity. This could be done by instituting a clinical examination, medical and psychological, of every delinquent before sentence is passed, and by taking advantage wherever possible of modern psychological knowledge. The psychological clinic is at present practically non-existent in Great Britain. It is high time this state of matters was remedied. School and law-court both demand its institution. That is the first step. When we have taken that step, we shall be able to take further steps in penal reform with the advantage of acting with adequate knowledge of what can be done, and what we are really doing in each particular case. Until that step is taken, every other change we introduce by way of reform has a hit or miss character, which cannot fail to be profoundly disturbing to any thoughtful student of social development.

It may be objected that we are in danger of losing sight of the fact that the topic under discussion is punishment, not simply the reformation of the criminal. The suggestion was made above that in certain cases at least it might be more appropriate to speak of treatment than of punishment, the suggestion involving the view that delinquency ought to be looked on as the outcome of something not unlike disease. However that may be, I do not think there is any warrant for excluding either the idea or the fact of punishment, provided we look to the future, and not simply to the past, in our conception of punishment. The action taken against an individual in the form of punishment must involve some disagreeableness or deprivation, and the reason for the punishment is some past act of the individual. But its purpose is the prevention of similar acts in the future. The fact that hitherto we have been discussing the individual aspect only has tended somewhat to obscure this deterrent function, and the consideration of this function will lead us over to the discussion of the social aspect.

The deterrent function of punishment has played no inconsiderable part in the discussion of penal measures at all times. The severity of past penal systems has been largely due—almost entirely so far as it has had a rational basis at all—to the attempt to deter others from similar offences to those for which punishment is inflicted on an offender. It is unquestionably the case that many a misdeed is prevented by the fact that the individual who is tempted knows that he will inevitably pay the penalty, and it is also a well-known fact that, where, through the inefficiency of the police or other cause, punishment is easily evaded, crime shows a corresponding increase.

It cannot be lightly assumed, however, that the deterrent effect of punishment depends merely on fear of the disagreeableness or suffering which the punishment in itself involves. The penal system is an expression, however imperfect, of the sentiments of society with respect to certain acts—sentiments of hatred in varying degrees. It is not the result of a purely intellectual review of the social results and bearing of these acts. Apart, therefore, from the punishment by law decreed and legally inflicted, the criminal act is inhibited, so far as the normal socialised individual is concerned, by this sentiment in himself and in his fellows, how developed we cannot at present stop to consider, but resting ultimately on the primitive anger evoked by injury. "The sentence of the law," to quote again the legal authority already quoted, "is the moral sentiment of the public in relation to any offence what a seal is to hot wax. It converts into a permanent final judgment what might otherwise be a transient sentiment." Fear of the punishment as such, fear of the social disapprobation dependent on the evoking of the moral sentiment, of which the punishment is a concrete and tangible embodiment, recoil from the act because of the existence in the individual who is tempted of the moral sentiment in question in however feeble, attenuated, and fragmentary a form—all these are motives holding back an individual member of society from wrongdoing. The legal punishment exercises its deterrent influence because it, as it were, embodies and presents all of them in unmistakable and arresting fashion. The relative force of the different motives will vary with individuals. But until we can rely on the last of these motives being of itself sufficiently powerful to restrain every individual member of society from the breach of social laws—which would seem to involve a radical change both in the existing social structure and in human nature—the social necessity of some kind of penal system, in the strict sense, must remain.

In conclusion I would revert to the varying motives upon which the deterrent influence of punishment depends. Two points in particular demand notice. In the first place we cannot assume that penal law and moral sentiment will always be in harmony, and so reinforce one another. There may, in fact, be acute conflict between the two, so far as a considerable minority of the members of a community are concerned. In certain cases also they may be, so to speak, indifferent to one another. In either case the psychological situation is very radically modified, and the problems of punishment may in practice become very difficult.

In the second place the influence of the different motives may, as we have seen, vary with the individual. If that be so, two consequences would appear to follow. On one hand—and this refers more particularly to the adult criminal—our penal system must be such as to appeal with sufficient cogency to all the motives, so far as the criminally disposed individual is concerned. On the other hand—and now we have in mind chiefly the juvenile delinquent—it is of capital importance that we should recognise as early as possible in their criminal career those individuals who, either by nature or circumstances, or both, are tending towards abnormality in their reactions to social claims and social penalties. This brings us back to the crux of the whole situation. Means must be provided by which a knowledge of the individual case may be made available, before the decision is taken as to how any offender is to be treated. The temperamentally defective individual may be born, the habitual criminal is largely made. It ought at least to be possible to prevent the making of criminals. Again the glaring defect of our penal system stands revealed. No provision whatever is made for the diagnosis of incipient criminality. It is not merely a case of locking the door after the horse is stolen; it is a case of providing neither lock nor door.

The Use of High Pressures for Steam Turbine Installations.

By STANLEY S. COOK.

THREE different methods are available for the measurement of the performance of a steam engine, and serve that purpose from different points of view according to the particular feature of merit it is desired to emphasise. Thus, from the point of view of the manufacturer whose aim is to produce a turbine of the highest efficiency, that is, one which will convert into useful work the highest possible proportion of the pressure energy that is available in the steam, a figure expressing this proportion appears to meet the requirements of the case. This figure is almost (that is, except for the work of restoring the water of condensation to the boiler) identical with the 'efficiency ratio' as defined by Willans and Sankey in terms of the Rankine cycle, a ratio for many years accepted as the criterion of merit of a steam engine. The user of a turbine, on the other hand, is not so interested in what may be called the intrinsic efficiency of the engine, as in knowing how many pounds of steam per hour he has to generate in his boilers in order to produce a horsepower or kilowatt of output; consequently, a more significant expression of the engine's efficiency from his point of view is the consumption in pounds of steam per horse-power hour, under standard conditions of steam generation.

The latter method of statement of performance has also been commonly adopted, is if anything more familiar than the former and in a sense more practical. Used without qualification, however, it gives the manufacturer of the engine credit for any improvement he may make or find in the vacuum or in the steam conditions, although these are frequently taken into account by means of correction factors which reduce the consumption rate to a standard basis.

It must be recognised, however, that neither of these values supplies the user with the exact information he requires as to the cost of producing a unit of energy. It might easily be found, for example, that as the result of utilising higher pressures or lower vacua the efficiency ratio was reduced, but all the same a better overall result secured as measured in pounds of steam per horsepower, and even actually. At the same time, an improvement in consumption rate by improved steam conditions and improved vacua fails to take into account the increased cost of generating the steam under the new conditions.

A third and more comprehensive method is required to give an adequate measure of the performance of the steam engine as a heat engine. It must be remembered that a turbine is not correctly speaking a heat engine, but only a part of it. The expansion which is carried out in the turbine is only one of the processes in the complete cycle of the heat engine, which consists also of processes of heat rejection, re-compression and heat reception. The complete heat engine therefore includes the boiler in which heat is given to the steam, the condenser in which heat is extracted from it, and the condensate pump and feed pump which restore the condensed steam to boiler pressure.

The third method therefore relates to the heat engine as a whole, and aims at expressing its performance as a ratio of the net output, in equivalent heat units, to the heat energy latent in the fuel consumed. Such a ratio is known as the overall thermal efficiency. Its use is clearly necessary if satisfactory comparison is to be made between heat engines of different types, employing thermodynamic cycles of different character.

Inquiry must therefore be made into the conditions which make for the highest thermal efficiency. Now if it be presupposed that the highest possible efficiency of heat transmission in the boiler has been obtained, and the highest possible intrinsic efficiency of the turbine, there still remains another factor of supreme importance, namely, the efficiency of the thermodynamic steam cycle which alone determines the ratio between the heat supplied to the steam and the pressure energy that is available for the turbine. The turbine is able to use efficiently all the available energy that can be given to it, and it therefore remains to provide that the efficiency of the thermodynamic cycle shall be made as high as possible subject to practical conditions. At this point the problem becomes a thermodynamic one, and this ratio is a function of the conditions of heat reception and heat rejection.

The law which governs this question was enunciated by Carnot more than a century ago. It is that in order to obtain the maximum thermodynamic efficiency the temperature of heat reception must be made as high as possible and the temperature of heat rejection as low as possible. In the perfect Carnot cycle heat is received at a constant high temperature and abstracted at a constant low temperature. The heat received is proportional to the absolute temperature of reception, and the heat abstracted to the absolute temperature of rejection. The difference between these quantities of heat is the amount transformed into work, so that the thermodynamic efficiency of the perfect engine becomes $(T_1 - T_2)/T_1$ where T_1 and T_2 are the higher and lower absolute temperatures. It is easily seen that this ratio is increased by increasing T_1, or by decreasing T_2, or both.

The past success of the steam engine as a prime mover is due to two causes, the high value of the latent heat of steam and its ability to work on what is known as the Rankine Cycle. In the latter the compression stage of the Carnot cycle is replaced by the simple process of elevating the condensed water to boiler pressure. The consequent reduction of negative work gives this cycle a great practical superiority.

On the other hand, the employment of such a cycle involves a departure from the above-mentioned principle of heat reception at a constant maximum temperature. The heat is in fact supplied to the steam at a variety of temperatures. The feed water has to be raised from condenser temperature to the boiling point corresponding to the pressure of the boiler. Evaporation in the boiler takes place at that temperature, and the temperature of the steam is then raised continuously to the maximum temperature of superheat. The thermodynamic efficiency of each portion of the heat so supplied is conditioned by the ratio of the absolute temperature of supply to the absolute temperature at which all the heat is abstracted in the condenser.

Now the heat given to the steam during the process of evaporation, namely, the latent heat, is a large proportion of the total heat supplied. For example, with a boiler pressure of 250 lb. per square inch, a superheat of 200° F. and a condenser vacuum of 29 in. Hg. the latent heat is 836 B. Th. U. per lb. of steam out of a total supplied of 1276 B. Th. U. per lb. during the three processes just mentioned, or 65·5 per cent of that total. Omitting the heat required to heat the feed water, since, as will be seen presently, the disability of the low temperature of this process can be overcome, the total heat required for evaporation and superheat is 950 B. Th. U., of which the latent heat added during evaporation is 88 per cent. It is clearly, therefore, of importance from the point of view of obtaining the highest thermodynamic efficiency of the cycle that the heat supplied during the stage of evaporation shall be supplied at as high a temperature as possible. The temperature of this part of the heat reception can only be raised by increasing the boiler pressure.

At the same time, an increase of the maximum temperature of the superheated steam will lead to further improvement in efficiency, since this means additional heat reception at the highest temperature. In the case of superheat, there is the additional advantage that with a higher degree of initial superheat, the steam is in a dryer condition in the final stages of its expansion.

The circumstances are best visualised by means of an entropy temperature diagram. Fig. 1 is such a

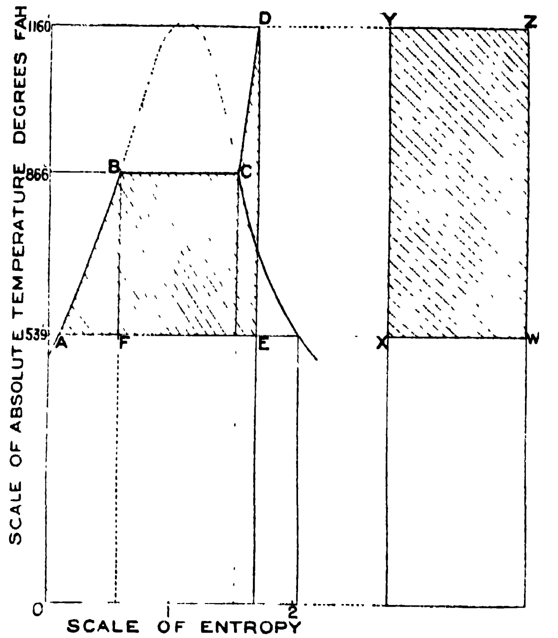

FIG. 1.—Entropy temperature diagram for the Rankine cycle for steam with boiler pressure 250 lb., condenser temperature 79° F. and superheat to 700° F.

diagram representing the Rankine cycle for steam with a boiler pressure of 250 lb. gauge, a condenser temperature of 79° F., and superheat up to a maximum temperature of 700° F. Each stage of the cycle is represented by a curve on the diagram, and the property of the diagram is that, with absolute temperature as the vertical ordinate, the area vertically beneath any curve, or portion of a curve, which corresponds to a change of state is proportional to the heat taken in or given out during that change. The rising curve *AB* represents the heating of the feed water to boiler temperature, by whatever means it is carried out; the line *BC* represents the generation of steam and is horizontal because this takes place at constant temperature; the rising curve *CD* represents the superheating of the steam. No heat is taken in or given out during expansion in the turbine, so that the vertical line *DE* represents expansion of the steam down to the temperature of the condenser. In the condenser, condensation takes place at constant temperature, and is therefore represented by a horizontal line *EA*, which completes the cycle. The area enclosed by the cycle *ABCDEA* represents the excess of the heat taken in from the boiler along *ABCD*, over that rejected into the condenser along *EA*. This area therefore represents the energy which is available for conversion into work.

The shortcomings of this cycle can be seen at a glance if we compare it with another cycle *XYZWX* in which all the heat received from the source is taken in at the highest temperature along *YZ*, and that rejected is rejected at the lowest temperature along *WX*. Here the work done is represented by the area of the rectangle *XYZW*, whilst the heat taken in is represented by the larger rectangle from *YZ* down to the base line. The proportion of the work done to the heat taken in is much higher than in the cycle *ABCDE*, and this is clearly seen to be due to the high temperature at which all the heat is taken in along *YZ*. The underlying areas of the first diagram shew us at once that, of the heat taken in along *AB*, that is, during the heating of the cold feed in the boiler, only a small percentage is converted into useful work. The heat taken in along *BC*, which is the latent heat of the steam, contributes a larger percentage, but still considerably less than the maximum. Even that received along *CD* during the process of superheating, yields less than the ideal maximum efficiency.

While the diagram thus exhibits the shortcomings of the Rankine cycle in comparison with an ideal Carnot cycle, it is of interest to remark that similar departures from the ideal are present in any type of engine in practical use. The internal-combustion engine, for example, contains an even greater departure from the ideal of constant temperature reception of heat, although its actual temperatures both of reception and rejection are higher throughout than in the steam engine.

Returning to the Rankine cycle for steam, it has been stated that the heat received during evaporation is a large proportion of the total heat received. That this is the case is readily seen from the diagram, this heat being represented by the area below *BC* down to the base line. By what is known as cascade feed heating, that is by heating the feed water by steam bled from the turbine at suitable successive stages, it is possible to a large extent to eliminate that part of the diagram which underlies *AB*, since by this process if carried out in its entirety the heat represented by the area from *AB* down to the base line can be saved, at the expense of a loss of work which can be shown to be equivalent to the area *ABF* for each lb. of steam. To raise the temperature of reception of the heat absorbed during

evaporation, which in the case already considered is 88 per cent. of the total heat absorbed along *BCD*, would clearly result in considerable improvement of the efficiency of the thermodynamic cycle. Thus not only high temperatures, as in the case of the adoption of high superheat, but also high boiler pressures, lead to a substantial increase in over-all thermal efficiency.

The question of the improvement of the thermal efficiency of the steam engine by such means is one of prominent interest in the engineering world at the present time. Advances in this direction have already been made for land installations, and recently we have witnessed an application of the same principles to marine work, which had been awaited with keen interest, and was not without an historic setting. It is just a quarter of a century since the first commercial application of the steam turbine to marine work was made in the Clyde river steamer the *King Edward*, which, built in 1901, has continued in successful service season by season up to the present time. A new vessel, which has a high-pressure steam installation of geared turbines on the lines indicated above, has been built for the same owners and for the same service. This vessel, which has been named *King George V*, becomes in its turn the pioneer of the new system.

Malaria and the Mosquito.

THE enthusiast who is 'eradicating' malaria by any or all of the well known methods, should cease for a while from his labours and study the short report recently issued by the League of Nations and referred to below.[1] In Col. James's words, "He will at least realise what a great waste of effort is involved in measures directed against the breeding-places of mosquitoes as a whole and even in similar measures directed against one species. He will begin to appreciate how the secret of a successful control of malaria lies not in the general knowledge that the disease is spread by mosquitoes of a certain kind, but in the particular exact knowledge of the life history of the few individual mosquitoes which succeed in becoming transmitters of the disease."

This is a refreshingly new aspect of the problem. The enthusiast eradicates all mosquitoes. He does not stop to distinguish a Culicine (non-malaria) from an Anopheline (malaria) mosquito; he is out to destroy them all. Now he is advised to study not only the species of Anopheles which are concerned in transmission, for all are not, but also actually to concern himself about infected individuals! Why should he do this? It is because "Malaria is essentially a household disease and particularly a disease of certain kinds of houses . . . . Malaria should be dealt with in the houses of the people rather than in the environment." We have called this a new aspect of the problem, but the author points out that some twenty-five years ago Stephens and Christophers in their reports to the Royal Society directed attention to "fever houses." They state: "We may look upon such a house and its accessory hovels as one infected with malaria or as 'a fever house.' Such is the universal condition of European houses indeed in the remote stations situated in the African bush. It is in such houses that the malarial cachectic is living, exposed to frequent or even constant re-infection and in which every traveller staying the night is liable to infection. From such fever houses the majority of our cases of blackwater have come."

It has always been somewhat disconcerting that while, for example, in a native African village more than 75 per cent. of the children may be infected with malaria, yet the infection rate of sporozoites (infective stage of the malaria parasite) among the anophelines may be low, less than 5 per cent. Once infected, however, a single mosquito becomes exceedingly dangerous; how much so is shown by the fact that a mosquito which has lived (in captivity) 1-3 months and has bitten nearly half a hundred people in that time may still have numerous sporozoites in its salivary glands and is consequently still potent for mischief. But, on the other hand, if not bitten oneself, one may draw comfort from the fact that a mosquito is gradually purging itself of infection by biting other people, so that while 85 per cent. of mosquitoes showed a salivary glands infection on the 50th day, on the 70th day this was reduced to 20 per cent. (the glands, moreover, containing but few sporozoites), the mosquitoes having bitten about a dozen people in the interval. This at first sight appears inconsistent with the previous statement, but the difference lies in the fact that in the first case the mosquitoes' stock of sporozoites in the glands was being replenished by the oocyst stage present in the stomach, as shown by dissection, while they were absent in the second case.

Col. James's observations lead him to formulate some very important conclusions, namely, that "in Nature the only mosquitoes which succeed in transmitting malaria are those rare individuals who happen to pass their lives in conditions which resemble very closely those which we have found to be essential for the successful transmission of the disease in experimental work" and of these "not many will ultimately become infective." Let the sanitarian then pause and study the individual infective mosquito in the fever house. Here is the real centre of gravity.

Among interesting data with regard to the life of the malaria parasite in the mosquito are those concerning the persistence of oocysts and sporozoites, the young and the mature stages of the malaria parasite in the stomach and salivary glands respectively of captive hibernating mosquitoes, a persistence which is held to explain primary attacks of simple tertian malaria in Nature in the early spring in northern latitudes.

The report concludes with a study of the infected cases from the clinical and microscopical sides. They suggest that we shall have to revise somewhat our idea of the Golgi cycle in relation to the temperature chart, but in blood work we must never forget that the peripheral blood is almost certainly not the same thing as that of the spleen or marrows. Very prudently, we consider, the author refuses to sail on the troubled sea of immunity where shipwrecks are inevitable. The report is written in an agreeably clear fashion with an absence of assumption of authority quite charming.

Obituary.

PROF. J. G. ADAMI, C.B.E., F.R.S.

GEORGE ADAMI was a great pathologist, though not a ' laboratory man ' in later years. A scholar and Darwin prizeman of Christ's College, Cambridge, he took a first class in the Natural Science Tripos, then studied in Paris with Pasteur and Roux, in Breslau with Heidenhain, and in Cambridge with Roy and Michael Foster. Afterwards he became John Lucas Walker student, and at the early age of thirty, professor of pathology and bacteriology at McGill University, Montreal. Through his inspiration, Sir Humphry Rolleston has written: "a continuous stream of papers" issued "from his laboratory dealing with all branches of pathology and its application to other sciences." He was awarded the F.R.S. in 1905 and the Fothergillian gold medal of the Medical Society of London in 1914. He was an ex-president of the Association of American Physicians, a fellow of both Jesus and Christ's Colleges, and held many honorary degrees. During the War, Adami became assistant director of Medical Services in the Canadian Army, for which he received the C.B.E. A member of the War Office Committee on the Medical History of the War, he published in 1918 vol. 1 of the "War Story of the Canadian Medical Corps." He was chairman of the Committee on Bacteriological Procedures, Medical Research Committee, and was largely responsible for the standardisation of Wassermann technique in the laboratories of Great Britain.

Adami's greatest contribution to science was the "Principles of Pathology." The first volume on general pathology, published in 1908, marked an epoch. It was, as stated in the preface, "not a mere record and description of phenomena, but an attempt to analyse those phenomena in an ordinary manner." It contained his exposition of inflammation and his original and helpful classification of neoplasms upon an embryological basis. Four years later he published with his friend Dr. John McCrae, of McGill University, his popular text-book of pathology. Other contributions to science included "The Physiology and Pathology of the Mammalian Heart" with Roy (*Phil. Trans.*), Pictou cattle disease, and a survey of the 1918 influenza epidemic in the British Army. In his Croonian lectures on adaptation and disease, delivered at the Royal College of Physicians in 1917, Adami argued against the doctrine that acquired characters are not transmitted. He was greatly interested in the problem of malignancy, and in the *Medical Journal and Record*, New York, August 18, 1926, controverted the view "that one particular order of microbe is concerned in the production of all malignant tumours;" he believed that the colloidal lead treatment was an "advance."

Adami accepted in 1919 the arduous post of vice-chancellor of the University of Liverpool. By his broad and practical outlook on life, his buoyant energy, his genial friendship, and his high ideals, he ennobled the University and the City of Liverpool and brought the two into closer and more intimate relationship. He faced his gradually failing health with unflinching courage, carrying out his duties to within a few weeks of his death. ERNEST GLYNN.

THE news of Vice-Chancellor Adami's death came as a great shock to his personal friends, and no man had more: for so great was his passion for pleasant intercourse, and his enjoyment of human fellowship, that he sought and made firm friendships where other men would have only multiplied acquaintances. To meet him was a pleasure which he always actively developed, striking sparks from stones, and even finding entertainment in dullards. Doubtless it was partly this side of his character which found satisfaction in the very onerous post of vice-chancellor in the midst of this busily employed provincial city: a post which he filled with distinction, and with a grace which few could imitate. Not very different was that other interest which could leave no medical problem untouched, and carried him, enthusiastically always, through the wide-spread fields of knowledge in the subject of which he was a master, ever curious to meet new developments and always with the firm hand which grasped what others were satisfied with merely touching.

Gifted with this spirit of adventurous and penetrating curiosity, a man of incessant industry, and with a natural facility of expression and delight in exposition, his scientific papers and lectures have since his earliest days excited marked admiration: and to many it was a matter for regret that this more widely-known side of his activities was submerged in the daily routine of an administrative post. However, in Liverpool, an occasional lecture to a local society frequently disclosed the talents which his administrative duties otherwise concealed: and even to those to whom his main subject was a closed book, he was a shining example of the light which the University represented in the lives of the younger generation to which he patiently struggled to make it more and more accessible.

Resident long in Canada, familiar with methods of co-operation better known there than in our more conservative home-surroundings, Adami was sincerely an advocate of modes of procedure, methods and manners of organisation, which are not quite our own: and this advocacy was not without some discovery that habits and tastes were not readily remodelled. Such surprises must come to every man of action who ventures into new fields, and there the weaker spirit fails. Adami's spirit never flinched. Through every temporary conflict his buoyancy survived, and the geniality of his character helped him ably to overcome any lingering remnant of hostility.

Nor is this perhaps without some application to the endeavours in medical progress with which Adami has been most closely associated in the last few years of his life. Cancer, as he phrased it, is a *killer*, therefore it must be fought, and that by *team-work*. Absolute sincerity, tremendous enthusiasm, great breadth of knowledge and keenness of insight, and yet opposition, as natural as the clouds, which he somehow failed to understand.

Splendid gifts, sturdily continued efforts, great endeavours, all carried in a nature that was poised and balanced as by an internal gyrostat of goodwill and honourable intention; none of these qualities have

been without success in the realms of science, medicine, and affairs. In Liverpool his efforts to strip the University of its shell and bare it to the life of the City have left a permanent effect of greatest value, by which he will be remembered here for many years to come. *Vale!* J. S. MACDONALD.

DR. J. L. E. DREYER.

ON September 14, Dr. John Louis Emil Dreyer died at the age of seventy-four years from an illness which he had resisted for the greater part of a year with an astonishing vitality. By his death astronomers are deprived of the presence of one of the most distinguished historians of their science. There are others who have treated the history of astronomy more comprehensively, but within the wide range of his labours there is certainly none who has excelled Dr. Dreyer in the combination of learning, sagacity, scholarly precision, and clear and well proportioned exposition.

Dr. Dreyer was descended from a family which had long been distinguished, largely as soldiers, in the public service of Denmark. The son of Lieutenant-General F. Dreyer, he was born at Copenhagen in 1852 and was educated at the University of Copenhagen. In 1874 he came to Ireland as astronomer at Lord Rosse's Observatory at Birr Castle. Lord Rosse's famous telescope had been found to be specially adapted to the observation of nebulæ, and Dreyer in consequence embarked on the study of nebulæ, with which, next to his studies in the history of astronomy, his name is most closely associated. In 1878 his work on nebulæ was interrupted by his appointment as assistant astronomer at the Royal Observatory at Dunsink, but it was revived on his appointment in 1882 to be director of the Armagh Observatory. While at Birr he prepared for publication the whole series of observations made with Lord Rosse's telescope from 1848 to 1878, published by Lord Rosse in the *Transactions of the Royal Dublin Society*, 1880, and he also published a supplement to Herschel's catalogue of nebulæ with numerous corrections. At Armagh, in addition to minor studies on nebulæ, he produced in 1888 the "New General Catalogue of Nebulæ and Clusters of Stars," included in the forty-ninth volume of the *Memoirs of the Royal Astronomical Society*, which, with his two supplementary catalogues published in the same series in 1895 (vol. 51) and 1908 (vol. 59), form the standard catalogues to which reference is always made.

While at Dunsink, Dreyer joined Copeland in founding an international astronomical journal called *Urania*, the first number of which appeared in January 1881. In July of that year its name was changed to *Copernicus*. The last number appeared in June 1884. The editors contributed their full share of reports and articles, and the journal is full of matter which, after more than forty years, remains both interesting and instructive. Dreyer's most important contribution was his "New Determination of the Constant of Precession," vol. 2, pp. 135-155, which, though never adopted in practical work, was used by Newcomb in his classical determinations.

At Armagh Dreyer produced in 1886 the "Second Armagh Catalogue of 3300 Stars," but his subsequent publications have been restricted to nebulæ and astronomical history. In 1890 he produced "Tycho Brahe, a Picture of Scientific Life and Work in the Sixteenth Century." Danish patriotism has given rise to much research on Tycho Brahe, but Dreyer found no scholarly biography, which should at once establish the facts in the light of the evidence available and at the same time place Tycho in his true position in relation to the progress of astronomy and to the life and thought of his time. Dreyer's volume, which is as illuminating as it is scholarly, supplies this want. In 1913 he began the publication of a complete edition of Tycho's works, of which ten volumes have appeared and the remaining four are stated to be complete in manuscript. This edition must probably be regarded as in the main a work of piety. The preparation of the text must have been a laborious task. The notes, in Latin, are brief, but exhibit the editor's usual scholarship. He has among other things taken the pains to discover what editions of the classics Tycho used.

In 1906 appeared Dreyer's "History of Planetary Systems from Thales to Kepler." The history of planetary systems for those ages is practically the history of astronomical theory. Here as usual we find that mastery of authorities and that sober judgment in weighing doubtful evidence that we should expect from a scholar alone, combined with that skilful interpretation and sympathetic exposition that only an astronomer could give. Dreyer returned to parts of this subject in two papers contributed to *Monthly Notices of the Royal Astronomical Society* in 1917 and 1918, in which he effectively disposed of the long prevailing idea that Ptolemy's star catalogue did not rest on his own observations, but on those of Hipparchus or Menelaus reduced to his own time. In 1920 he succeeded, largely as a result of research on manuscripts at Oxford, in restoring the original form of the Alfontine Tables (*Mon. Not. R.A.S.*, vol. 80, pp. 243-62). He took the leading part in the editing of Sir William Herschel's "Scientific Papers," published in 1912, and a very large share in the volume which the Royal Astronomical Society has recently produced on the first hundred years of its history.

Distinctions came as a matter of course. In 1916 Dreyer received the gold medal of the Royal Astronomical Society, of which he was president from 1923 until 1925. He received the honorary degree of D.Sc. from the University of Belfast, and of M.A. from the University of Oxford, in which city he had settled on his retirement from Armagh in 1916.

In private life Dreyer was unobtrusive, but accessible. He spoke quietly, and with the same deliberation and authority with which he expressed himself in public. His learning was always available to those who wished to benefit by it, and he will be greatly missed. His wife, a daughter of John Tuthill, of Kilmore, Co. Limerick, whom her friends hold in affectionate remembrance, died in 1923. He leaves three sons, all distinguished in the fighting services of the British Crown, and one daughter, who is married to Mr. Warham Shaw-Hamilton, late of Dartan, Co. Armagh.

MR. J. H. MUMMERY, C.B.E.

THE death of John Howard Mummery on August 30, whilst on a holiday visit to Cornwall, deprives the world of an eminent microscopist. Born on January 19,

1847, he was educated privately, previous to entering the medical school of University College Hospital. After qualifying as a member of the Royal College of Surgeons, and taking his L.D.S. diploma, he joined his father, a well-known dental surgeon and research worker, in practice in Cavendish Place, London, W.

During his studentship, whilst working under Sharpey, Mummery showed great aptitude for microscopic technique; this bent he developed to a remarkable degree. Specialising in dental histology, admittedly one of the most difficult branches of the art, he achieved a world-wide reputation. His most important papers were contributed to the *Philosophical Transactions of the Royal Society*, and include "Some points in the Structure and Development of Dentine," Ser. B, vol. 182, 1892; "On the Distribution of the Nerves of the Dental Pulp," Ser. B, vol. 202, 1912; "On the Process of Calcification in Enamel and Dentine," Ser. B, vol. 205, 1914; "On the Nature of the Tubes in Marsupial Enamel and its Bearing on Enamel Development," Ser. B, vol. 205, 1914; "On the Structure and Development of the Tubular Enamel of the Sparidæ and Labridæ," Ser. B, vol. 208, 1914; "The Epithelial Sheath of Hertwig in Man, etc.," Ser. B, vol. 209, 1919; "On the Nerve-end Cells of the Dental Pulp," Ser. B, vol. 209, 1920. Of these, the most remarkable is that dealing with the final distribution of the nerves of the dental pulp. Here was a problem the solution of which had been attempted by many workers; by dogged patience Mummery succeeded in demonstrating the passage of fine neuro-fibrils into the dentinal tubes. His work, too, on enamel tends to prove that this tissue is not wholly inorganic in structure but possesses an organic content, and is capable of exhibiting a vital reaction to injury and disease.

It is impossible here to allude to all of Mummery's numerous papers, dealing not only with the histology of normal tissues, but also many others of a pathological nature. These are to be found in the *Transactions of the Odontological Society of Great Britain*, *Proceedings of the Royal Society of Medicine*, and various British and foreign medical and dental journals; his last, "The Pathology of Chronic Perforating Hyperplasia of the Pulp," appeared in the *British Dental Journal* within a month of his death.

In 1919 Mummery published his text-book "The Microscopic Anatomy of the Teeth," which at once became popular with students. A second edition in 1924 was enlarged to include the general anatomy of the teeth, both human and comparative, and will no doubt remain a standard text-book for years to come.

Mummery was a first-class draughtsman, and his publications are enriched and their value enhanced by his own delightful drawings, in addition to the photomicrographs of his brilliant sections. He was also a water-colour painter of considerable merit.

It is given to but few to remain in active work, with intellectual powers undiminished, for four score years. To his intimate friends Mummery never appeared old. After visiting him in his study one came away stimulated by the suggestions emanating from his fertile brain, and steeped in admiration of his broad and catholic outlook.

Many honours came to Mummery; he was a past president of the old Odontological Society of Great Britain, and the first president of the Section of Odontology of the Royal Society of Medicine, which Society afterwards elected him an honorary fellow. The Royal College of Surgeons of England elected him a fellow and awarded him the Sir John Tomes Prize in 1897. He was a past president of the British Dental Association, and chairman of its representative board. International honours were also his; the University of Pennsylvania gave him its D.Sc. degree; he was president of the sixth International Dental Congress, and was awarded the Miller Prize by the International Dental Federation in 1922 for his original research in dental histology. During the War he acted as superintendent and registrar of the Maxillo-Facial Hospital, for injuries of the face and jaws, at Kennington, and for his services there received the C.B.E.

Mummery will ever rank among the worthies of his profession, as a distinguished follower of Thomas Bell, James Salter, John and Charles Tomes. M. F. H.

WE regret to announce the following deaths:

Prof. F. W. Gamble, F.R.S., Mason professor of zoology and comparative anatomy in the University of Birmingham, on September 14, at fifty-seven years of age.

Dr A. W. Rowe, Lyell medallist of the Geological Society in 1911, who was distinguished for his researches on the zones of the White Chalk of Kent and Sussex, on September 17.

News and Views.

ON September 17, the *Morning Post* published a Reuter message from Berlin to the effect that Profs. Paneth and Peters of that city had, after years of experimenting, succeeded in transforming hydrogen into helium "with the aid of particles of metal." This announcement, if correct, is of great importance and will evoke even more interest than the claim by Miethe and Stammreich to have transmuted mercury into gold. The two claims differ, however, in the important respect that whereas the experiments of Miethe and Stammreich, and of Smits, indicated disintegration of heavy atoms into lighter ones, those now announced involve the synthesis of an element from a lighter one, thus more nearly approaching the alchemist's dream of changing the relatively light base metals into the heavier gold and silver.

To judge by the published literature, recent efforts at the transmutation of elements seem to have been concentrated on disintegrating heavy atoms—a course doubtless suggested by radio-active disintegration and by Rutherford's transmutation experiments with α-particles—but modern views on atomic structure also adumbrate the possibility of synthetic transformations. According to these views the hydrogen atom consists of one positively charged unit of electricity (a proton) with a single electron revolving round it; and the helium atom contains a nucleus

of four protons and two electrons with two external electrons; so that the problem, on paper, consists in condensing, as it were, four hydrogen atoms into one helium atom, or of bringing into close association four independent protons and two electrons. No particulars are yet to hand concerning the methods adopted by Profs. Paneth and Peters, for the statement "with the aid of particles of metal" is meaningless as it stands. The experimental difficulties must be very great, not only in obtaining the energy necessary for such a change, but also in applying it under the appropriate conditions. Moreover, helium is an atmospheric gas, and traces of it are extremely difficult to eliminate by the methods of evacuation and adsorption at present in use; so that belief or disbelief in the Reuter message must be reserved pending further and more definite evidence.

THE German Scientific and Medical Association (Gesellschaft Deutscher Naturforscher und Ärzte) has now issued a handbook of the eighty-ninth assembly at Düsseldorf on September 19-26. From May to October of this year there is in Düsseldorf an exhibition for Hygiene, Social Welfare, and Physical Exercises: 'Gesolei' (GEsundheitspflege, SOziale Fürsorge, und LEIbesübungen). A series of separate societies hold their meetings at the close of the association assembly, which has therefore something of the character of a federation. Excursions include Bonn, Eifel, Neanderthal, and Holland, but chiefly the Rhine-Westphalian industrial area, for example, the Leverkusen dye-works. Dusseldorf is not now in the occupied area, but it has been occupied and is still near the occupied area. As in Innsbruck in 1924, the emotional undertone of the meeting may emphasise that political boundaries cannot divide the solidarity of civilisation (Kulturgemeinschaft).

THE Press bureau at Düsseldorf is in charge of Dr. R. Plohn, and two kinds of abstracts will be prepared—a general report for the daily Press and detailed abstracts for the technical Press. Those using the Press bureau are asked to acknowledge its assistance by sending two copies of any published report. The long list of papers to be presented is arranged in 34 sections. Sections 1 to 15 are the scientific sections. Section 15, presided over by Dr. Rein, is concerned with scientific education; and to the discussion on educational reform medical members are particularly invited. The remaining sections, 16 to 34, are medical, but 16 deals also with the general history of science. The chief addresses will appear in *Die Naturwissenschaften* and also as *Verhandlungen*, to be obtained by members and *Teilnehmer* for 4·50 gold marks either in Düsseldorf or by sending to the Geschäftstelle der Gesellschaft, Leipzig, Gustav-Adolf Strasse 12, to the public through booksellers for 6 gold marks.

A VIVID and intriguing discussion of possible developments in the cotton industry, by Dr. W. Lawrence Balls, will be found in the pages of the *Nineteenth Century* for August. Dr. Balls points out that cotton as a crop suffers from the fact that it inevitably competes for space which is suitable for a food crop, a competition in which the scales are weighted against it in the long run by the continual growth of population; on the other hand, some forms of its new competitor, artificial silk, are made from wood pulp and can be nourished by the spaces in the world that are not available for arable cultivation. Reference is made to the difficulty met with by the grower in the new areas trying to develop cotton production, when he tries to learn what demands the industry makes as to quality in his crop. The industry is so complicated, and divided into so many water-tight compartments, that from different types of spinner and weaver different and often contradictory demands are emphasised, often on very inadequate because too specialised experience. From that point forward, Dr. Balls indicates the inestimable value of the formation of the British Cotton Industry Research Association and the Empire Cotton Growing Corporation; these two organisations have made it possible "for the man from overseas to learn more in a day than he could formerly glean in a month, while the mill manager has become independent of Press stunts." The growing extension and improvement in technique in the production of artificial silk have undoubtedly brought about a new stage in the development of the cotton industry. Much interest therefore attaches to Dr. Balls' forecast, which he admits is heterodox, that whilst cotton will retain its place as a 'structural' material it will lose it as a mere 'covering' material; a change that implies a considerable shrinkage in volume of the cotton industry coupled with specialisation in quality, both of raw product and manufactured article.

PROF. JOHN M. COULTER gives an account of the new Boyce Thompson Institute for Plant Research at Yonkers, New York, in the *Scientific Monthly* for August. This account, with its accompanying photographs, shows how private endowment in the United States has supplied an instrument for fundamental research upon plants which has no counterpart in Great Britain. The only endowed institute which is directing research into fundamental problems of plant culture in Britain is the John Innes Horticultural Research Institution, which, under the late Dr. Bateson, obtained world-wide recognition as a centre of investigation into genetics, and under its new director, Sir Daniel Hall, may be expected to widen its field of attack. The new Boyce Thompson Institute provides a laboratory and greenhouse equipment for the study of the plant under controlled conditions which far exceeds that at the disposal of any British research station whether supported by public funds or private endowment. Col. W. Boyce Thompson was impressed, in making his liberal endowment of the institute that bears his name, with the dependence of the whole population upon plants and their products. In a crowded isle like Britain this is even more impressed upon the consideration of both Government and liberally minded citizens, and though the resources provided by the State may not permit of such extensive researches upon physiological problems of plant development and growth, the annual reports for

1925 of such stations as Long Ashton, near Bristol, and East Malling in Kent, which have recently been issued, show what extensive and thoroughly scientific work into problems of fruit and vegetable culture is in progress.

EAST Malling Research Station has now been established for some fourteen years, whilst Long Ashton commenced work about the beginning of the century. Both these stations have to confine themselves to fruit and vegetable problems, but for many years the Edinburgh Botanic Gardens have been noted for their experimental study of problems of propagation with both garden and greenhouse plants. Valuable aid in the study of commercial greenhouse plants is also given now by the Cheshunt Station in the Lea Valley, which has been associated both with Rothamsted and with the Department of Plant Physiology of the Imperial College of Science and Technology. A brief account of the work of this station from the pen of Prof. Mangham, appears in *Modern Science* for August 1926.

THE *Chemist and Druggist* for July 10 contains a beautifully illustrated account of the chief botanical gardens of Europe, and also a separate account, with equally charming illustrations, of the wonderful gardens established by the late Sir Thomas Hanbury at La Mortola. British botanists will be interested in both these articles, and many of them will have benefited by the generous policy pursued at La Mortola in the distribution of seed to British botanical departments. Another article of considerable interest in the same issue is the account by Prof. Jan Muszyński, of Vilna, of the medicinal herb fair held annually at that town on June 24. No fewer than 122 different kinds of herbs are collected and offered for sale by the peasant drug harvesters at the annual fair, and as the author, who is professor of materia medica at the University, points out, recent work on vitamins, hormones, etc., rather stresses the fact that the herb may mean considerably more in therapeutics than the pure drug extracted from it.

THERE are so many phenomena in connexion with the reception of long distance radio signals that it is very difficult to give satisfactory explanations of the variations in the intensities of the signals. Mr. L. W. Austin in the *Journal of the Washington Academy* (vol. 16, p. 398) gives a résumé of measurements made by the Bureau of Standards on these signals and on atmospheric disturbances during 1925. One of the methods used was to compare the intensity of the received signal with that of an artificial signal of adjustable intensity produced by a local radio frequency generator. The principle of the method is identical with some of those used in Europe. No certain relationship has been discovered between sunspots and abnormal signals. To do this a complete study over at least one complete sunspot cycle would be necessary. Directional measurements on the atmospheric disturbances were made at frequencies of 21·4 and 15 kilocycles at the U.S. Naval receiving stations at Colon and Balboa, the two ends of the Panama Canal. During the dry season, that is, from January 15 to April 1, the disturbances at both stations come almost entirely from the direction of the high Andes in Northern Colombia. When the dry season is over, local storms begin and disturbances coming from the low mountains of the isthmus are prominent. In midsummer the direction of the incoming disturbances at Colon is roughly south-east, while at Balboa the direction of the disturbances is north or north-west. The observations prove that both stations give equally good reception to signals coming from the north during the dry season, but during the rest of the season the Colon station should give much better reception. Observations in Washington show that in winter the prevailing afternoon disturbances seem to come from the direction of eastern South America or possibly from Africa. In summer the direction is south-westerly, apparently from Mexico or the south-western United States. This agrees with the hypothesis that disturbances generally originate over land and are most intense in the afternoon and evening in the regions where the sun passes very nearly overhead.

MR. J. T. CUSWORTH, Upperthorpe, Sheffield, sends us a copy of notes made by him during the severe winter of 1885–6 on the vitality of a frog which was frozen in the centre of a block of solid ice. At the end of eight weeks the block of ice was carefully broken, and the frog, which was frozen stiff, was placed near a fire. In less than half an hour it was leaping about. Mr. E. G. Boulenger, director of the Aquarium at the Zoological Gardens, Regent's Park, has been good enough to send us the following comments upon this communication: "It is well-known that batrachians and fishes may revive after having been frozen stiff for several months. So far as I am aware, however, exactly how long life may be thus suspended is not established. In the rivers of Siberia, which may be frozen solid, fishes are often imprisoned for months on end and during such period assume a rigid condition, their vital functions being temporarily suspended. This fact suggested experiments in the freezing of live fish for transportation, and some were conducted in Switzerland and America several years ago. As a result of these, it was found that fish could be frozen stiff for from two to three months, showing no signs of ill-health, when thawed, as a result of their prolonged imprisonment. The fish which in certain parts of America are now sometimes transported on a commercial scale embedded in ice, are first placed in a closed tub of water into which oxygen under pressure is introduced. After being kept just above freezing-point for three days they are frozen solid. The blocks of ice containing the fish are then removed from the tubs and are surrounded with heat insulating packing. Under such conditions they can be kept in cold storage until wanted. The cost of transporting live fish in water is prohibitive, about ten gallons being required for each pound of fish. The freezing method therefore saves expense."

PROF. J. W. MCBAIN, Leverhulme professor of physical chemistry, who for twenty years has been

on the staff of University College and the University of Bristol, has now accepted an appointment at Stanford University, California, U.S.A., where he will take up his duties after Christmas of this year. Miss M. E. Laing and Miss M. H. Norris have also been appointed to the staff of Stanford University.

THE Mineralogical Society, which was instituted on February 3, 1876, has just celebrated its jubilee in London. The programme included visits of delegates from foreign mineralogical and geological societies and invited guests to the British Museum (Natural History), South Kensington, and to other museums and institutions in London; a conversazione in the Geological Society's Rooms at Burlington House on September 21; and a dinner at the Connaught Rooms on the following evening. The celebration in London was preceded by an excursion (September 12-18) to Devon and Cornwall under the direction of Mr. Arthur Russell, and is to be followed by an excursion (September 23-30) to the north of England under the direction of Prof. A. Hutchinson

THE news columns of the daily papers during the past few days have contained long accounts of the disastrous hurricane which visited Florida on the night of September 17. According to the New York correspondent of the *Times*, the coastal region from Palm Beach to Miami was the area most affected, and it is estimated that 800-1500 lives were lost. The material damage is put at 30,000,000*l*. In Miami, wooden houses were ripped apart, concrete houses broken from their foundations, 'skyscrapers' were badly twisted, small shipping were lifted into the Royal Park, and the new docks were destroyed. The wind is stated to have reached a velocity of 130 miles per hour, and the first visitation lasted nine hours. Farther north there were also damage and casualties. The West Indies is one of the five regions of the globe where these violent tropical cyclones occur. When such storms arise in or near the West Indies, they generally pursue a curved path towards the north-west or into the Gulf of Mexico and then north-eastward along the Atlantic coast They lose their violence as they pass into the temperate zone The Galveston hurricane was apparently of even greater violence than that which has just occurred. It occurred in the same region on September 8, 1900, and on this occasion 6000 lives were lost and 6,000,000*l* worth of damage was done. The wind velocity was estimated as 120 miles per hour, and much destruction was caused by high tides and a storm wave. These storms occur in the West Indies most frequently between August and October. It seems a little remarkable that buildings of the character of 'skyscrapers' should ever have been erected in a region which is known to be liable to these violent tropical cyclones.

AN attractive series of lectures or popular 'talks,' calculated to interest the most diverse tastes, has been arranged for the coming winter on behalf of King Edward's Hospital Fund for London. The lecturers and subjects announced are as follows: Mr. H. L. Baird on seeing by wireless (October 7); Air Vice-Marshal Sir Sefton Brancker on flying to-day and to-morrow (October 14); Mr. W. E. Garner on liquid air (November 12); Sir Richard Paget on the artificial production of the human voice (November 19); Mrs. Rosita Forbes on her trans-Saharan journey (November 25); Dr. Ezer Griffiths on the romance of refrigeration (November 26). The lecture hour in each case is 5 P.M. The fact that these distinguished people are giving their services, and that the charges for the lectures are moderate, should insure that King Edward's Hospital Fund derives considerable financial benefit from the lectures, details of which can be obtained from the secretary of the Fund, 7 Walbrook, London, E.C.4.

IT has been pointed out that the table in the article on "Patent Office Statistics" in NATURE for September 18, p. 428, contains errors arising from the fact that 'inclusive' salaries and those carrying bonus are shown intermingled in the estimates. The writer of the article has accordingly prepared the following corrected table:

Department.	Total personnel	Number of personnel with salaries rising to a maximum of		Total of higher posts	Percentage of higher posts.
		1000*l* to 1800*l*	2000*l* and over		
Treasury	331	17	9	26	7·8
Foreign Office	839	24	3	27	3·2
Ministry of Transport	524	9	2	11	2·1
Board of Trade	567	7	5	12	[illegible]
Ministry of Agriculture	1197	14	3	17	1·4
Patent Office with Trade Marks and Design Branches	685	1	0	4	0·38

A SHORT manual on First Order Triangulation, by Rev. C. V. Hodgson, forms *Special Publication* No. 120 of the United States Coast and Geodetic Survey. Its purpose is to summarise the methods employed in executing first-order triangulation and base measurement The Survey now uses the term 'first order' in place of the term 'precise' or its earlier equivalent 'primary.' First order triangulation must have an average triangle closure of about 1″ or less, and a maximum closure not exceeding 3″. The closure in length upon a measured base must not exceed an error of 1/25000. The pamphlet contains chapters on instruments, organisation of parties, routine, sources of error, field computations, and base-line measurement. It is essentially practical, and pays little attention to theoretical considerations.

A CATALOGUE (Dept. No. 3, August) of second-hand books on natural history has reached us from Messrs. W. and G. Foyle, Ltd., 121 Charing Cross Road, W.C.2. It should be seen by readers on the look-out for natural history books, the range being large and the prices low.

DR. C. W. STILES, secretary of the International Commission on Zoological Nomenclature, informs us that a new (English) edition of the International Rules,

together with the summaries of 'Opinions' 1 to 90, has been printed in the *Proceedings of the Biological Society of Washington*, D.C., vol. 39, pp. 75-104, July 1926. Copies can be obtained from Dr. Thomas E. Snyder, the Secretary of the Society (address: Bureau of Entomology, U.S. Dept. of Agriculture, Washington, D.C.), price 1 dollar.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A chemist for research work on the evaporation rates and the ignition temperatures of vapours, of certain inflammable spirits used in industry as solvents, under the Safety in Mines Research Board —The Under-Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1. (September 29). A head of the mining department of the Central School of Science and Technology, Stoke-on-Trent—The Clerk to the Governors, Town Hall, Hanley, Stoke-on-Trent (September 30). An assistant for technical records work in connexion with the Department of Scientific and Industrial Research—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1 (October 4). A senior lecturer in electro-technics at the University of the Witwatersrand—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (October 15). An engineer to take charge of the section of Wood Preservation of the Forest Products Research Laboratory at Princes Risborough—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1 (December 1). A director of agriculture in the Territory of New Guinea—The Official Secretary for Australia, Australia House, Strand, W.C.2 (December 15). An assistant lecturer in agriculture at the South-Eastern Agricultural College, Wye, Kent—The Secretary. Junior professional assistants in the Meteorological Office—The Secretary, Air Ministry, Adastral House, Kingsway, W.C.2. A senior woman library assistant at the School of Oriental Studies—The Librarian, School of Oriental Studies, Finsbury Circus, E.C.2. A laboratory assistant for the Veterinary Research division of the Agricultural Department of the Government of Kenya—Crown Agents for the Colonies, 4 Millbank, Westminster, S.W.1 (quoting M/14661). A mistress for physics at the Cowley Girls' School, St. Helens—The Secretary to the Governors of the school, 17 Cotham Street, St. Helens.

Our Astronomical Column.

RECENT NAKED-EYE SUNSPOTS.—The last naked-eye group of sunspots noted in these columns was No. 9, seen on the sun's central meridian on July 30. Another large group bordering on naked-eye visibility was in transit across the disc between August 10 and 22, but as some observers failed to see it, a number has not been assigned to it in our tabular list of these large spots. Since September 13, however, an important group has been an easy naked-eye object. This new group is composed of two very large spots, both of which could be seen separately through morning fog on September 18. On that day their apparent separation was 3½′, corresponding to 14½° of solar longitude between their respective centres.

When the spots first appeared round the sun's east limb on September 13, they were evidently of recent origin and growing rapidly, for within 48 hours their total area had doubled. On September 18 the area of the group was 3000 million square miles or 1/400th of the sun's hemisphere. The group ranks accordingly in size with the spot of last December as the second largest group seen as yet this cycle. The region of the sun in which the group occurs is very near that of No. 8, the central meridian passage of which was June 29. During the interval between the disappearance of group No. 8 and the formation of No. 10, the photosphere of that region was marked fairly strongly with faculæ. Particulars of position and area of the August and September spots are given below:

No.	Date on Disc.	Central Meridian Passage.	Latitude.	Area.
—	Aug. 10-22	Aug. 16·2	18° S.	1/1400
10	Sept. 13-25	Sept. 19·5	24° N.	1/400

COMETS.—Two periodic comets, Giacobini-Zinner and Neujmin, are due at perihelion in a few months. The former is interesting from the near approach that its orbit makes to that of the earth. Mr. Cripps has calculated the perturbation and finds December 7 as the date of perihelion. The following ephemeris for 0^h U.T. is from the B.A.A. Handbook:

	R.A.	N. Decl.	log r.	log Δ.
Sept. 30	16^h $50·3^m$	7° 15′	0·136	0·144
Oct. 8	17 8·2	5 5	0·115	0·133
„ 16	17 28·5	2 48	0·093	0·120
„ 24	17 51·7	0 25	0·070	0·105

The comet is fairly well placed in the evening sky being on the meridian about 4 P.M.

THE SPECTRUM OF ο PERSEI.—The results of a detailed photometric study of certain features of the spectrum of the star ο Persei (Sp. type Bope), by Dr. W. J. S. Lockyer, Director of the Norman Lockyer Observatory, are recorded in *Monthly Notices, R.A.S.*, vol. 86, p. 474 (1926). Bright hydrogen lines appear in this spectrum, superposed on broad absorption lines. Each of these bright lines appears double, owing to the superposition of a fine absorption line which undergoes a periodic oscillation, presumably due to a Doppler effect. The two bright components accordingly undergo a periodic change of relative intensity, and the paper records the measurement of this change by the wedge photometer at frequent intervals throughout a complete cycle (Sept. 9, 1925–Jan. 13, 1926). Interesting conclusions are drawn from the measurements, some of which are contrary to what was expected from the observations of other workers. A similar study of the narrow absorption lines of hydrogen confirms an indication of a preliminary investigation that a variation of short period with quite a considerable amplitude is superposed on the primary variation. Pulses of activity are suggested, which seem to increase up to the epoch of maximum negative velocity and decrease down to that of maximum positive velocity. Bright lines of helium and other substances also occur in the spectrum, and the paper includes some comments on their behaviour. The character and intensity of the helium lines suggest a period of variation equal to half that of the primary variation, but the components of the bright ionised metallic lines, although their relative intensities occasionally alter, do not all behave alike, nor do they present any apparent cyclical change.

on the staff of University College and the University of Bristol, has now accepted an appointment at Stanford University, California, U.S.A., where he will take up his duties after Christmas of this year. Miss M. E. Laing and Miss M. H. Norris have also been appointed to the staff of Stanford University.

THE Mineralogical Society, which was instituted on February 3, 1876, has just celebrated its jubilee in London. The programme included visits of delegates from foreign mineralogical and geological societies and invited guests to the British Museum (Natural History), South Kensington, and to other museums and institutions in London; a conversazione in the Geological Society's Rooms at Burlington House on September 21; and a dinner at the Connaught Rooms on the following evening. The celebration in London was preceded by an excursion (September 12-18) to Devon and Cornwall under the direction of Mr. Arthur Russell, and is to be followed by an excursion (September 23-30) to the north of England under the direction of Prof. A. Hutchinson

THE news columns of the daily papers during the past few days have contained long accounts of the disastrous hurricane which visited Florida on the night of September 17. According to the New York correspondent of the *Times*, the coastal region from Palm Beach to Miami was the area most affected, and it is estimated that 800-1500 lives were lost. The material damage is put at 30,000,000*l*. In Miami, wooden houses were ripped apart, concrete houses broken from their foundations, 'skyscrapers' were badly twisted, small shipping were lifted into the Royal Park, and the new docks were destroyed. The wind is stated to have reached a velocity of 130 miles per hour, and the first visitation lasted nine hours. Farther north there were also damage and casualties. The West Indies is one of the five regions of the globe where these violent tropical cyclones occur. When such storms arise in or near the West Indies, they generally pursue a curved path towards the north-west or into the Gulf of Mexico and then north-eastward along the Atlantic coast. They lose their violence as they pass into the temperate zone. The Galveston hurricane was apparently of even greater violence than that which has just occurred. It occurred in the same region on September 8, 1900; and on this occasion 6000 lives were lost and 6,000,000*l* worth of damage was done. The wind velocity was estimated as 120 miles per hour, and much destruction was caused by high tides and a storm wave. These storms occur in the West Indies most frequently between August and October. It seems a little remarkable that buildings of the character of 'skyscrapers' should ever have been erected in a region which is known to be liable to these violent tropical cyclones.

AN attractive series of lectures or popular 'talks,' calculated to interest the most diverse tastes, has been arranged for the coming winter on behalf of King Edward's Hospital Fund for London. The lecturers and subjects announced are as follows: Mr. H. L. Baird on seeing by wireless (October 7); Air Vice-Marshal Sir Sefton Brancker on flying to-day and to-morrow (October 14); Mr. W. E. Garner on liquid air (November 12); Sir Richard Paget on the artificial production of the human voice (November 19); Mrs. Rosita Forbes on her trans-Saharan journey (November 25); Dr. Ezer Griffiths on the romance of refrigeration (November 26). The lecture hour in each case is 5 P.M. The fact that these distinguished people are giving their services, and that the charges for the lectures are moderate, should insure that King Edward's Hospital Fund derives considerable financial benefit from the lectures, details of which can be obtained from the secretary of the Fund, 7 Walbrook, London, E.C.4.

IT has been pointed out that the table in the article on "Patent Office Statistics" in NATURE for September 18, p. 428, contains errors arising from the fact that 'inclusive' salaries and those carrying bonus are shown intermingled in the estimates. The writer of the article has accordingly prepared the following corrected table:

Department.	Total personnel.	Number of personnel with salaries rising to a maximum of		Total of higher posts.	Percentage of higher posts.
		1000*l*. to 1800*l*.	2000*l*. and over		
Treasury	331	17	9	26	7·8
Foreign Office	839	24	3	27	3·2
Ministry of Transport	524	9	2	11	2·1
Board of Trade	567	7	5	12	1·8
Ministry of Agriculture	1197	14	3	17	1·4
Patent Office with Trade Marks and Design Branches	685	4	0	4	0·38

A SHORT manual on First Order Triangulation, by Rev. C. V. Hodgson, forms *Special Publication* No. 120 of the United States Coast and Geodetic Survey. Its purpose is to summarise the methods employed in executing first-order triangulation and base measurement. The Survey now uses the term 'first order' in place of the term 'precise' or its earlier equivalent 'primary.' First order triangulation must have an average triangle closure of about 1″ or less, and a maximum closure not exceeding 3″. The closure in length upon a measured base must not exceed an error of 1/25000. The pamphlet contains chapters on instruments, organisation of parties, routine, sources of error, field computations, and base-line measurement. It is essentially practical, and pays little attention to theoretical considerations.

A CATALOGUE (Dept. No. 3, August) of second-hand books on natural history has reached us from Messrs. W. and G. Foyle, Ltd., 121 Charing Cross Road, W.C.2. It should be seen by readers on the look-out for natural history books, the range being large and the prices low.

DR. C. W. STILES, secretary of the International Commission on Zoological Nomenclature, informs us that a new (English) edition of the International Rules,

together with the summaries of 'Opinions' 1 to 90, has been printed in the *Proceedings of the Biological Society of Washington*, D.C., vol. 39, pp. 75-104, July 1926. Copies can be obtained from Dr. Thomas E. Snyder, the Secretary of the Society (address: Bureau of Entomology, U.S. Dept. of Agriculture, Washington, D.C.), price 1 dollar.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned :—A chemist for research work on the evaporation rates and the ignition temperatures of vapours, of certain inflammable spirits used in industry as solvents, under the Safety in Mines Research Board—The Under-Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1. (September 29). A head of the mining department of the Central School of Science and Technology, Stoke-on-Trent—The Clerk to the Governors, Town Hall, Hanley, Stoke-on-Trent (September 30). An assistant for technical records work in connexion with the Department of Scientific and Industrial Research—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1 (October 4). A senior lecturer in electro-technics at the University of the Witwatersrand—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (October 15). An engineer to take charge of the section of Wood Preservation of the Forest Products Research Laboratory at Princes Risborough—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1 (December 1). A director of agriculture in the Territory of New Guinea—The Official Secretary for Australia, Australia House, Strand, W.C.2 (December 15). An assistant lecturer in agriculture at the South-Eastern Agricultural College, Wye, Kent—The Secretary. Junior professional assistants in the Meteorological Office—The Secretary, Air Ministry, Adastral House, Kingsway, W.C.2. A senior woman library assistant at the School of Oriental Studies—The Librarian, School of Oriental Studies, Finsbury Circus, E.C.2. A laboratory assistant for the Veterinary Research division of the Agricultural Department of the Government of Kenya—Crown Agents for the Colonies, 4 Millbank, Westminster, S.W.1 (quoting M/14661). A mistress for physics at the Cowley Girls' School, St. Helens—The Secretary to the Governors of the school, 17 Cotham Street, St. Helens

Our Astronomical Column.

RECENT NAKED-EYE SUNSPOTS.—The last naked-eye group of sunspots noted in these columns was No. 9, seen on the sun's central meridian on July 30. Another large group bordering on naked-eye visibility was in transit across the disc between August 10 and 22, but as some observers failed to see it, a number has not been assigned to it in our tabular list of these large spots. Since September 13, however, an important group has been an easy naked-eye object. This new group is composed of two very large spots, both of which could be seen separately through morning fog on September 18. On that day their apparent separation was $3\frac{1}{2}'$, corresponding to $14\frac{1}{2}°$ of solar longitude between their respective centres.

When the spots first appeared round the sun's east limb on September 13, they were evidently of recent origin and growing rapidly, for within 48 hours their total area had doubled. On September 18 the area of the group was 3000 million square miles or 1/400th of the sun's hemisphere. The group ranks accordingly in size with the spot of last December as the second largest group seen as yet this cycle. The region of the sun in which the group occurs is very near that of No. 8, the central meridian passage of which was June 29. During the interval between the disappearance of group No. 8 and the formation of No. 10, the photosphere of that region was marked fairly strongly with faculæ. Particulars of position and area of the August and September spots are given below :

No.	Date on Disc.	Central Meridian Passage.	Latitude.	Area.
—	Aug. 10-22	Aug. 16·2	18° S.	1/1400
10	Sept. 13-25	Sept. 19·5	24° N.	1/400

COMETS.—Two periodic comets, Giacobini-Zinner and Neujmin, are due at perihelion in a few months. The former is interesting from the near approach that its orbit makes to that of the earth. Mr. Cripps has calculated the perturbation and finds December 7 as the date of perihelion. The following ephemeris for 0^h U.T. is from the B.A.A. Handbook :

	R.A.	N. Decl.	log r.	log Δ.
Sept. 30	$16^h\ 50{\cdot}3^m$	7° 15′	0·136	0·144
Oct. 8	17 8·2	5 5	0·115	0·133
„ 16	17 28·5	2 48	0·093	0·120
„ 24	17 51·7	0 25	0·070	0·105

The comet is fairly well placed in the evening sky, being on the meridian about 4 P.M.

THE SPECTRUM OF φ PERSEI.—The results of a detailed photometric study of certain features of the spectrum of the star φ Persei (Sp. type Bope), by Dr. W. J. S. Lockyer, Director of the Norman Lockyer Observatory, are recorded in *Monthly Notices, R.A.S.*, vol. 86, p. 474 (1926) Bright hydrogen lines appear in this spectrum, superposed on broad absorption lines. Each of these bright lines appears double, owing to the superposition of a fine absorption line which undergoes a periodic oscillation, presumably due to a Doppler effect. The two bright components accordingly undergo a periodic change of relative intensity, and the paper records the measurement of this change by the wedge photometer at frequent intervals throughout a complete cycle (Sept. 9, 1925–Jan. 13, 1926). Interesting conclusions are drawn from the measurements, some of which are contrary to what was expected from the observations of other workers. A similar study of the narrow absorption lines of hydrogen confirms an indication of a preliminary investigation that a variation of short period with quite a considerable amplitude is superposed on the primary variation. Pulses of activity are suggested, which seem to increase up to the epoch of maximum negative velocity and decrease down to that of maximum positive velocity. Bright lines of helium and other substances also occur in the spectrum, and the paper includes some comments on their behaviour. The character and intensity of the helium lines suggest a period of variation equal to half that of the primary variation, but the components of the bright ionised metallic lines, although their relative intensities occasionally alter, do not all behave alike, nor do they present any apparent cyclical change.

Research Items.

'SÔMA.'—A note by Prof. G. Jouveau Dubreuil, in the *Indian Antiquary* for September, deals with the identity of the sacred Sôma plant. Dr. Vincent Smith pointed out that while the plant used in the sacrifices of the Parsis of Yezd and Kirmân, as well as of the Deccan and Bombay, is identified with one or other of the species of Asclepias, the real Sôma plant may have been different. Mr. Havell has suggested that it is Eleusine, the common millet still found in the Himalayas. An inquiry has been made as to the plant used by the Sômayagis, who practise the Sôma sacrifice, among the Nambudris, a very high caste of Brahmans in the district of Malabar who, having been sheltered from invasion and change, have thus preserved the Vedic tradition. A reply was received from the great temple of Taliparamba where are the best examples of the *agnidrîvas*—the temples of the Vedic fire—that the Sômavalli plant was a rare plant found in the mountains and was obtained from a raja who lived at Kollangôd (ten miles south of Pâlghât). After some difficulty a specimen of the plant was obtained. It proved to be a climbing plant having a stem which was green, bare, round, and woody, and containing a milky liquor. It is absolutely without foliage, and has been identified as belonging to the genus Asclepias.

ANTIQUITIES FROM KEDAH.—Mr. Ivor H. N. Evans, in the *Journal of the Federated Malay States Museums*, vol. 12, pt. 3, describes the results of a visit to the Langkawi Islands, the neighbourhood of Sungai Patani, Baling, and Weng, to obtain additional examples of antiquities from these localities, and in the last-named place to collect specimens of the manufactures of the Negritos, whose presence had been reported there Excavation work was undertaken on the Sungai Batu estate towards the foot of the Kedah Peak, where an ancient statue, some brickwork, and four worked stones had been obtained in 1921 and 1923. Of these last, two were conduit stones, and another had apparently at some time borne a bas-relief of an elephant-headed god (Ganesha). The excavations revealed the remains of a shrine consisting of wallings of laterite and bricks and, apparently, the sill of a doorway, as well as boulders embedded in a cement of laterite. A number of sculptured stones were found including a highly conventionalised ancient Hindu *Yoni* (female sex organ) apparently of quartzite, a sharpening stone with two depressions for holding the water used in whetting, and two stones with spiral markings, probably the terminals of a balustrade. The conclusion suggested is that the early inhabitants of Sungai Batu were Hindus and worshippers of Siva or related deities. Probably they were non-Malayan traders or miners or, if Malays, they had learnt the art of stone carving from Indian sources. Occupation goes back to a time when stone implements were in use, as is shown by a beautifully made chalcedony celt, and lasted until an ancient Mohammedan settlement. Here also strong Hindu influence is to be observed in four graves of obviously important personages.

INTESTINAL SECRETION OF INSECTS.—In *Memoirs of the College of Science, Kyoto University*, Series B., Vol. 2, No. 2, 1926, Mr. Osamu Shinoda contributes an important paper on this subject. It has long been known that in insects the mid-intestine performs the dual function of digestion and absorption. There exist various theories and hypotheses as to whether these two functions are performed by two distinct kinds of cells or whether they represent different physiological phases of the same kind of cells. Mr. Shinoda's studies were mainly carried out on larvæ of the Saturniid moth *Dictyoploca japonica*. He finds that the epithelial layer is composed of goblet cells and ciliated cylindrical cells which are, in his opinion, homomorphous at different phases of their activity. The cylindrical cells are those in the phases of secretion and absorption, while the goblet cells are nothing more than a resting phase of the cylindrical cells. In the secretory phase the nuclei of the cylindrical cells are large and loosely filled with irregularly shaped basophile granules: the nuclei, it may be added, are situated slightly higher than the middle points of the cells. The cytoplasm just beneath the ciliated border is filled with secretory granules. In the stage of absorption the nuclei lie near the distal ends of the cells; they are small and densely filled with chromatic granules. When the phase of absorption is over the accumulation of secretory granules begins while the nuclei increase in volume and migrate downwards in the cells.

INSECTS AND THE TRANSMISSION OF RINDERPEST.—Very few attempts appear to have been made to transmit rinderpest by the agency of arthropods. Certain bacteriological data obtained by the Director of the Veterinary Research Institute at Muktesar, India, seemed to indicate that the causative organism of rinderpest was possibly not very unlike the Leptospira of yellow fever, which is transmitted from host to host by the mosquito *Ædes argenteus*. This analogy appeared to be worth following up with reference to the possible insect-transmission of rinderpest, and a lengthy paper on this subject has recently appeared in *Memoirs of the Dept. of Agriculture in India*, Vol. 9, No. 5, May 1926. The author, Mr. S. K. Sen, carried out a series of transmission experiments which resolve themselves into three categories. In one series the mosquito *Ædes albopicta* was used as the transmitting agent. The results of the experiments on hill bulls were negative, but some of the rabbits employed showed thermal reactions when infected mosquitoes fed upon them. In another series the possibility of the mechanical transmission of rinderpest through the agency of *Musca domestica* was tested. In a fair proportion of the experiments positive results were obtained when bodies of flies fed upon infective material were inoculated into susceptible bulls. The results, however, were negative when the trials were carried out with reference to transmission under conditions more likely to occur in a state of Nature. The third series was carried out with *Pediculus humanus*. The infectivity of saline suspensions of crushed infested lice was tested upon three bulls, and one of these developed rinderpest. The effects of the transference of infested lice on to a healthy bull, however, were negative.

THE CLIMATE OF NORTH-EAST LAND.—In a paper in the *Geographical Journal* for September on the weather of North-East Land, Spitsbergen, during one month in the summer of 1924, Mr. K. S. Sandford has collected some evidence of value in relation to the problem of glacial anticyclones. In this relatively small but almost entirely ice-covered area he found no fixed anticyclone but a definite tendency towards the establishment of anticyclonic conditions with radial gravitational winds. This intermittent glacial anticyclone is blotted out by interference from outside the area but quickly re-establishes itself. Winds are markedly outflowing and lead to an augmentation of the bordering ice at the expense of the higher parts of the interior. On the other hand, interference from outside is great and leads to melting

of ice in the bordering zone and to a less extent in the interior. During the maintenance of anticyclonic conditions there is some indication of a pulsation, from calm to blizzard. Mr. Sandford believes that in New Friesland, on the mainland of Spitsbergen, there is a similar but modified system. Other parts of Spitsbergen have an insufficient ice-covering for its development. Up to the present there are no winter observations available from North-East Land.

THE NEW MAP OF FRANCE.—The standard map of France is the Carte d'État Major on a scale of 1 to 80,000, from which other scales are derived. So long ago as 1881, on the completion of this map, it was proposed to produce a new coloured map on a scale of 1 to 50,000 In the *Revue Scientifique* (Nos. 12 and 13, 1926) Col. G. Perrier traces the history of these proposals. It was not until 1899 that a specimen sheet of the new map was prepared and then the project was again suspended, eventually to be resumed, but restricted to certain regions in the north-east, east, and south-east for purely military purposes. In 1914 the number of published sheets was only 42. Some provisional sheets for Alsace-Lorraine were produced during the War, and a few for the Saar basin have been since published. But the scheme, which embraces about 1000 sheets, is now definitely suspended owing to expense. Apart from the provisional issues, only 53 sheets are available of this new survey.

THE AGE OF THE EARTH.—In the *Transactions of the New Zealand Institute* (March 6, 1926) the Hon. Sir Frederick Chapman discusses the origin of living organisms and their evolution with the view of reaching a reasonable idea of the period during which the earth has been inhabited. He thinks it is now possible to draw the conclusion that the first organisms were very minute; perhaps far smaller than the typhus bacillus or the invisible microbe of foot-and-mouth disease. Traces of micro-organisms have been found by Walcott in the pre-Cambrian rocks of North America, and from that beginning organisms have become larger and larger up to the massive creatures of the Mesozoic and the 150-ton whales of to-day. The broad question is raised: how many generations are required, and how long would it take, for evolutionary processes, to develop such enormous animals from ancestors of which a thousand million would make up less than a pin's head in bulk? No definite estimate is suggested, for the author recognises that no law of uniformity—either arithmetical or geometrical—can possibly be assumed. Nevertheless, it is made clear that his own sympathies are in favour of the longer estimates of geological time. He rightly protests against the idea that the evolution of the horse within the Cainozoic era could have been accomplished in the four million years that were formerly allowed to that era by certain geologists, then intimidated by the authority of Lord Kelvin. However, this is now of no more than historical interest. It is scarcely likely that Sir Frederick Chapman's problem will ever be directly soluble, even by the integration of its parts. Biologists will probably do better to take their time-scale from the study of geological and radioactive processes, and to make such deductions as to the rate of evolution as may be useful for their purposes. The only direct contribution from palæontology is the broad conclusion that hundreds of millions of years would be preferable to tens of millions.

THE NATURE OF ISOSTASY.—An important paper on isostasy from the pen of Dr. Harold Jeffreys appears in *Gerland's Beitrage zur Geophysik* (Bd. 15, 1926, p. 167). He shows that the work on which the theory of isostasy has been founded is adequate to prove that surface inequalities are compensated at depths of the order of tens of kilometres, but that it fails to provide satisfactory criteria for discriminating between the Pratt and Airy types of compensation or between local and regional compensation. Theoretically there is an infinite number of density distributions which would fit the gravity data, but excluding those that are physically unplausible there is a general likeness between those that are left. The Airy compensation is found to be much the more probable from the point of view of the physical and geological processes involved; and regional compensation spread out to a distance comparable with the depth of compensation as usually inferred is more probable than local compensation. Unfortunately, the depth of the compensating matter and its lateral extent are complementary in the sense that they cannot be disentangled by gravity observations alone. However, regional compensation must be effected at a smaller depth than an equivalent local compensation, and from this consideration it is inferred that the thickness of the granitic layer of the continents must be about half the least value (41 km.) found for the depth of compensation on the local hypothesis. As seismic and thermal evidence suggests a thickness of 15 or 20 km. there is already independent evidence in favour of Jeffrey's conclusions.

TRIETHYLAMINE AND DIETHYLAMINE.—A communication received from the Mellon Institute of Industrial Research, Pittsburg, Pa., states that a new process for manufacturing triethylamine and diethylamine has been developed there by Dr. D. K. Tressler and his assistants. The cost of production of the amines is said to have been considerably reduced, and it is anticipated that they will find extensive industrial applications, many of these being suggested. No details of the method are disclosed.

THE HISTORY OF CHEMISTRY IN AMERICA.—We have received a copy of a paper by E. F. Smith, reprinted from the *Journal of Chemical Education*, Vol. 3, No. 6, June 1926, containing fragments relating to the history of chemistry in America. The six sections refer to such varied subjects as Dr. L. Spalding's "New Nomenclature of Chemistry," 1799; Priestley's visit to America, 1794; alchemists in the New England Colonies, *c.* 1700; mineral analysis, 1824; Amos Eaton's "Chemical Instructor," a very practical text-book, *c.* 1800; and articles from the *Pennsylvania Magazine*, or the *American Monthly*, first published in 1775 by Robert Aitken.

IGNITION OF GASES.—Paper No. 24 (Part 1, by N. S. Walls and R. V. Wheeler; Part 2, by W. Rintoul and A. G. White), published by the Safety in Mines Research Board, describes some of the work being carried out on the ignition of gases. When mixtures of methane and air are exposed to flame, combustion does not take place instantaneously, but an exposure of a definite period is required. The period depends on the character of the flame, being shorter for larger flames. With fully aerated flames, mixtures containing between 9·5 and 10 per cent. of methane are the most readily ignited, but if the flame is not completely aerated and abstracts oxygen from the mixture to which it is exposed, the most readily fired mixtures are those containing an excess of oxygen. When fully oxidised explosives are employed to ignite the mixtures, the optimum methane content is 9·25 per cent., suggesting that the flame of the explosive is not the only factor involved.

Industrial Psychology.

IN the programme of Section J (Psychology) at the Oxford meeting of the British Association, industrial psychology was the subject of several papers and demonstrations of which the following is a brief review:

(1) Mr. R. J. Bartlett, King's College, read a paper on the judgment of value of individual advertisements. The paper arose from an inquiry undertaken by the National Institute of Industrial Psychology three years ago. The first essential of a good advertisement is attracting power and the second holding power. The grading of individual advertisements according to 'attracting-holding' power was taken as the principal task. But in a world as inconstant as that of Paris fashion a 'scale' for measuring this power can have only a temporary value. The scatter of some 180 advertisements when arranged in a scale of 7 grades was found to be normal. Most advertisements fell in the central three grades and very few indeed in grades 1 or 7. For the advertiser the lesson is the old one: 'There's plenty of room at the top.' Another feature is that when the 16 Bovril posters were judged by 15 members of the advertising profession, great variability of judgment from subject to subject was exhibited, yet the resulting order of merit correlated with the winning ballot order as high as $0{\cdot}8 \pm 0{\cdot}1$, showing that there is a common factor in the judgments which is shared by the large population that contributed to the ballot figures.

It was concluded that with a small number of advertisements, up to say 20, the method of paired comparisons, though tedious, is trustworthy. Above that number a fractionation method using 7 groups was recommended. Some practised subjects are even capable of employing this method using 15 groups. Simplicity and unity of design coupled with artistic treatment of shape and balance make for the good advertisement, while overcrowding, distraction from competing foci, and failure to secure the illusion of perspective are among the principal causes of failure In conclusion, two kinds of variability were discussed, namely, the common variability from some nodal value, and that founded on the limited appeal of certain advertisements; for example, pipe smokers agreeing very closely in their disagreements with cigarette smokers. The latter kind is important and deserves further study. This, however, was set aside in forming the present scales, the aim being to assess the value of an advertisement on the assumption that the reader is a prospective purchaser.

(2) Mr. Arthur Stephenson, of the National Institute of Industrial Psychology, read a paper on some observations on accidents in industry. Although one must not belittle the success of mechanical safeguards, yet 90 per cent. of present-day accidents are to be accounted for as failures on the part of the human subject. The U.S. Federal Board for Vocational Education gives many examples of efficient safety work in various industries, but only one-third of the reductions in the personnel sustaining accidents has been effected by mechanical safeguards: two-thirds have been accomplished through organisation and education. Mr. Davis, Secretary of Labour, states that the fatal industrial accidents in the U.S.A. probably exceed 23,000 per annum and non-fatal accidents $2\frac{1}{2}$ millions, and he is advised by experts that 85 per cent. of these are preventable. In Great Britain there are about 1200 fatal accidents per annum in factories and workshops, and another 1200 in coal mines and quarries. Non-fatal accidents of sufficient severity to cause disablement for a week or more number 120,000 a year in factories, and 200,000 a year in coal mines.

The National Institute of Industrial Psychology, so far back as 1922, recommended preliminary surface instruction of youths entering the mine and applied a scheme of training. Mr. Stephenson described an experiment where learners were trained in an industrial process along certain lines. Some of the learners were raw novices while others had had previous experience. Periodical tests of efficiency were made and those who proved incapable of profiting by instructions were discharged. After the scheme had been in operation for 10 months the accident frequency was analysed. The frequency rate for novices dismissed was $1\frac{1}{2}$ times as great as for novices retained, while for experienced learners dismissed it was $3\frac{3}{4}$ times as great as for experienced learners retained. The data obtained made it probable that ability to acquire the neuro-muscular co-ordination required by the particular process, is at least as important a factor as age or experience. Whilst agreeing that a considerable advance may be made by educational and propaganda methods, it is considered probable that the scientific selection of the workers would probably tend to diminish the frequency rate of accidents.

(3) Mr. A. Angles read a paper on restriction of output. In no case within the experience of the National Institute of Industrial Psychology has restriction of output been attributable to the particular trades union as such. It is usually brought about by a strong feeling of class loyalty which, in known cases, has even overcome individual self-interest. Two of the reasons given by workers for this policy are sufficiently frequent to be outstanding:

(*a*) Fear of rate-cutting. Examples are on record where employers have reduced rates in order to keep the workers down to a certain minimum.

(*b*) Fear of unemployment, or increased short-time. The work is spread out so that time-rate workers shall have the benefit of longer hours and more pay. Other reasons are: The fear of discharge of less competent workers, general dissatisfaction with present conditions, influence of the foreman, satisfaction with present earnings. General conditions and systems of wages vary enormously according to the efficiency of the management, but where the 'mental atmosphere' of the factory is good, restriction of output will very rarely be found.

(4) Miss W. Spielman gave a lecture on recent progress in vocational selection. The older methods of vocational selection were compared with modern methods employing mental and physical tests. This lecture served as an introduction to the demonstration given at the conversazione, by Miss Spielman and her assistants, of psychological tests in use at the National Institute of Industrial Psychology. There were tests for vocational guidance (*e.g.* of intelligence, mechanical ability, and manual dexterity); and tests for vocational selection (*e.g.* for engaging weavers, packers, clerks, sales assistants, etc.). In addition, the material collected from various countries by the Research Committee on Vocational Guidance was on view and the various reports of this Committee were distributed to those interested.

(5) Mr. Eric Farmer, investigator to the Industrial Fatigue Research Board, arranged an exhibition, and gave a demonstration at the conversazione, of apparatus designed for the Board by Dr. Schuster, namely, a pursuit-meter, steadiness-meter, a fatigue-inducing apparatus, a dotting apparatus, an original type of chronoscope for serial reactions, and a figure-setting apparatus which serves excellently as a non-verbal test of intelligence. All were original in design and ingenious in workmanship and well calculated to render effective service in the hands of the industrial psychologist.

LL. W. J.

Early Egypt and the Caucasus.

DURING the recent meeting of the British Association at Oxford, the question of the origin and date of the Badarian culture of Egypt was again raised by Sir Flinders Petrie, and provided the material for an animated discussion which, with two closely related papers on the geology and archæology of the Fayum by Miss Gardner and Miss Caton-Thompson respectively, occupied the whole of an afternoon session in Section H (Anthropology).

Sir Flinders Petrie in opening gave a brief summary of the paper which he read before the Section last year at the Southampton meeting. It may perhaps be a convenience to recapitulate here the facts. While working at Badari, a site thirty miles south of Asyut, four seasons ago, members of the British School of Archæology in Egypt discovered a settlement which had in its lowest stratum pottery of a very fine type, entirely hand made, and the thinnest and hardest of any age, with a polish never surpassed. With it were associated ivory statuettes and flints finely worked in technique and form and resembling the Solutrean, and identical with the finely worked flints already known, though from surface finds only, to occur in the Fayum and across the desert up to Palestine. A later investigation by Miss Caton-Thompson produced similar implements from the settlement sites of the Fayum.

Sir Flinders Petrie suggested an Asiatic origin for this culture, its centre possibly being the Caucasus. As regards its dating, basing his conclusions in the levels of the Nile as a time scale, he suggested something like 12,000 to 15,000 B.C. as the period at which the sites had still been uncovered. The chronological evidence was thus, on this reckoning, not contradictory of an attribution of the culture to the Solutrean, following the indication of form and technique in the flint work Obvious difficulties stand in the way of accepting the Badarian culture as an Egyptian offshoot of a Solutrean culture, not the least of course being the presence of pottery. To this the reply is that while one branch of the original Solutrean culture on its migration into Europe along a glacial fringe lost certain elements in that culture, such as the pottery, the other branch, proceeding southward in easier conditions of travel, was able to retain them.

Further, among other criticisms, it has been pointed out that flint working of this delicate type occurs at what is known and admitted to be a later date: it is not to be accepted as being beyond question Solutrean on the ground of its form and technique. In Scandinavia, implements known to be neolithic present a resemblance to the Solutrean form and technique. Sir Flinders Petrie is prepared to accept the facts, but not necessarily as militating against his conclusions. Just as the European Solutrean lost in its way across the Continent, so the south-western branch lost something and degenerated after it had reached Egypt, there was a descent from the finest to the coarsest pottery and from the finest to the coarsest flint work. The recurrence of the finer technique is to be regarded as evidence of a long-continuing Asiatic civilisation which sent off branches from time to time at long intervals.

Apart from the recapitulation and expansion of the argument in favour of the Solutrean date of the Badarian culture, Sir Flinders Petrie brought forward at Oxford two pieces of evidence bearing upon the question of its northern origin, one of which is certainly of first-rate importance if it should be ratified by subsequent examination. Among the finds made by Miss Caton-Thompson in her excavations on the settlement sites of the Fayum during the past season, straw granaries were found buried in the ground which were made of the straw of wheat. This wheat has been pronounced to be neither the old wheat of Babylon and Egypt nor the wheat of Roman times, but a northern wheat. This wheat was certainly unknown in later times, and if the claim that it is of a northern origin can be substantiated, it is a conclusive piece of evidence for, at least, an intrusive element from the north.

The second class of evidence which, in Sir Flinders Petrie's opinion, pointed to a Caucasian origin, was derived from the coincidence between names mentioned in the "Book of the Dead" and certain place-names in the Caucasus. Recently Mr. Fessenden of U.S.A. has advanced the view that in the Caucasus area we are to find the cradle of civilisation, basing his theory upon a multitude of coincidences between Caucasian place-names and names mentioned in legend and tradition. Among others he identified names mentioned in the "Book of the Dead." Sir Flinders Petrie has carried the investigation further. Extracting place-names in the "Book of the Dead" in their local relation to one another, he finds that they equate with place-names in the Caucasus, and, what is more, their local relation corresponds to the correct geographical relation of the equivalent place-names in that area. Further, the mention of a lake of fire in a fertile valley surrounded by barren hills could only correspond in actual fact to the conditions of a naphtha lake in the Caucasus. The traditional origin of Osiris, the god of the corn, in this legendary region is corroborated by the northern origin of the corn now discovered.

It is perhaps scarcely necessary to say that Sir Flinders Petrie's theories found many stern critics, ranging from Prof. Sollas, who pointed out that the conditions of the Badarian culture could not be regarded as corresponding to the conditions of the Solutrean, certainly as regards dating, to Mr. Peake, who, while inclined to accept the northern origin of the culture of the pottery and the grain-growing worshippers of Osiris, not only raised the question as to the equation of Badari and the Fayum, but also in regard to the last argument pointed out the necessity for certainty in the transliteration of the names taken from the "Book of the Dead." Such experts in the technique of flint working as the Abbé Breuil, Dr. Bosch Gimperâ, and Mr. M C Burkitt concurred in thinking that the finely worked flint might be an independently developed Solutrean-like technique entirely African in origin.

It was, however, the papers by Miss Gardiner and Miss Caton-Thompson which most strongly emphasised the difficulties inherent in Sir Flinders Petrie's theories. As already mentioned, he had based his dating of the Badarian culture on the height of the water level. Miss Gardiner's investigations of the recent geology of the Fayum showed that the lake beds north of the Birket Qarun must be divided into at least two series—those of an earlier lake occurring up to 222 ft. above the Birket Qarun level, which were at one time connected with the Nile, as is shown by the fauna, and a later series which only reached the maximum of 205 ft. above the present level. Miss Caton-Thompson's examination of the settlements yielded flint implements of the characteristic type, pottery, and ample evidence of the agricultural, hunting, and fishing culture of the people. It is a characteristic culture of advanced neolithic type. Further, it was found that the sites fringe the shore of the second lake period, resting upon the sands and clays of the old high-level lake. There is

no sign of subsequent submergence. Both topography and the distribution of the high-level gravels emphasise the long period which elapsed between middle palæolithic times and the arrival of the Fayum flint-workers.

It would appear that both the geological evidence and the evidence of culture—unless we are to revise entirely our conception of the culture attainable by a palæolithic people—preclude the attribution of a very high antiquity to this civilisation of the Fayum. In so far it has failed to support the early dating of the analogous culture found at Badari, where too it must be remembered that it has been stated that copper beads were found, not, it is true, in the settlement, but in a grave in the adjacent cemetery.

Animal Breeding and Genetics.[1]

THE report under notice contains the record of a series of most interesting researches, not by any means all of which deal with what may be termed genetical problems, for a considerable number consist in studies of abnormal development. Thus the Director, Dr. F. A. E. Crew, has studied the so-called 'bull-dog calf.' These calves are born dead, and their anatomy shows a close resemblance to the so-called achondroplasia in human dwarfs. Dr. Crew maintains that the tendency to produce such offspring is hereditary and 'mendelises' when crossed with the type. He attributes it to the retardation of the coming into action of the pituitary gland; this may be so, but the immediate mechanism is doubtless as it is in human dwarfs, amniotic pressure, *i.e.* a too closely clinging amnion.

Mr. Nichols investigated a cross between Leicester and Cheviot sheep, the result of which had been stated to produce a hybrid of stable character. When the F_2 generation was raised, however, it was found that whereas 64 out of 103 resembled their F_1 parents, 18 approached the Leicester type and 20 had mixed characteristics of both Cheviot and Leicester. This result does not, as Mr Nichols imagines, prove Mendelian segregation in the proper sense of the word. It is a result always obtained when two natural races are crossed; every conceivable intermediate turns up, but the attempt to express the result in 'factors' leads to interminable confusion. The number examined (100) is far too small to warrant any statistical conclusions.

Mr. Blyth has been engaged in a microscopical survey of the various types of wool raised in the British Islands. Four types are distinguished, namely, mountain long wool, lustre (also long wool), mountain short wool, and short wool (Down breeds). There are two main types of hairs making up the fleeces, namely, (*a*) long coarse hairs with reticular scale markings, and (*b*) short, fine hairs with coronal markings. Type (*a*) is found only in the long wools, type (*b*) in varying proportions in all the breeds. Short coarse fibres called 'Kemp,' frequently shed, are found in all the breeds. This and type (*a*) are regarded as equivalent to the primitive hair of the wild progenitor, whilst type (*b*) represents the original wool.

Mr. Greenwood has been following the fate of grafts of gonads implanted in fowls. This is especially interesting in view of the claim of Zawadovsky to have changed a cock into a hen by two operations, (*a*) cutting out the testes, (*b*) implanting an ovary. Mr. Greenwood finds that the ingrafted ovary frequently assumes a testicular structure by the ingrowth of sex-tubules from its periphery, and that sometimes the removal of the ovary stimulates the development of the vestigial right gonad. This gonad in one case was testicular in structure, in another ovarian, but with ingrowth of sex-cords indicating that it was being transformed into a testis.

Mr. L. Tamura is engaged in investigating the sex dimorphism of the suprarenal gland, which, as a result of previous work, he asserts, is different in the two sexes, the gland of the female showing a wide zona reticularis, whilst this region is vestigial in the male gland. It was found that when the male was castrated the suprarenal underwent enlargement, which was entirely due to the appearance of a wide zona reticularis. A sterile Dingo bitch which was investigated showed an infantile vagina and uterus with degenerating ovaries whilst the teats were normally developed, but not only the suprarenal but also the thyroid and pituitary glands showed obvious and gross signs of degeneration.

In conclusion, we should like to congratulate Dr. Crew on the variety and interest of the researches which are being carried on under his supervision.

E. W. M

[1] Animal Breeding Research Department, the University, Edinburgh. Report of the Director for the year April 12, 1924, to March 31, 1925 (being the Fifth Annual Report). Pp. 21. (Edinburgh.)

University and Educational Intelligence.

THE Brighton Technical College in its calendar for 1926–27 is able to offer substantial evidence of the efficiency of their instruction in engineering subjects, six of the students having gained directly from the College the B.Sc. (Engineering) degree of the University of London in 1926. The College has a flourishing school of pharmacy, and provides courses of building, architecture, commercial subjects, and domestic science, as well as in arts and pure science subjects.

THE Technical College, Bradford, gives particulars in its prospectus for 1926–27 of diploma courses in textile industries, arranged with special reference to the needs of the worsted industry, chemistry, dyeing, civil, mechanical and electrical engineering, physics, and, exceptionally, biology. In recognition of the importance to students in all branches of technology of a knowledge of the fundamental principles of economics, courses in the department of commerce and banking have been developed in relation to those in the various other departments of the College, and particularly to those in the department of textile industries. Conversely, a special course for merchants has been established to equip those students who are to be engaged in the distributive side of the industry with a sufficient knowledge of dyeing and textile subjects.

FROM the Czech Academy of Sciences and Arts, Prague, we have received an 'Almanach" for 1924. It is beautifully printed on 240 pages and is embellished with a large number of remarkably fine portraits accompanying biographical notices It is printed throughout in the Czech language without any summary or abstracts in more widely known languages, and it was with some difficulty that we ascertained the purport of even the title-page. One of the recommendations made by the Directors of National University offices at their recent reunion at Paris was that the official publications of universities should, if printed in a language the use of which is not widely diffused throughout the world, have appended to them abstracts in one of the languages in more general use. The adoption of this recommendation is no doubt impossible in many cases without a certain sacrifice of *amour propre*, but it is

one the practical utility of which is obvious, and the "Almanach" in question is a case in point.

THE London County Council Education Officer has issued a remarkably attractive programme for 1926–27 of lectures and classes for teachers. Ninety-three different courses are offered, each course comprising, in most cases, six or more lectures. They are designed with the admirable objects of bringing London teachers into touch with the latest developments in educational methods and giving them opportunities of hearing leading authorities on questions of national and civic importance. Under the general heading of science are ten courses and four special single lectures. These four are: on eugenics, by Prof. Karl Pearson; production of voice sounds, by Sir Richard Paget; talking by light, by Prof. Rankine, of the Imperial College of Science; and surveying by aerial photography, by Dr. H. H. Thomas, of Cambridge. Among the most valuable of the courses is one on the relationship between science (physics, chemistry, biology, bacteriology, economics) and domestic work, by members of the staff of the Household and Social Science Department, King's College for Women.

THE Royal Technical College, Glasgow, directs attention in its calendar for 1926–27 to the fact that its new building (completed 1910), comprising over seven acres of floor space, forms the largest structure in Great Britain devoted to education. It might also boast that of all institutions included in the University Grants Committee's returns it had in 1924–25 the largest number, 2645, of part-time students, the next largest being the 1926 of the London School of Economics. Among the specialist courses provided by the college which are recognised by the University of Glasgow for attendance by students preparing for the degree of B Sc. in applied chemistry may be mentioned: fuels, dyes and their applications, oils and fats, sugar manufacture, technical bacteriology, metallurgical chemistry, coal tar and intermediate products. The college maintains one of the five principal schools of pharmacy in Great Britain. The Glasgow School of Architecture is under the superintendence of a committee representative of the College and the School of Art. Among the numerous courses in technology not forming parts of degree courses are important series, both day and evening, in textile manufacture.

THE functions of municipal universities are discussed in a paper by George F. Zook, President of the Municipal University of Akron, published in the May number of *School Life*. The paper is concerned chiefly with the question whether municipal universities should continue to regard the traditional four-year curricula as their main business or should develop, alongside of these, one-year, two-year and three-year completion courses of a technical or semi-professional character. It is admitted that the experience of the land-grant colleges in establishing and maintaining one- and two-year curricula in agriculture and mechanic arts has not been very encouraging, but conditions in the municipal universities are very different and they would be failing in their duty to the communities which support them if they did not cater for the requirements of the large number of young people who, after completing their high school course, want to spend less than four years in university studies in preparation for such careers as those of pharmacist, librarian, school teaching, nursing, and the hundred and one occupations lumped under the headings of 'business' and 'industry.' In this connexion it is pointed out that the whole field of evening instruction, both general and technical, is awaiting vigorous development.

Contemporary Birthdays.

September 24, 1874. Prof. Alexander Findlay.
September 26, 1854. Major Percy Alexander MacMahon, F.R.S.
September 28, 1873. Prof. Julian Lowell Coolidge.
October 2, 1875. Prof. Arthur William Conway, F.R.S.
October 2, 1876. Mr. Thomas Sheppard.
October 3, 1858. Prof. Percy Faraday Frankland, C.B.E., F.R.S.

Prof. FINDLAY, occupant of the chair of chemistry in the University of Aberdeen since 1919, was educated at that city's grammar school, proceeding afterwards to the University there, and to the University of Leipzig. Early he was a research student in University College, London, whilst from 1902 until 1911 he held a lectureship in chemistry in the University of Birmingham, leaving to take up a professorship in science at University College, Aberystwyth. He has published several books, among them being a stimulating volume entitled "Chemistry in the Service of Man."

Major MACMAHON (Royal Artillery, retired), late Deputy Warden of the Standards, Board of Trade, was born at Malta. He was educated at Cheltenham College, passing thence into the Royal Military Academy, Woolwich, where later (1882–88) he was instructor in mathematics. The Royal Society awarded him a Royal medal in 1900 on the ground of the number and range of his contributions to science in the department of pure mathematics. Further recognition by the Society came with the allotment of the Sylvester medal to Major MacMahon for studies in the partition of numbers. General secretary of the British Association from 1902 until 1914, he is a past president of the London Mathematical Society.

Prof. J. L. COOLIDGE, mathematician, was born at Brookline, Mass., U.S.A. A graduate of Harvard, he also studied at the Universities of Oxford and Bonn. He has been successively instructor in mathematics, assistant professor, and, from 1918, professor in that subject at Harvard. Prof. Coolidge is an Officer of the Legion of Honour. He is the author of "Elements of Non-Euclidean Geometry" (1909), and "Geometry of the Complex Domain" (1924).

Prof. CONWAY, registrar and professor of mathematical physics in University College, Dublin, was born at Wexford. He was educated at Dublin and Corpus Christi College, Oxford.

Mr. THOMAS SHEPPARD, the zealous director of the Hull Museum, was born at South Ferriby, Lincolnshire. He has long rendered sterling service as editor of various Yorkshire society publications relating to natural history, numismatics, geology and archæology. Mr. Sheppard is the author of "Yorkshire's Contribution to Science" (1915).

Prof. PERCY FRANKLAND is a Londoner. He was educated at University College School, the Royal School of Mines, and the University of Würzburg. From 1888 until 1894 he was occupant of the chair of chemistry in University College, Dundee, leaving there to take up a similar post in Mason College, Birmingham, continued also in its University. He was president of the Institute of Chemistry in 1906, and of the Chemical Society in 1911. Prof. Frankland was awarded the Davy medal of the Royal Society in 1919 for distinguished work in chemistry, especially on optical activity, and on fermentation.

Societies and Academies.

LONDON.

The Institute of Metals (Liége meeting), September 2.—L. **Boscheron**: An account of the non-ferrous metals industry in the Liége district. An historical account is given of the development of the zinc industry of the Liége district, with particular reference to the discovery of the distillation process by Dony and the subsequent improvement and application of this process. The absence of water-power and the high cost of electrical energy in Belgium renders the new electrothermic and electrolytic methods of manufacture of zinc inapplicable in Belgium. The discovery of a method of continuous production would be welcomed.—A. G. C. **Gwyer** and H. W. L. **Phillips**: The constitution and structure of the commercial aluminium-silicon alloys, with an appendix by D. **Stockdale** and I. **Wilkinson** upon the properties of the modified aluminium-silicon alloys. The investigation deals with the constitution, structure, and mechanical properties of modified aluminium-silicon alloys, and a theory based upon colloidal lines is put forward to explain the nature of the modified structures. The alloys possess good founding qualities; are appreciably lighter than pure aluminium, and in both chill- and sand-cast states possess a high resistance to shock, excellent ductility, and a high degree of incorrodibility.—J. D. **Grogan**: Some mechanical properties of silicon-aluminium alloys The sodium and 'salts' methods of modifying these alloys are described. The 'salts' method is preferred. Ternary alloys containing also magnesium or zinc are not superior to the binary alloys.—Buntaro **Otani**: Silumin and its structure The chief development of aluminium-silicon alloys during the last three years has been in the direction of a marked increase in mechanical properties, due to the modifying action caused by the addition of metallic sodium or alkali fluoride to the molten alloy. The present paper puts forward a theory to explain the process of modification.—H. J. **Gough**, S. J. **Wright**, and D. **Hanson**: Some further experiments on the behaviour of single crystals of aluminium under reversed tortional stresses. The resulting distortion under this complex type of straining action is observed using slip-band measurements, and is related to the atomic orientation of the crystals by means of X-ray analysis The complicated system of slip-bands observed is in agreement with the simple law that slip is confined at any point of the surface of the crystal to one of the octahedral planes and in the direction of the most highly stressed (shear stress) principal lines of atoms. The progressive hardening during a long endurance test has been studied.—P. **Chevenard**: Thermal anomalies of certain solid solutions. Certain feebly magnetic solid solutions show transformations which are similar to those of ferromagnetic substances in that they occur without change of phase (that is, change of space lattice), they are spread out over a large range of temperature, they are subject to relatively slight hysteresis, and result in anomalies in the different physical properties, dilatation, specific heat, resistivity, thermo-electric power, etc. They differ from the magnetic transformations in that the temperature of their occurrence does not vary with change of composition. Evidence is given of the existence of these so-called 'X' transformations in copper-aluminium, nickel-chromium, and copper-nickel solid solutions, and a detailed study is made of their effect on the dilatation of the first two groups of alloys and on the resistivity of the last.—W. T. **Cook** and W. R. D. **Jones**: Preliminary experiments on the copper-magnesium alloys. The chief feature is the production of sound chill-cast bars free from smooth-sided internal gas cavities by means of a double-melting process similar to that recently recommended by Archbutt for the production of castings in aluminium free from pinholes. Details are given of the method adopted of a type of bottom-pouring crucible used to eliminate inclusions of flux and slag.—Kotaro **Honda**: A comparison of static and dynamic tensile and notched-bar tests. Machines for testing materials have recently considerably increased in number; for example, referring to the methods of testing, there are the following tests: tension, bending, torsion, toughness, fatigue, abrasion, hardness, and single and repeated impact tests, etc. Since for each of these tests we have several types of machines, it is of importance to study the merits and demerits of these machines and to make a selection of those which are best for the purpose.

September 3.—C. J. **Smithells**, H. P. **Rooksby**, and W. R. **Pitkin**: The deformation of tungsten crystals. When metals are rolled or drawn the crystal fragments tend to take up a definite orientation with respect to the direction of working; the same effect is produced during the swaging of tungsten rods. The micro-structure and X-ray diffraction pattern at various stages of the swaging have been examined with the view of learning the mechanism by which this preferred orientation is attained.—A. **Pinkerton** and W. H. **Tait**: Season-cracking in arsenical tubes. While severely hollow sunk tubes made from arsenic-free, deoxidised copper are not liable to season-cracking, tubes made from arsenical copper, according to the British Engineering Standard specification, are liable to season-cracking when made under certain conditions. The temperature at which annealing renders such tubes immune from season-cracking has also been determined.—Cyril S. **Smith** and C. R. **Hayward**: The action of hydrogen on hot solid copper. When copper (wire) containing oxygen is heated in hydrogen, maximum brittleness is obtained at intermediate temperatures, and a marked recovery occurs when the action is carried out at temperatures approaching the melting-point. The rate of penetration of hydrogen into cast copper has been determined and certain peculiarities observed. When the oxygen in the copper exceeds 0·07 per cent the depth of penetration in a given time is greater at about 800° C. than at higher temperatures When brittle gassed copper is annealed and forged in a non-oxidising atmosphere, the cracks responsible for the brittleness close, and metal of remarkable properties is obtained.—Francis W. **Rowe**: Bronze worm-gear blanks produced by centrifugal casting.—Kathleen E. **Bingham**: The constitution and age-hardening of some ternary and quaternary alloys of aluminium containing nickel. This investigation is part of a scheme of research on aluminium alloys which has been in progress in the Metallurgy Department of the National Physical Laboratory, under the direction of Dr. W Rosenhain. The first part deals with the age-hardening of some of the ternary alloys of copper, nickel, and aluminium; and the second with the constitution and age-hardening of similar alloys, with the addition of small percentages of magnesium.—Captain F. R. **Barton**: Development of the use of nickel in coinage. In its pure form, and also as a constituent of binary alloys, nickel has been widely adopted during the last half-century as a coinage metal. Experience shows that pure nickel coins wear longer in circulation than those made of silver, and that they were equally proof against counterfeiture.—C. H M. **Jenkins**: The constitution and the physical properties of the alloys of

cadmium and zinc. The constitution and properties of the zinc-rich alloys seem to be considerably influenced by the two polymorphic changes which appear to exist in zinc. One of these changes caused an increase in the solid solubility of cadmium in zinc above the eutectic temperature; the resulting equilibrium diagram is therefore somewhat unusual, containing a region representing a completely solid alloy occurring above an area which is composed of both liquid and solid alloys. The cold-worked alloys very slowly soften at room temperature, but the effect of ageing does not cause any unfavourable alteration. The zinc-rich alloys should not, however, be annealed after this ageing. The properties of cast and rolled zinc are improved by the addition of cadmium. The eutectic alloy previously proposed for use as a medium hard solder possesses very suitable physical properties for this purpose.—G. B. **Phillips**: The primitive copper industry of America (Pt. 2). Many thousands of copper objects have been investigated; they show a somewhat sporadic industry, but considerable mechanical skill and artistic taste in their manufacture with stone and bone tools by the aborigines. Analysis indicates the source of the metal to be the native copper from the mines of northern Michigan and not copper brought from Europe.

PARIS.

Academy of Sciences, August 23.—**Bigourdan**: A means of verifying the uniformity of the earth's rotation.—A. **Bigot**: The Bathonian of Chailloué (Orne).—Jacques **Chokhatte**: Some applications of the polynomials of Tchebycheff with several variables.—N. **Stoyko**: The precision of time of the rhythmic signals of the Bureau International de l'Heure.—Louis de **Broglie**: The possibility of connecting the phenomena of interference and diffraction with the quantum theory of light.—J. **Cayrel**: Double detection with galena and chalcosine. The generality of the phenomenon.—Robert **Régnier** and Roger **Pussard**: The conditions under which the disease communicated to field mice by the Danysz virus is propagated.—E. P. **Fortin**: Histological investigations on certain elements of the retina.—P. **Wintrebert** and Yung **Ko-Ching**: The protoplasmic contraction of the early embryonic forms in *Gasterosteus aculeatus* and *Pygosteus pungitius*.—E. **Iwanow**: Time of persistence of the fertilising property of the spermatozoids of mammals in the epididymus separated from the organism.—L. **Nattan-Larrier, G. Ramon,** and E. **Grasset**: Antitetanus immunity in the newly-born.

CAPE TOWN.

Royal Society of South Africa, July 21.—J. Smeath **Thomas**: The action of sulphur chloride on mercaptan—the existence of diethyl-tetrasulphide. The author has previously shown that in the case of the alkali metals the maximum number of S atoms that can be introduced into the polysulphide molecule increases with increasing electro-positivity of the metal, that in the polysulphide series some members are of greater stability than others, and that only these more stable compounds are obtained by ordinary laboratory methods of preparation. In every case the disulphide is stable, but the composition of the higher stable compound varies; the more electropositive the metal the greater the number of S atoms in the molecule of the higher stable polysulphide. An extension of the work to organic polysulphides led to a similar conclusion. Here again the disulphides are always stable and the higher stable polysulphide, in the case of the alkyl compounds, seems to be the pentasulphide. Thus both sodium *tetrasulphide* and potassium pentasulphide on treatment with ethyl iodide yield diethyl pentasulphide mixed with a little disulphide.—W. A. **Jolly**: On the rhythmical functions of the spinal cord. The author discussed the oscillations which appear on the electromyograms in reflexes and the intraspinal delays, and pointed out the relation which subsists between the time intervals in the two phenomena.—J. **Moir**: Colour and chemical constitution, Part xxii.—A study of methyl derivatives of the phenolphthaleins. Nearly all the methyl derivations of phenolphthalein (ordinary and orthopara) have been examined. The effect of all substitutions on colour is additive, each item acting independently.

SYDNEY.

Royal Society of New South Wales, August 4.—R. H. **Cambage**: Acacia seedlings. Part xii. The seedlings are described of the following ten species: *Acacia binervosa*, *A. Burkittii*, *A. Cambagei*, *A. Cuthbertsoni*, *A. latipes*, *A. leptoclada*, *A. pruinosa*, *A. restiacea*, *A. rupicola*, *A. salicina*. In regard to the vitality of Acacia seeds in the soil, it is recorded in the paper that 200 seedlings of *Acacia mollissima* sprang up immediately after the ploughing of an area of four acres which had not been cultivated and on which Acacia trees had not grown for sixty years. In a second case, six acres of grass land had been enclosed and ploughed. No Acacia trees had grown on the area since it was cultivated sixty-eight years before, although some were growing a quarter of a mile away, but after the land had been ploughed, more than 1000 seedlings sprang up on one particular acre of the enclosed area, evidently at a spot where many trees of the same species formerly grew.—A. R. **Penfold**: The essential oil of *Zieria macrophylla* (Bonpland), and the presence of a new cyclic ketone. The leaves and terminal branchlets yield from 0·3 to 0·66 per cent. of a brownish coloured oil of peculiar odour. The following constituents have been identified: d-limonene (10-20 per cent.), a new cyclic ketone, $C_{13}H_{20}O$, about 50-60 per cent. (called zierone), together with sesquiterpene, sesquiterpene alcohol, amyl alcohol, a low boiling isovalerianic ester, etc.—F. R. **Morrison**: The fixed oil of the kidney fat of the emu. The oil, which was yellow in colour, had an odour resembling mutton fat, and was of a soft buttery consistency during the winter months. The oil consisted of the glycerides of oleic, linolenic, palmitic and stearic acids The occurrence of linolenic acid is of interest, this acid being rarely found in animal oils.—A **Grady** and H. **Hogbin**: Mountain lagoon and the Kurrajong fault. Mountain lagoon is apparently formed by the damming up of a small stream by the rising Kurrajong fault. The lagoon is a topographic feature which will soon disappear, for creeks, on all sides, have cut back by headward erosion, almost to the lagoon itself.

of potash is very localised, but the deposits are enormous, Germany and the Upper Rhine being estimated to contain no less than 21,000 million tons of crude potash salts situated at workable depths. Phosphate deposits are more numerous, although the life of the most important of them has been estimated at from twenty-one to seventy years; there are, however, vast deposits that are poor in grade or badly situated. Apart from the Chilean nitrate-beds, which have a definitely limited life, and the wonder-workings of the nitrogen-fixing bacteria, the world is ill-supplied with natural nitrogenous fertilisers, but the chief raw material of these fertilisers—nitrogen—is extraordinarily abundant: no less than eight tons of it are present in the air over every square metre of the earth's crust; and few human achievements can compare in importance with the recent work of physical chemists in making this mine of potential fertility available for agricultural purposes.

To Germany belongs most of the credit for having elaborated the manufacture of synthetic nitrogenous fertilisers by means of the Haber process. That process, together with the modifications due to Claude, Casale, and Fauser, consists in uniting nitrogen from the air with hydrogen from water to form ammonia; and to-day it is by far the most important of nitrogen-fixation methods, the cyanamide process coming next and the arc process third. The estimated production of combined nitrogen in Germany during the fertiliser year 1925–26 (June-May) was 600,000 metric tons (equal to nearly 3 million tons of sulphate of ammonia), of which 90 per cent. was to be made by synthetic processes. Although the Haber and cyanamide processes were much used in Germany during the War, it was not until 1923–24 that Germany had sufficiently recovered from its effects to be able to export nitrogenous fertilisers; for the year 1925–26 her estimated exports were about 135,000 tons of fixed nitrogen, equivalent to about 675,000 tons of sulphate of ammonia. Following Germany's lead, the manufacture of synthetic ammonia has been taken up in many lands, and although, in general, achievements have not so far corresponded with effort and *réclame*, there is no doubt that within the next decade production will attain a figure undreamed of before the year 1914. It is satisfactory to note that, next to Germany, Great Britain is the most important producer of synthetic nitrogen compounds, an achievement that is due to the initiative and enterprise of Messrs. Brunner, Mond and Co., Ltd., through its associated company, Synthetic Ammonia and Nitrates, Ltd.

The future of the British nitrogen industry, its ability to retain the home market and to withstand foreign competition in the outlying parts of the Empire, are matters of national concern, not only in respect of the peace-time manufacture of fertilisers, but also in respect of the war-time production of nitric acid and high explosives. In Great Britain the chief source of supply of manufactured nitrogenous fertilisers has long been, and is still, the ammonia that is obtained from coal as a by-product in the manufacture of metallurgical coke and town's gas. This ammonia is converted into ammonium sulphate, which is still the most popular of manufactured nitrogenous fertilisers, and of which very large quantities are sold at home and abroad. Our total production of nitrogen as ammonium sulphate in the year 1925–26 was 429,517 tons, of which 238,611 tons was exported. Exports and prices, however, are falling as the result of severe German competition, and the outlook is not cheerful. At the recent International Conference on Nitrogen Propaganda in Biarritz, it was stated that the British Sulphate of Ammonia Federation, of which Synthetic Ammonia and Nitrates, Ltd., is a member, had made an arrangement with the German Nitrogen Syndicate by which new German nitrogen compounds that are suitable to English conditions would be made available to English farmers; but nothing in the nature of a *quid pro quo* was mentioned. Now the Germans are very active in producing new fertilisers, which play an important part in their propaganda.

Dr. J. Bueb told the conference at Biarritz that when Germans enter a foreign market they are very careful to 'push' only well-known fertilisers until they have obtained a firm foothold; then they introduce their novelties, usually mixed fertilisers, that are especially suitable to the local conditions. In 1919–20 it was recognised in Germany that ammoniacal nitrogen could never completely replace nitric nitrogen (as in Chile saltpetre); and the hygroscopic and explosive ammonium nitrate being regarded as unsuitable, efforts were concentrated on producing mixed fertilisers like ammonium sulphate-nitrate and ammonium-potassium nitrate. To compete with Chilean nitrate, a white calcium nitrate of the same nitrogen content, but without its bad effect on 'sticky' soils, has been successfully marketed. In 1924 the manufacture of urea was started on a large scale, and this highly concentrated fertiliser (46 per cent. nitrogen) is selling very well, being especially valuable for tobacco, hops, vine, garden plants, meadows and pastures. Pure di-ammoniumhydrogen phosphate ('Diammonphos'), and a mixture of it with ammonium sulphate ('Leunaphos'), are among the chief products of the well-known 'Badische' company; whilst a compound fertiliser containing nitrogen, phosphoric acid, and potash in the ratio 1 : 0·75 : 1 has been specially worked out for sale in China under the name of 'Leunaphosphate.' Variety of form, low price, and intensive

propaganda are the outstanding features of the rapidly expanding German trade in fertilisers.

With regard to the security of the British home market, it appears highly probable that Synthetic Ammonia and Nitrates, Ltd., will come to an arrangement with the German Nitrogen Syndicate whereby spheres of influence will be defined and selling prices will be fixed and adjusted in ways advantageous to both. Failing the conclusion of such an arrangement, or in the event of its future collapse if made, competitive ability will depend upon quality, manner of marketing, production costs, selling policy and salesmanship. On the score of quality we need entertain no fear. British goods are not always best, as the Government post-mark asserts (though they may be always the best to buy), but in the case of chemical products made by a firm of the standing of Brunner, Mond and Co. there is no doubt that they can hold their own against all comers. In the matter of producing costs there is much less certainty. The cost of labour and fuel, together with paralysing taxation, constitute at present enormous handicaps to cheap production; and it is unlikely that any Government would succeed in restricting foreign competition under the provisions of the Safeguarding of Industries Act. On the other hand, it is understood that Synthetic Ammonia and Nitrates, Ltd., has effected a number of improvements and economies in the Haber process; it commands a personnel, financial and administrative as well as technical, that is second to none; and it has ample capital resources.

Competition at home is not to be feared, for synthetic nitrogen compounds will be produced at a cost which, in the event of unrestricted competition, would oust by-product ammonium compounds from the market. Both coke-ovens and gas-works will have to toe the line set by the nitrogen factory. The gas companies will continue to produce sulphate of ammonia, because they will not be allowed to turn their poisonous gas-liquor into streams and estuaries; and what they lose on the swings of ammonia they will make up on the roundabouts of gas and other residuals. Coke-oven works will suffer an important loss of revenue, so that the price of metallurgical coke may rise, and with it the prices of iron and steel. The home industry will therefore be able to present a solid front to the foreigners who would invade the home market; but if that market is to be preserved, producing costs must be kept low by all possible means; and if labour is refractory we must cheapen overhead costs by extending sales, the possibilities of which are very considerable. The recent appointment by Synthetic Ammonia and Nitrates, Ltd., of Sir Frederick Keeble to take charge of research into the application of synthetic nitrogenous compounds to agricultural purposes, and to be director of propaganda, is of especial significance, for it shows that the company is fully aware of the possibilities of the application of science and scientific method to the problems of industry, and of the value of trained experience in organising propaganda among potential consumers.

Among the more promising new outlets for nitrogenous fertilisers is their application to meadow and pasture land. In the past only arable land has been fertilised in this manner, but three years ago the German manufacturers initiated a series of large-scale tests on the use of nitrogen, with or without phosphates, for grass-land, and the results have shown that the treatment is economically profitable, provided that due regard is had to the nature of the soil and the vegetation, although the increased returns are lower than in the case of arable land. The capital cost of this extension to farming practice would undoubtedly put an additional burden on the small farmer, but the constantly diminishing price of combined nitrogen, and the increasing cost of artificial feeding-stuffs, are factors that should encourage him to undertake the risk. Another possibility lies in the breeding of new types of the most important species of cultivated plants that will assimilate much larger quantities of nitrogen than existing types, and so yield much bigger crops from the same acreage. Such an achievement is held to be quite feasible, although many years may elapse before it is consummated. Further progress would result from the devising of means to retain in the soil the nitrogen that is applied to it in the form of nitrogenous fertilisers and manures. Sir John Russell estimates that under good farming conditions only about one-half of the applied nitrogen is recovered in the first year's crop, and but very little of the residual nitrogen in later crops. Such an economy would at first sight appear to be disadvantageous to the manufacturer, but the farmer would be able to extend his purchases of fertiliser and bring under intensive cultivation land which could not previously stand the cost of artificial dressings.

Quite apart, however, from novel developments of the above kind, there is no doubt that the field of consumption of nitrogenous fertilisers is capable of almost unlimited extension. Russia, Argentina, Canada, Australia, and South Africa are practically virgin fields for the use of manufactured fertilisers, whilst of all the countries that already use them, only Germany, the United States, France, Great Britain, Holland, and Italy are important consumers. The order for consumption of fertilisers of all kinds is that given; for nitrogenous fertilisers only, it is Germany (easily first), the United States, France, Great Britain, Holland, Italy, and Egypt. A better view of the present position is, however, obtained by considering the

consumption per unit area of cultivated land. From the statistics published by the International Institute of Agriculture at Rome for nitrogen consumption in the fertiliser year 1921–22, it is seen that Holland comes first, followed closely by Germany, and then at a long interval come Egypt, Belgium, Great Britain, Japan, France, and Sweden, whilst the United States and Canada rank very low indeed.

When we consider that intensity of cultivation differs very greatly in these countries, and that experts in Germany maintain that her soil would respond to twice the quantity of fertilisers which are now applied, we obtain some idea of the great possibilities in store. There is big business in fertilisers to-day ; there will be bigger business to-morrow ; and no progressive country will be able to afford to neglect provision of these basic raw materials of food production. With expansion of the world's demand for them, we may expect the chemical industry to occupy a more prominent place in the industrial world than it does to-day, and even the chemist may receive that meed of recognition for which he has been striving so long. In Germany to-day it is openly said that the I.G.- the enormous combine of chemical manufacturers—*is* the Government.

If Great Britain is to hold her own in the world's markets, better men must be attracted to the profession and industry of chemistry by offering more adequate rewards; and salesmanship and propaganda, which are playing an increasingly important part in mundane affairs, must not be neglected. We must abandon the attitude of 'take it or leave it,' and study actual demands, local conditions, and the psychology of our customers. The farmer is proverbially one of the 'toughest nuts to crack.' Conservative by nature, he is also frequently regarded as simple. In reality he is very astute, although his time-reactions are slow. He is also suspicious, as he has good reason to be, because of his past experience of quack wares and of good wares sold at extortionate prices. He is apt to regard the adjective 'chemical' with grave suspicion : did not his forbears denounce nitrate of soda as 'the scourge'? He is also more resistant than the average town-dweller to the lure of printed advertisements ; but he is not impervious to the advances of the well-qualified agricultural lecturer, and still less to the evidence of the demonstration plot. What does appeal to him strongly is the success of a neighbour or a rival in obtaining yields and results which he has been unable to achieve; and, of course, he is very susceptible to the argument of *l. s. d.*; in other words, he should be approached through his primary instincts of positive self-feeling and acquisition. In this respect he is not markedly different from the rest of us ; as Goethe said, "Mankind progresses, but man remains the same."

Peasant and Pundit in India.

Bihar Peasant Life: being a Discursive Catalogue of the Surroundings of the People of that Province. By Sir George A. Grierson. (Prepared (in 1885) under Orders of the Government of Bengal.) Second and revised edition. Pp. iv + 4 + 443 + xvii + clv + 40 plates. (Patna: Government Printing Office, 1926.) 10 rupees.

BIHAR, the homeland of Buddhism, came under the East India Company in 1765, and remained merged in Bengal until 1912, when it reappeared as senior partner in the new province of Bihar and Orissa. In area Bihar is larger than Hungary; its population (nearly 600 to the square mile) is greater than that of Canada, Australia, and the Union of South Africa combined. Of its people, only 8 per cent. live in towns, a fact not easy for the 80-per-cent.-urbanised Englishman to appreciate.

The Bihari peasant is reputed boorish, but a certain young civilian who landed in India in 1873 found him well worth study. There is only one way to get to know a peasant, and that is by talking to him. His language is not the language of poets and pundits, nor can it be learned from a dictionary, for many of its concepts have no equivalents in English and many of its words are as strange to literature as 'zoles' and 'spitters' (unless he come from Devon) to the average professor of classical Greek. So it was that one of the most masterly linguists of the age became the peasant's pupil; "every word in this book," writes the author, "has been collected from the mouths of the people" The task took seven years.

The plan of the book is modelled on a work by the late Dr. Crooke. It is a pity that the lead was not followed in every province of India; for a better key to the life and mind of the ryot could not be proffered to the new-fledged civilian.

Sir George Grierson describes his book as a "discursive catalogue." It is more than that; for, though intended only as a foundation for serious research, it throws in vivid relief the things that count in Indian peasant life. Its main interest centres, of course, in the land; the rich belt nearest the home, the leaner belt on the village outskirts, and the belt between; land new made and land washed away by the vagaries of rivers; soils sandy, clayey, loamy, saline, or stony; soils water-logged and soils which will not retain moisture; the ploughing and reploughing—"a hundred ploughings for cane, fifty for wheat," as they say in Gaya—the sowing, transplanting, irrigating, weeding, and watching; and then the harvest, and the division of the crops between landlord

and tenant; the deductions and remissions, and the perquisites due to the village carpenter and blacksmith, the weaver and shoemaker, the sweeper, the accountant, the weighman, and the watchman; a tough business was this settlement of grain rents, by custom and without contract, and the variety of tenures is bewildering. Then there is the problem of labour; the serf who cannot leave his job, or marry, or do anything without his lord's consent; the debtor who binds himself to work until his debt is cleared; the one-year servant and the half-day servant; the man who, in lieu of wages, borrows a plough and oxen one day in three; the pair of cultivators who join and till each other's land in turn; and, in the background, advances of grain and cash, and loans and mortgages on terms unthinkable in generous England.

Other sides of peasant life there are, subsidiary always to the land; the live stock, the home life, the cottage industries. It would puzzle a lexicographer to discriminate in English between the 140 odd varieties of earthenware vessels named (the list is not exhaustive), let alone vessels of metal, wood, or leather, baskets, boxes, and nets, the 100 or so different kinds of jewelry, or the 250 or more different kinds of food.

Of domestic ceremonies, the rites of birth, marriage, and death, the treatment is necessarily cursory; such subjects can only be dealt with adequately by an intensive study of each separate community, for in no two castes are they exactly alike. The same applies to religion generally, for each cult requires separate handling, and more than a hundred cults are named.

The list of country craftsmen, so unlike anything European, shows how little the simple self-contained culture of the Indian peasant is dependent on Western industrialism. Of local products, the only one of industrial importance was (before German chemistry strangled it) indigo.

In mechanics, the Bihari shares with the rest of India the oil-mill and the water-lift, but his masterpiece of ingenuity is the two-wheeled 'large complete country cart,' in which the art of adjusting strains and stresses seems to run riot; the why and wherefore of its three pairs of intersecting spokes, which run from felloe to felloe, its twin axles, one for each wheel, and its 'spinal curvature,' deserve an expert monograph.

Needless to say, Sir George Grierson is scrupulous to observe the niceties of scientific writing, the neglect of which too often impairs the value of books on India. He is careful to define his geographical units, and to explain them with a map; each vernacular word is printed twice, once in the vernacular script, and again transliterated in italics; and, a point most necessary in a land of more than 200 languages, plants are given their botanical names, though the terms used are sometimes out-of-date and generic names seldom begin with capitals. To question Sir George's accuracy would be presumptuous, but (p. 401) Bakr-Id does not always fall in December or Barah-Wafat in March; these festivals, like the rest of the Moslem calendar, fall a little earlier year by year.

Events in India in recent years have somewhat obscured the ryot's interests, and the timely reissue of this valuable work is to the credit of the Bihar and Orissa Government. But in 'get up' this second edition is a sorry travesty of its former self. The first edition was neatly printed on excellent paper, smartly bound and lettered, and beautifully illustrated. In the new volume the paper is coarse, the binding clumsy, the printing dirty and irregular, the pictures blurred; while the errata list covers 29 printed pages and yet records but a fraction of the misprints which disfigure almost every page of the text, making it everywhere untrustworthy, and sometimes unintelligible. Such being the case, it is not a little surprising to read in the 'Foreword' that the proof-reading was entrusted to two distinguished officers who are thanked by the Government "for the care they have taken to produce an accurate reprint."

F. J. R.

Wilhelm Hofmeister.

Wilhelm Hofmeister: the Work and Life of a Nineteenth Century Botanist By Prof. Dr. K. von Goebel. With Biographical Supplement by Frau Professor Ganzenmüller. Translated into English by H. M. Bower, and edited botanically by Prof. F. O. Bower. (Ray Society Volume (No. 111) for 1925.) Pp. xi + 202. (London: Dulau and Co., Ltd., 1926.) 12*s*. 6*d*. net.

THE Ray Society has just published a translation into English of a volume which appeared in Leipzig in 1924 to celebrate the centenary of the birth of Wilhelm Hofmeister, a botanist to whom is generally assigned the premier place in plant-morphology during the nineteenth century. This version follows as a fitting sequel to the volume of Hofmeister's researches published in English in 1862 by the same Society under the title "On the Germination, Development and Fructification of the Higher Cryptogamia, and on the Fructification of the Coniferæ," which for more than sixty years has been held as a classic by all English-speaking students of plant-morphology. The volume last named was, however, not merely a translation of works already published by him in German: its

text was specially revised and enlarged by the author himself for the Ray Society, so as to be a complete record of all known at that time on the subject to which it related. Thus on two occasions, far apart in date, the Ray Society has promoted the interest of botany by presenting in English works concerned with the same great discoverer.

The centenary volume was written by Hofmeister's most distinguished living pupil, Dr. K. von Goebel, now professor of botany in Munich: a man whose outstanding position in science has recently been recognised afresh by his election as foreign member of the Royal Society of London. He is the heir to Hofmeister's dominant place, not only as a formal morphologist but also as a philosophical biologist. This union of the study of form and function has indeed been stereotyped by the title given by von Goebel to his own great work. "Organographie."

Botanists, and biologists generally, recognise in Hofmeister the exponent of alternation of generations in plants. They admire his keen and unswerving perception of the homologies of those successive phases which in divers plants are so often disguised by differences of form and proportion. He first disclosed, in 1851, that underlying cycle of events which normally characterises Archegoniate plants, including the Coniferæ. The similarity of the constant cycle in them all was indeed shown to be so close that when Darwin's "Origin of Species" was published, the common underlying plan appeared at once to gain evolutionary significance.

Hofmeister's work on the Archegoniatæ is doubtless his best-known title to fame. But it is far from being the actual sum of his achievements. It is one of the great merits of von Goebel's book now under review, that it places the life-work of a master of technique and of thought in its true relation, not only to the period in which he lived, but also to the general march of science. It shows Hofmeister as a man of singularly alert mind and clear vision, coupled with a remarkable capacity and enthusiasm for work. There was something almost prophetic in his outlook on science. His perception of alternation was the natural precursor of the discovery of the cytological cycle as we now know it. But more significant still was his pursuit of causal morphology, as developed in his other great work, entitled "Allgemeine Morphologie." This book is unfortunately unpopular in style and almost plethoric in content. But it touched many matters that are still in eager debate: none more so than the inheritance of acquired or impressed characters. On the last page of that work he says: "It appears to me probable that only gradually, in the course of many years' development, the influential effects on outer form appeared and became hereditary." Twenty years later, Sachs advocated the same idea, saying with regard to the perpetual operation of gravity and light: "Many of these effects we are able to-day artificially to call forth or hinder; but others have become entirely hereditary and constant. Evidently one of the most fruitful regions of botanical research lies here before us." It is well to accord full weight to such expressions from great experimental botanists, while considering the later view put forward by Weismann with special relation to animals.

It is impossible in a short review to do justice to von Goebel's thoughtful estimate of his master's life and work. The pupil is, however, also a critic, and he does not hesitate to expose points where Hofmeister's views are out of harmony with later aspects of the science. This feature, associated with the broad outlook of an unusually penetrating mind, makes von Goebel's volume a most valuable addition to philosophical botany.

The remarkable wealth of facts early observed by Hofmeister, and the acute comparisons based on them, revealed the young bookseller as already a leader in his science. Recognition followed quickly. In 1851 he was awarded the honorary doctorate of philosophy of the University of Rostock. A few years later, in 1854, he received a call to the chair of botany in Heidelberg; and in 1863 he was appointed to Tübingen. As professor, he could not be called a popular lecturer. But the list of such pupils as Askenasy, Engelmann, Kienitz Gerloff, Muller, Pfitzer, Timiriassieff, Millardet, Zacharias, and von Goebel shows how powerful and prolific was his advanced teaching. He was, in fact, "a heaven-gifted genius such as in every science appears only at long intervals of time."

This volume presents Hofmeister both as a genius and also as a personality. His character is not only indicated by the pupil who saw him at near hand, in the laboratory and in the field, but also more fully by his daughter, Frau Prof. Ganzenmüller, in a chapter telling of his family life. Several vivid letters to his wife are quoted, and reveal a vivacious and very affectionate nature. But, as said in the translator's introduction to the English version: "The story which the daughter relates of her father's family happiness, and of his phenomenal success in a profession he was never trained for, becomes poignantly tragic as the tale of grievous bereavements quickly following one another reaches its sad climax in solitude of spirit. Her closing paragraphs, as well as his works, claim remembrance for one who, overtaken in 1877 by sickness and death, had persistently devoted almost his last broken powers to the science he had so brilliantly illuminated."

Radioactivity.

A Manual of Radioactivity. By Dr. George Hevesy and Dr. Fritz Paneth. Translated by Dr. Robert W. Lawson. Pp. xix + 252. (London: Oxford University Press, 1926.) 15*s*. net.

IN the hands of the translator and the Oxford University Press, the modest, beautifully printed "Lehrbuch der Radioaktivität" of 1923 has become the imposing, beautifully finished, and handsome English edition of 1926; the little German two-seater is now a handsome blue Daimler saloon complete with coat-of-arms on door.

This book is intended as a manual for senior students and young research workers. In size and scope it is not unlike the earlier books of Fajans and of Russell; and like that of the former, but unlike that of the latter, it pays attention more to the physical than to the chemical side of the subject. This to our mind is a pity, because it was on the chemical side of the subject of radioactivity that the authors made their names, and, whereas the physical side can be expounded by many, a fuller informed discussion by the authors of the chemical problems involved would have been invaluable.

For the most part, the English follows the German edition closely, but whereas the latter takes account of the literature up to the beginning of 1922, the former has been considerably modified and extended, particularly in the sections relating to atomic structure, to embody the results of more recent research. Several of the figures in the German text are now reproduced as plates, which, of course, are much clearer. These include the famous one in which the newly-born nucleus of atomic number 8 and mass 17 is seen bending thickly round to the right while the ejected hydrogen particle makes a bee-line to north-west almost in line with the α-particle which begat it.

The book is not fully documented in the ordinary sense, but many references to the literature during the period 1916–1925 are collected in an appendix, and these suffice for the purpose of the work. The first nine chapters deal with the specially physical side of the subject: the theory of disintegration, the constitution of the atom, and the nature of radioactive particles and rays. This is well but much too briefly put, is up-to-date, and is well illustrated. Too much information is packed away in these chapters which, in length, are not much more than sections, and they are made weightier because any looseness of thought or of statement which the authors have allowed themselves in making clear their subject is sternly corrected in their copious footnotes.

In Chap. x. the transformation series are given. In our opinion the authors are unduly conservative in taking the view that the actinium series arises as a branch from the main uranium series, instead of the more likely view that it derives from a uranium isotope of mass 235 (or 239). In a work of this scope, however, there is little room for a discussion of this point.

Several chapters are devoted to the subject of isotopes, radioactive and non-radioactive, and the possibility of their separation, a subject in which the senior author has done notable work. The three chapters which deal particularly with the chemical side of the work could be enlarged with advantage, since they embody the research work of the authors themselves on such subjects as the chemical behaviour of extremely small concentrations of substances and the use of radio elements as indicators.

A long chapter deals with the various effects of the rays from radium and other radioactive substances, such as their chemical or physiological action or their use in promoting atomic disruption. Few workers are aware how far investigation has penetrated in these regions. Of particular interest at the moment is the work of Lind and his collaborators on the chemical effects of radium rays on liquids and gases. The translator must not, however, call hydrocarbons hydrocarbonates (p. 242), for that may remind chemists of the physicist who in translating a text-book of organic chemistry rendered throughout as *carbohydrate* the German for hydrocarbon. Geologists as well as physicists will find the bearing of radioactivity on geology, and particularly on the age of minerals, ably discussed in Chap. xxvi.

The authors have included a chapter on the historical development of the science of radioactivity. This, we consider, is unnecessary. To the uninitiated the names of all but the greatest of the pioneers convey very little, while those who have borne the burden and heat of the day know that the real history is not that given in any text-book. The translation is very good, and it is quite clear that the translator has contributed considerably to the excellence of the volume. He should, we think, use more extensively the nomenclature of the Chemical Society in rendering chemical terms; for example, *protoactinium* is preferable to *protactinium*, and the name of a chemical element should be written out in the text, the symbol being reserved for chemical equations.

Here then is a book, well-translated, clear, informed, up-to-date, and all too brief, which can be heartily recommended to the student and research worker. May the reviewer, with all respect, give it an affectionate 'pat on the back' in memory of happy days with the senior author in Sir Ernest Rutherford's laboratory in Manchester, in the great days before the War?

A. S. R.

Our Bookshelf.

The Further Studies on Decrementless Conduction. By Prof. Genichi Kato. Pp. vii + 163 + 7 plates + 88 figures. (Hongo, Tokyo: Nankōdō, 1926.) n.p.

IN this second monograph Prof. Kato describes further numerous experiments which he and twenty collaborators at Keio University have carried out on the passage of the impulse in narcotised nerve. An abundance of evidence is adduced to support the now well-known theory that there occurs no gradual decrement of the nerve impulse in its passage through a narcotised region of nerve, but rather diminution to a steady level, as soon as the fully narcotised region is gained. Owing to diffusion at the border of the narcotising chamber, the nerve at that place must needs show a decreasing depth of narcosis at the outer part. This region (the 'limit length') is 6 mm. long and can be accurately defined by mechanical stimulation. Electrical stimulation is attended by the pitfall of 'escape of current,' which, the author maintains, has not been avoided by previous workers. Crushing the nerve is not a proper control of 'escape of current.' 'Escape' or 'spreading' must be differentiated into 'external spreading' along the surface of the nerve (for some 2 mm.) and 'internal spreading' among or within the nerve fibres. This latter, which may amount to some 25 mm., is stopped and therefore not controlled by nerve-crushing. It is estimated in the present series of experiments by determining the apparent diminution of the latent period of the muscle twitch on a smoked record as the stimuli are made stronger and the effective kathode thereby approaches the muscle. This method, though accurate enough, might have been subordinated to one of the elegant and precise electrical methods which are now in vogue for observing nervous phenomena. In most experiments the nerve-muscle preparation of the large Japanese toad has been used. From the few with frog-nerve, there is some evidence that in this tissue the spread of current occurs less readily.

Later chapters describe decrementless conduction in narcotised regions of the vagus and sympathetic trunks and in narcotised muscle - skeletal and cardiac. Experiments have also been made bearing on the relative refractory phase of nerve-fibres. Since the existence of decrement is so much in doubt, the conditions during that phase have had to be investigated from the new point of view. It seems probable that the principle of the all-or-none response is true for the relative refractory phase.

A further communication is promised which, if it is as provocative of thought as the present monograph, will be most welcome to physiologists.

Francis Jenkinson, Fellow of Trinity College, Cambridge, and University Librarian: a Memoir. By H. F. Stewart. Pp. viii + 152 + 6 plates. (Cambridge: At the University Press, 1926.) 10*s.* 6*d.* net.

BIOGRAPHIES of men of renown and national heroes—naval, military, and political—are necessary for the due appraisement by the historian, not merely of the men themselves but also of the times in which they lived. Of greater personal interest are the lives of men of talent, fulfilling faithfully and unostentatiously their daily round, raising their everyday duties to a high level by infusing them with conscientiousness and energy.

Such records are, to most of us, of greater value because they set an example and a standard to which the average can strive to attain. In his memoir of Francis Jenkinson, Fellow of Trinity College, Cambridge, and for more than thirty years University librarian, Mr. H. F. Stewart brings clearly before us the character, as revealed by his daily acts, of one of the most lovable of men. We see Francis Jenkinson as a man of many talents, as a naturalist, a lover of music, and, greatest of all, as a bibliographer and a book-lover. The work he accomplished was little short of marvellous when we know that he rarely felt in perfect health. Though not successful in winning any of the great University prizes, he took as high a place as his limited physical capacity would permit, and was consequently a marked man from the first, and he found his true *métier* as a bibliographer. Succeeding Henry Bradshaw, with whom he had previously been associated and whose methods he whole-heartedly admired, he maintained as librarian the high standard of scholarship exhibited by his predecessor, and carried on in the same spirit the enrichment of the library which was under his care.

The author has related the main events of Jenkinson's official life in a most entertaining book, not overweighted, as many biographies are, with insignificant detail. His subject's efforts, which were largely instrumental in winning the battle of the Copyright Bill and in establishing the unique War Collection, are vividly narrated. Other chapters tell us of his hobbies and recreations — entomology, ornithology, music, gardening—so that we have presented to us an engaging picture of the man as he was and as he will live in the memory of his many friends. The last lines of J. D. Duff's inscription in the ante-chapel of Trinity College admirably sum up his nature:

"Naturam musicam libros
Sed magis homines homo amavit."

His portrait, painted by Sargent in 1915, excellently reproduced here, forms a fitting frontispiece to the memoir, the writing of which has clearly been a πόνος ἄπονος.

H. H. S.

The Migration of Symbols: and their Relations to Beliefs and Customs. By Donald A. Mackenzie. (The History of Civilization Series.) Pp. xvi + 219 + 16 plates. (London: Kegan Paul and Co., Ltd.; New York: Alfred A. Knopf, 1926.) 12*s.* 6*d.* net.

MR. MACKENZIE deals here with four symbols or groups of symbols—the swastika, the spiral, ear symbols and tree symbols—and the religious beliefs associated with them. As a devoted adherent of the 'diffusionist' school, he sees in each the manifestation of an idea or complex of ideas, which, notwithstanding certain local variations in detail, on the whole is universal and derivative from a common origin. The swastika

represents the sun, the four cardinal points, the deities of these points, givers of life associated with the deities, such as gold, and so forth.

While in the case of such a highly specialised form as the swastika there may appear to be a reasonable possibility of a common origin, it might well be argued that a form of such frequent occurrence in both natural and artificial objects as the spiral might have a multiple origin even within a single cultural area. It has been suggested, for example, that in Egypt it is derived from the lotus, while Dr. H. R. Hall derives it from coiled wire used purely for ornament. Mr. Mackenzie does not deny the possibility, although he thinks that the earliest form may have been the spiral derivative from a shell in view of the magico-religious ideas appertaining to shells among the peoples of Upper Palæolithic age in western Europe. He holds, however, that, whatever the material origin, a precedent condition was the fundamental idea of movement, as in whirlpools and the whirlwind, as a giver of life. This opens up an interesting field of speculation in which it is not possible to follow the author here. He has gathered together a large number of examples, which he interprets to support his views in the case of each symbol, and if all are not equally cogent and the argument not in all cases equally convincing, they will at least serve to stimulate discussion.

The Secretion of the Urine. By Dr. Arthur R. Cushny. (Monographs on Physiology.) Second edition. Pp. xii+288. (London: Longmans, Green and Co., Ltd., 1926.) 16*s*. net.

THE appearance of the second edition of this monograph reminds us of the great loss which science has suffered in the untimely death of Prof. A. R. Cushny. It is indeed fortunate that the book was almost ready at the time of his death, since it reflects the considered views of the author on the subject of the function of the kidneys in the light of the most recent researches in this province of physiology. The theory put forward in the first edition nine years ago has formed the starting-point of the majority of the researches carried out on the secretion of the urine during this period: that the work stimulated research is shown by the increase in the number of references from four hundred to six hundred.

The author considers that the modern theory of filtration through the capsule with reabsorption of an optimal fluid in the tubules has been greatly strengthened by the more recent work: in fact, reabsorption has been definitely proved to occur. A slight modification of the theory has been necessary, following the increase in our knowledge: the distinction between threshold and no-threshold bodies, that is, between those substances which do not appear in the urine unless their concentration in the blood exceeds a certain value and those which are excreted, whatever their plasma concentration, appears to be less clean cut than was formerly supposed. Thus, with a modification affecting the nature of the optimal fluid absorbed in the tubules, the author considers that the theory covers all the more recently discovered facts.

We note that the chapters on the perfusion of the kidney and on nephritis have been largely re-written: the latter especially is noteworthy in its broad outlook upon clinical problems and in its suggestion for the best methods of investigating the functions of the kidneys in disease in the light of the modern view of renal secretion.

The Mammals of South Australia. By Dr. Frederic Wood Jones. (Handbooks of the Flora and Fauna of South Australia, issued by the British Science Guild (South Australian Branch), and published by favour of the Honourable the Premier.) Part 3 (conclusion), containing *The Monodelphia.* Pp. 271-458. (Adelaide: R. E. E. Rogers, 1925.)

THE appearance of the third and concluding part of Prof. Wood Jones's work on the mammals of South Australia is a timely reminder that Australia has quite an extensive indigenous fauna of non-marsupial mammals. The overwhelming interest of the marsupials has led to the neglect of the other native mammals, even by the professional zoologist, and adequate material for study is wanting. This state of affairs should be remedied as a result of this memoir. More than one hundred species of monodelphians are known from Australia, over seventy of which are carefully described and figured by the author. His appeal for more work on the Australian non-marsupial mammalia comes with all the stronger force when so useful a guide to them accompanies it, and it is made not a moment too soon, for the inroads into the native fauna by introduced species extends equally to these mammals as to the marsupials. Prof. Jones tells a sad tale of the effects of rabbits, rats, mice, foxes, and cats on the indigenous species. His chapter on the dingo is of special interest. He believes it to be an introduced domestic dog of the true northern wolf type, and the evidence he brings forward on this point is convincing. We are glad to have so authoritative an opinion on the origin of this animal.

The completed work is a most valuable study of Australian mammals, for though only dealing with South Australia, it is virtually a guide to the whole continent. The author and the South Australian Branch of the British Science Guild are to be congratulated on the publication of so valuable, useful, and much-needed a work.

Psycho-Analysis for Normal People. By Geraldine Coster. Pp. 232. (London: Oxford University Press, n.d.) 2*s*. 6*d*. net.

"THIS little book on a big subject" (preface) aims at giving, more particularly for nurses and women teachers, an elementary introduction to the theories of Freud, Adler, and Jung in a form more acceptable than that of "the early exponents of analytic psychology . . . [who] succeeded for the most part in arousing disgust and revulsion" (p. 173). It would seem to be an attempt to neutralise certain ill-effects of 'psychoanalysis' in its rôle of 'rather dangerous plaything of society' (p. 14).

Under the headings instinctive energy, fear, the power instinct, the sex instinct, dreams, sublimation and religion, we are given an account of the libido theory that may possibly be wholly acceptable to some sections of the Jungian school of thought. The bibliography consists of three books on psychology, twelve on the so-called 'new psychology,' and forty-two novels.

Calculation of the Ages of Radioactive Minerals.

IT is now well known that, granted certain conditions of suitability, the age of a primary radioactive mineral is given to a first approximation in millions of years by the formula $\mathrm{Pb} . C / (\mathrm{U} + k . \mathrm{Th})$, where k is the amount of uranium which is equivalent in lead-producing capacity to 1 gm. of thorium, and $1/C$ is the amount of lead produced by 1 gm. of uranium in a million years. Unfortunately, there has been a serious divergence in the values adopted for these constants by different authors, as a consequence of which the calculated ages are not always directly comparable. It is greatly to be desired that uniformity should be attained in this respect, and we feel that the time is now ripe for the adoption of agreed values of k and C by the various workers in this field of research, at least until unequivocably better data are available.

In a recent paper by one of us (A. Holmes: Estimates of Geological Time with Special Reference to Thorium Minerals and Uranium Haloes, *Phil. Mag.*, May, 1926, p. 1055) the value 6600 was accepted for C. This value was given by Dr. H. Jeffreys in his book, "The Earth," as "the revised value obtained by Lawson and Hess." We have now found, however, that it involves errors both in interpretation of the data and in arithmetic, and that, on the experimental data of Hess and Lawson, the value should have been 7400. On the other hand, H. V. Ellsworth and C. W. Davis in recent papers in the *Amer. Jour. Sci.* have used $C = 7900$, a value suggested by Lawson in 1917; and still more recently in the same journal L. A. Cotton uses $C = 8000$, while O. Hahn in a German publication adopts $C = 8200$.

Probably the most accurate determination of the number of α-particles emitted per second by 1 gm. of radium is that made by Hess and Lawson, using the electrical method of counting. Their value, $3 \cdot 72 \times 10^{10}$, almost exactly corresponds with the measured heat production by radium (NATURE, 116, 897, 1925), and for this and other reasons we believe it to be the most trustworthy at present available. Accepting it, and combining it with the ratio of radium to uranium in uranium minerals, $3 \cdot 40 \times 10^{-7}$, we find $C = 7400$, which we propose as the most trustworthy value on current data.

The values adopted for k have varied between 0·3 and 0·4. Rutherford and Geiger's scintillation experiments on uranium and thorium indicate that per annum 1 gm. uranium gives $1 \cdot 26 \times 10^{-10}$ gm. uranium-lead, and 1 gm. thorium gives $0 \cdot 485 \times 10^{-10}$ gm. thorium-lead. Whence it follows that 1 gm. of thorium produces lead at the same rate as 0·38 gm. of uranium. Judged by later experience, the individual results for uranium and thorium are both probably rather low, but they were reached by the same method in either case, and are thus directly comparable. A slight correction to each of the results makes no appreciable difference to the ratio between them, as in each case it is in the same direction and of the same relative order. We therefore propose $k = 0 \cdot 38$ as the most reliable value at present attainable.

The approximate age of a mineral (omitting the time-average correction) is, therefore, on present data, given most reliably by the formula:

$$\text{Approximate Age} = \frac{\mathrm{Pb}}{\mathrm{U} + 0 \cdot 38\ \mathrm{Th}} \times 7400 \text{ million years.}$$

The application of the time-correction has the effect of reducing the value of the age so obtained. The corrected age can be most conveniently obtained by means of the formula:

$$\text{Corrected Age} = \text{Approximate Age} . \left(1 - \frac{x}{2} + \frac{x^2}{3}\right);$$

where $x = 1 \cdot 155 \cdot \frac{\mathrm{Pb}}{\mathrm{U} + 0 \cdot 38\ \mathrm{Th}}$.

Adopting the factors here advocated, the Middle Pre-Cambrian pegmatites of Ontario, Texas, Colorado, Sweden, and India have an age of about 1000 to 1100 million years.

Protoplasmic Viscosity as determined by a Temperature Coefficient of Biological Reactions.

IN a previous note [1] I have shown that the majority of biological processes depend on temperature according to the formula:

$$y = \frac{a}{x^b},$$

when x is temperature in degrees centigrade, y time, a and b constants. I have given some examples which seem to indicate that this equation is very general. I have also mentioned that the constant b, which is a real temperature coefficient (because it does not change with temperature), probably has a wider biological interest.

Let us compare the values of b for one and the same reaction in different species:

Reaction	Species	Author.	b
Amoeboid movement .	Marine amoebae	Pantin [2]	0·90
" " .	Human leucocytes	McCutcheon [3]	2·11
Embryonic development .	*Cyclops fuscus*	Ziegelmayer [5]	1·16
" " .	Drosophila	Loeb and Northrop [4]	2·10
" " .	*Rana virescens*	Lillie and Knowlton [6]	2·36
" "	Chick	cf. Morgan [7]	4·10
Heart-beat . .	Anodonta	Koch [8]	1·10
" .	*Rana temporaria*	Clark [9]	1·06–1·48
"	*Emys europaea*	Galeotti and Piccinini [10]	1·44
" .	*Hynobius lichen.* larva	Inukai [11]	1·15
" .	Duck embryo	"	2·92
"	Dog	Frank [12]	2·06
" . . .	Rabbit	"	3·00
" . .	Cat	Langendorff [13]	2·38

As may be observed from these data, b is generally higher in homoiothermic than in poikilothermic forms. But this is evidently not an exclusive feature of homoiothermy, since b is relatively high also in poikilothermic forms living at high temperatures:

Reaction.	Species.	Author.	b.
Cleavage of egg .	Strongylocentrotus	J. Loeb [14]	0·99
„ „ .	Ascaris	Fauré-Fremiet [15]	2·50
Growth in plants .	Lupinus (moderate)	Vogt [16]	1·90
„ „ .	*Scirpus Kisoor* (tropical)	Bose [17]	9·50

When we consider further a given reaction in one and the same species, we may observe that *b* increases with the age of the individual :

Reaction.	Species.	Author.	b.
First cleavage of egg	Strongylocentrotus	J. Loeb [14]	0·99
Second „ „	„	„	1·13
Heart-beat . .	*Amblystoma* larvæ, 8, 2·9, 1 mm	Laurens [18]	1·41
„ . .	*Amblystoma* larvæ, 13, 0·25, 1 mm.		1·50
Larval stage . .	Drosophila	Loeb and Northrop [4]	2·10
Pupal stage .			2·28
Imaginal stage . .			1·56 (see later for discussion)

I have calculated the constant *b* also for the rate of development in different stages of the beetle *Dytiscus semisulcatus*, according to observations by Blunck.[19] In this case also the value of *b* increases with age :

Period.	b.
1. Embryonic	1·10
2. First larval instar . .	1·14
3. Second „ . .	1·26
4. Third „ .	1·38
5. Præpupal . . .	1·48
6. Pupal . . .	1·60

These results, when plotted against time, give a regular S-shaped curve (Fig. 1). From Krogh's[20]

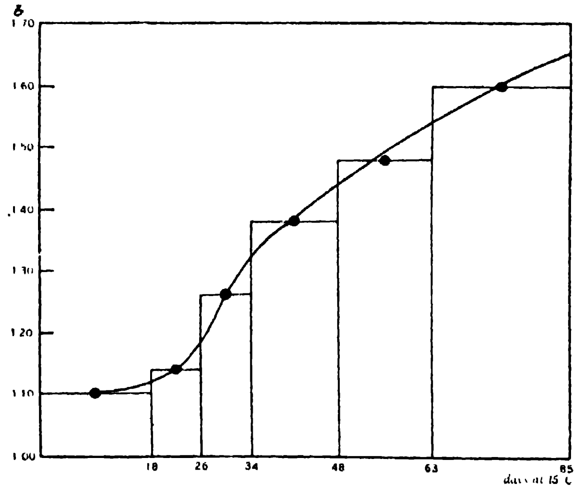

FIG. 1 - The constant *b*, which indicates the degree of protoplasmic viscosity, increases with the age of individual; development of *Dytiscus semisulcatus*.

experimental data concerning the embryonic development of the frog (*Rana fusca*), I have found that *b* increases with time in a similar way, as follows :

Period.	The Beginning and the End of the Period characterised by Stages.	b.
1	Fertilisation—end of the first cleavage .	1·20
2	End of the first cleavage—closure of neural fold	1·64
3	Closure of neural fold—formation of external gills	1·76
4	Formation of external gills—formation of gills with 3 branches. . . .	1·92
5	Gills with 3 branches—embryo 7 mm. long	1·69
6	Embryo 7 mm. long—embryo 7·8 mm. long	2·52

The graph of these values plotted against time probably corresponds to the first part of an S-shaped curve, the most advanced stage in Krogh's experiments being embryos only 7·8 mm. long.

The following example will show that *b* is also increased under the action of narcotics :

Pulsation of vacuole, *Paramaecium caudatum*, normal (Khainsky[21])	1·60
Pulsation of vacuole, *Paramaecium caudatum*, under chloretone (Cole[22]) . . .	1·87

The next example, computed from Hennings'[23] experimental data, demonstrates that *b* increases not only with the age of individual, but also that it is higher in a dry than in a humid atmosphere :

Tomicus typographus.	b in Dry Atmosphere.	b in Humid Atmosphere.
Embryonic stage . . .	2·02	1·87
Larval	3·52	2·98
Free beetle	2·90	2·44
Total development . . .	2·48	2·37

From these data it may be seen that the coefficient *b* varies not only for different biological reactions, but also that it changes even in one and the same reaction under varying external and internal conditions. It would be therefore impossible, at least at present, to identify biological reactions by means of our new formula. But the variations of *b* may be understood without great difficulty if we assume that *b* indicates the degree of protoplasmic consistency (or, physically, viscosity and rigidity). It has been partly demonstrated, partly made highly probable by different investigators, that the viscosity of protoplasm increases with the age of individual as well as under deeper narcosis (see F. Weber[26]). The case of embryonic development in *Tomicus typographus*, cited above, would then indicate that the protoplasm may become more viscous owing to loss of water in dry air.

The S-shaped curve which represents the increase of *b* with age fits well with my previous experiments made on cells of *Elodea densa*, in which the protoplasmic viscosity, plotted against the age of cells, also gives an S-shaped graph.[24] In the development of insects, it may be noted that *b* drops suddenly between the larval period and the imaginal stage (see above, Drosophila and Tomicus). This points to the possibility that protoplasmic viscosity decreases during metamorphosis, which then would involve some sort of rejuvenation. But as the material upon which my calculations are based is not sufficiently large, I do not venture to accept this idea as a definite explanation.

[24] Bělehrádek, *C. R. Soc. de Biol.*, 92, 1925; *Publ. Fac. de Médec.*, Brno, 1925.

The difference in the constant b which exists between poikilothermic and homoiothermic organisms seems to indicate that the protoplasmic viscosity is regulated with regard to the thermal adaptation of a given species.

Any biological reaction is a complex of many physical and chemical processes forming a chain. In determining the temperature coefficient of such a complex, we in effect determine the temperature coefficient of only one of the underlying processes, namely, that which is least accelerated by rising temperature and is therefore the limiting factor of the whole complex (Blackmann's and Putter's principle). In the majority of cases, however, the rate of molecular diffusion in the protoplasm is the limiting factor (see W. M. Bayliss[25]). As the rate of diffusion depends on the viscosity of the reacting system, our hypothesis is justified also from a purely physicochemical point of view.

Thus the protoplasmic viscosity may be studied by simply measuring the effect of temperature on any biological reaction in which the new formula holds good. Further investigations will show whether this way of determining the protoplasmic viscosity would be not only less injurious to the living system, but also more accurate than the existing methods of protoplasmic viscosimetry (see F. Weber[26]).

Science and Psychical Research.

HAVING read with interest the correspondence in recent issues of NATURE arising out of Dr. Tillyard's article on Sir A. Conan Doyle's "History of Spiritualism," I beg space for the following remarks which I shall try to confine so far as possible within the editorial limits stated in the issue of September 11 to be the main point of the reviewer's article of July 31, namely, "that scientific men generally presented an unscientific attitude to the subject of psychical research." But Dr. Tillyard in his article appears to prefer the substitution of the term 'supernormal phenomena' to the term 'subject of psychical research.' Therefore my remarks will deal almost wholly with that department of 'psychical research' which concerns itself with such supernormal phenomena as may be included under the head of *accounts given of communications between living persons and the* 'discarnate' spirits, or 'intelligencies,' or 'ghosts' of those who are normally called the dead, and thus omit here all reference to much of the material studied by the Psychical Research Society, for example, telepathy, etc., as quite irrelevant to this correspondence.

All the statements regarding the above-named accounts hitherto published and believed to be true by some of all descriptions of persons, including such as are or have been students of various branches of science, lack any evidence of a character which could make possible their submission to strict scientific investigation, the requirements of which I need not repeat in these pages. In this statement I include all the accounts given or referred to by Sir A. C. Doyle or his reviewer in the "History of Spiritualism." Recently when talking with Sir Ray Lankester about a review he had written of Sir A. C. Doyle's book, and the ghost-stories it contained, he brought to my notice the following quotation from some remarks made by Mr. T. P. O'Connor in the *Sunday Times* of August 15 in connexion with a conversation with Sir Edward Clarke, the chief counsel for the plaintiff in the case of O'Shea *v.* Parnell. In the course of this case it was proved that there was no 'fire-escape' in the house in question. "This," says Mr. O'Connor, "was not the first time I realized the truth of the statement that you cannot be quite sure that you know all the facts of any historical or personal transaction. I never trust implicitly any historical statement. I have rarely seen any of the historical transactions in which I myself have taken a part strictly recorded according to the facts." Sir Ray thoroughly endorsed Mr. O'Connor's attitude as to placing no reliance on such 'story-telling,' and holds that it applies equally to reputed researches by eminent scientists—all hearsay—and useless as evidence.

On all of the many occasions, within a period of more than fifty years, when I have given serious attention to allegations of facts made by students of the 'occult' or so-called 'supernormal phenomena,' I have found that the actual necessities for carrying out scientific investigation were unattainable, the consent of the 'medium,' whether 'professional' or not, being withheld.

Scientific men generally do not refuse to examine into any matters of reputed or seeming importance on the ground of certain alleged facts being impossible, or even highly improbable. They cannot, however, but refuse to make inquiry into any matter when the conditions of investigation, necessarily required, are denied or restricted and actual experiment thus excluded. As one example only of an unproved statement made in the course of the present correspondence, I quote that of Dr. Tillyard's in which he says that in a certain class of cases "the medium is actually in trance and does not know what is going on." I do not know what he means by the word 'trance,' but his statement would seem to be of some importance to spiritualists and the Psychical Research Society, as in the present dispensation of their doctrines the 'entranced' medium plays a most important part in the manifestations of occult phenomena generally. I am not aware, after making several inquiries into this point, of any thorough investigation having been made into the condition of a 'medium' reported to be 'entranced.'

BRYAN DONKIN.

September 17.

THE present controversy, which the editor of NATURE has wisely confined to a discussion of the "*scientific* study of what are called *supernormal phenomena*," is somewhat confused by the irrelevancies which have been introduced into the debate.

The entomologist, Dr. Tillyard, complains that his critics confuse psychical research with spiritualism, when the fact is that his original article was a review of a book on spiritualism and not on psychical research. Moreover, when he accuses Dr. Lotsy of making "the usual blunder of those who, knowing nothing of the elementary principles of psychical research, persist in regarding the medium as the 'guide' in the experiments," he himself is betraying his lack of acquaintance with the subject. This is readily excusable since, I believe, his experience with physical mediums is limited to less than a dozen sittings. Apart from this, Dr. Tillyard's statement strikes at the root of the present discussion. The majority of scientific men suspect that what Dr. Tillyard denies is true, namely, that the medium is the 'guide' in the experiments. In this they are right, although the words 'and his/her manager' might be added to the word 'medium.'

The conditions of experiment are usually arranged

[25] Bayliss, "Principles of General Physiology," London, 1918, p. 41 *seq.*
[26] F. Weber, *Abderhalden's Handb. d. biol. Arbeitsmeth.*, vol. 11, 2, 1. half, 1924.

by the medium or by the manager in conformity with a set of arbitrary rules laid down by generations of spiritualists for reasons into which we need not enter here. The séances are of the nature of performances at which the 'investigator' takes his place in a 'chain' of believers, who see that he does not violate the rules, which are framed in such a way that any real investigation is impeded. Can Dr. Tillyard tell us of any single medium who can produce some simple raps, under conditions which render their normal production impossible? He will doubtless reply by stating that 'supernormal' phenomena are subject to certain conditions and it is only under certain conditions that they occur. This appears reasonable, but Dr. Tillyard's experience is too slight for him to be able to recognise that the conditions are not "just exactly what the researchers choose to make them" (NATURE, September 11, 1926, p. 370), but what the medium plus his manager or employer have chosen to make them.

In this respect the cordial invitations which are so often extended to prominent persons are highly suggestive. It is now becoming a common thing when a new medium appears for his or her manager to invite scientific men in other spheres of work, journalists, actors, etc., to be present at the 'experiments.' Great care is taken to prevent the systematic attendance of critical psychical researchers and others with much experience of mediums, for these are not likely to be impressed by the trappings of a pseudo-investigation, and are also acquainted with those sources of error which, from their very nature, must remain unknown to the ordinary scientific worker, who has not specialised in this line of inquiry.

There is a good case for the scientific study of what are called supernormal phenomena. The difficulty lies in obtaining the opportunities for any such investigation under conditions satisfactory to those whose experience leads them to adopt a critical attitude towards the problems in dispute.

The Egyptian Shadouf and the Rate of Human Work.

THE interesting paper by Drs. Haldane and Henderson in NATURE for August 28, p. 308, merits emphasis on two or three points. Above all, the mechanical beauty of the shadouf, in spite of its crude construction, deserves notice It will be observed that trunnion bearings, which would wear and need lubrication, are replaced by almost frictionless hinges in the form of ropes. These ropes, in addition to their antifriction qualities as hinges, confer an important property on the system, namely, elasticity.

In short, the shadouf is a pendulum, and almost without doubt the men who work it move with it in its natural free period. If this is so, it would constitute a remarkable anticipation of recent developments in Germany, where many reciprocating machines have been constructed on resonance principles with marked gain in efficiency.

About the middle of last century, when most cranes and winches were operated by hand, it was necessary, for purposes of design, to have some standard of human activity. A widely accepted figure for such work was one-tenth of a horse-power or 3300 foot-pounds per minute. D. K. Clerk, a respected authority of that period, gave this rate as "the average net daily work of an ordinary labourer at a pump, a winch or a crane, for eight hours a day." "For shorter periods, from four to five times this rate may be exerted." Taking the rate given by Clerk for eight hours, we have 1,584,000 foot-pounds per day, in close agreement with the shadouf worker's 1,550,000 foot-pounds.

As to exteme rates of activity for short periods, comparisons are most difficult. Probably the highest rates are exhibited by professional wrestlers and strong men, whose feats are sometimes performed at a rate of the order of four horse-powers.

H. S. ROWELL,
Director of Research,
Research Association of British Motor
and Allied Manufacturers.

Chiswick, W.4,
August 30.

THE figures of 4290 foot-pounds per min. for raising water, and 4230 foot-pounds per min. for raising earth, given by Dr. Haldane and Prof. Yandell Henderson in NATURE of August 28, as examples of the rate at which work can be kept up for lengthy periods, are confirmed by the common experience of hill climbers. A man of average weight, dressed in climbing kit, and carrying a load of, say, 15 or 20 lb., may be assumed to weigh about 180 lb. To walk uphill at the rate of 1250 feet per hour, at low or moderate altitudes, is quite ordinary; while 1500 feet per hour is generally considered as distinctly fast. Such figures would apply to persons in good training, and to ascents lasting for, say, 4 hours. The rate to correspond with 4200 foot-pounds per min. would be 1400 feet per hour.

It would be interesting to measure the rate of oxygen consumption of persons walking uphill for lengthy periods; for given rates of ascent and for various gradients; and to compare the results with figures obtained from the same individuals working an ergometer in a laboratory. The question of gradient cannot be entirely ignored. Clinometer measurements of Alpine paths indicate that the economic gradient is about 18°, or 1 in 3. It certainly lies between 16°, which is unnecessarily flat, and 20°, which is uncomfortably steep.

Antagonistic Action of Electrolytes and Permeability of Membranes.

THE problem of the antagonistic action of electrolytes in biological systems has attracted attention for a long time, but a similar effect on inorganic colloidal systems has been investigated only in recent years. This study has, however, thrown considerable light on the mechanism of such antagonistic action, and we are now probably able to give a rational explanation on the basis of these physico-chemical investigations. About a decade ago Clowes (*Jour. Phys. Chem.*, **20**, 407, 1916) showed that a marked analogy exists between the transformation of an emulsion of oil-in-water into an emulsion of water-in-oil, or of blood plasma into a blood clot, or of a casein suspension into a casein clot. In all these cases salts of calcium promote and alkalis and salts of sodium inhibit the transformation of a system consisting of a non-aqueous phase dispersed in water into the reverse type of system, consisting of water more or less perfectly dispersed in a non-aqueous phase, and the ratio in which given electrolytes, say

sodium or calcium chloride, exert a compensatory effect upon one another, is almost the same as that in which the electrolytes in question exert antagonistic or compensatory effects on one another in biological systems.

In some recent papers (*Zeit. anorg. Chem.*, **142**, 345; **149**, 139, 1925; *Jour. Phys. Chem.*, **29**, 517, 1925) I have examined the behaviour of several colloidal solutions from this point of view, and have shown that a general explanation for all these cases of ionic antagonism is that the similarly charged ion goes to stabilise the suspension, which effect is antagonised by the presence of a coagulating ion. The equilibrium in biological systems, the inversion of emulsions, and the coagulation of colloids in the presence of mixtures of salts can all be explained from this simple view, which is also supported by experimental facts.

The effect of such non-electrolytes as the organic anæsthetics in antagonistic experiments is similar to the salts of calcium, as has been shown by Lillie and others. In these cases we are dealing with the coagulating effect of the non-electrolytes on the dispersoid system. Thus it is now known that copper ferrocyanide membranes, which also show under suitable conditions a reversible variation in permeability like protoplasmic membranes, can be coagulated by means of propyl and other alcohols, but in the presence of membrane-forming materials the coagulation of the membrane is retarded. This is to be attributed to an antagonism between the non-electrolyte and the electrolyte in question. Consequently a general statement of the observed antagonism in diphasic systems is that *all antagonistic actions occur between a peptising agent and a coagulating agent.* This antagonism need not be confined to two electrolytes only, but may occur between an electrolyte and a non-electrolyte. If the concentration of one of these is constant, then at a particular concentration of the other the whole system will be in equilibrium. In freely reversible systems the equilibrium ratio of these will be approximately constant, but this cannot be expected in systems which are irreversible. In the case of ionic antagonism, it has been found that the adsorption of similarly charged ions stabilises the suspension towards another coagulating ion and naturally, therefore, the nature of the electric charge on the surface of the dispersoid or emulsoid particles in the case of physiological systems must be of fundamental importance in showing a variable permeability under different conditions. Lightning.

DR. SIMPSON'S rejoinder accompanying my recent letter (NATURE, August 7) indicates that I have signally failed to convey to him the ideas which I endeavoured to present. For this I am sorry. A more detailed discussion, being inappropriate for these columns, will be presented elsewhere, but two items of his rejoinder should be mentioned here and now. Dr. Simpson quotes and by implication interprets an isolated sentence. I fail to see how this implied interpretation can be considered to be compatible with the remainder of the paragraph from which the sentence was taken. Second, he is quite mistaken in thinking that the electronic darts which I pictured are but little different from the negative discharges which he considered. His discussion of the latter contains no suggestion of such darts. N. ERNEST DORSEY.

August 17.

DR. DORSEY complains that my interpretation of the sentence which I quoted from his letter is incompatible with the remainder of the paragraph from which it was taken. If this is so it is not my fault, for the paragraph in question contains the two following incompatible sentences: "the branches are not outgrowths from the trunks but ingrowths to it" (which is the sentence I quoted), and "a branch may grow in length and may branch."

I can assure Dr. Dorsey that I did my best to understand his difficult letter and to explain the points in which his theory appears to differ from mine. I cannot, of course, expect him to agree with me, but I regret that he considers that he has cause for complaint. G. C. SIMPSON.

August 31.

The Absorption Spectrum of Formic Acid Vapour in Relation to Molecular Associations.

THE absorption spectrum of formic acid vapour at room temperature and above (to 145° C.) consists of about thirty-five bands, lying between $\lambda = 2565$ and 2250 Å.U.; at the ultra-violet end of this band spectrum there appears to be a continuous absorption.

The law of distribution of practically all the bands may be represented with close approximation by the formula:

$$\frac{1}{\lambda} = 41700 + n \,.\, 1050 + p \,.\, 385,$$

where $n = -2, -1, 0, +1, +2$ and $p = -7$ to $+7$.

The null-band ($n = 0$, $p = 0$) is the strongest band and corresponds to

$$\lambda = 2398{\cdot}0 \text{ Å.U.}, \quad \frac{1}{\lambda} = 41700 \text{ cm.}^{-1}$$

There are two fundamental periods of atomic vibrations in the molecule, $\alpha = 1050$ and $\beta = 385$ cm.$^{-1}$. It is important to mention that the larger fundamental period is of the same order of magnitude (about 1000 cm.$^{-1}$) as is obtained for a number of molecules with a C-O group: formaldehyde (V. Henri and Shoù, $\alpha = 965$ cm.$^{-1}$), diacetyle (V. Henri and L. Light, 1100 cm.$^{-1}$), paraquinone (V. Henri and L. Light, 1110 cm.$^{-1}$), benzaldehyde (V. Henri and Almasy, 945 cm.$^{-1}$), furfurol (V. Henri and Almasy, 1080 cm.$^{-1}$), acroleine (V. Henri, 1260 cm.$^{-1}$), phosgene (V. Henri and Howell, 902 cm.$^{-1}$). In the infra-red there is a strong carbon monoxide band at $\lambda = 9{\cdot}2\mu$, $1/\lambda = 1087$ cm.$^{-1}$. It is therefore quite probable that this period 1050 cm.$^{-1}$ of formic acid vapour corresponds to the vibration of the oxygen relative to the carbon atom.

With increasing temperatures (using a constant mass of 60 mgm. in the absorption tube, between the room temperature and 145° C.) the absorption limit approaches the visible, and more bands of the same kind appeared towards the visible end of the spectrum.

The simplicity with which the above formula represents all the bands leads to the belief that these bands are due to the absorption of one kind of molecular species. The fact that at elevated temperatures the number of single molecules (HCOOH) is much increased, while the number of double molecules $(HCOOH)_2$ is decreased, leads to the conclusion that the banded absorption spectrum is due to the single molecules. (At 145° C. the ratio of single molecules to double is about 7 : 1, and at the room temperature it is about 0·3 : 1.)

The Scope of Organic Chemistry.[1]

By Prof. J. F. THORPE, C.B.E., F.R.S.

THE chemistry of the compounds of carbon covers a wide field, wider than that covered by any other element. Its scope embraces all living matter, as well as the vast number of non-living substances which are produced through the agency of life. Moreover, it includes a very great number of compounds unrelated to life or to living processes which have been built up by the chemist in the laboratory by methods he has devised.

Already some 200,000 definite compounds have been tabulated in Richter's Lexicon and in the supplements thereto, and this number is increased yearly by several thousands through the agency of a band of zealous workers scattered over the globe. It may well be asked what is the good of continuing to increase this already astonishing number; and is the expenditure of time, labour, and energy justified which lead to the discovery of some new fact having, apparently, no useful application to any department of human activity?

The answers to these questions are quite clear and definite. We must acquire a knowledge of the simple before we can attack the complex with any hope of success. The element carbon has been used by Nature as the basis of organised life because the capacity of carbon to combine with itself is shared by no other element, and it is upon this capacity that Nature has relied in order to build up the tissues and reserve materials which form the living world around us. Moreover, since the compounds of carbon containing a moderate number of atoms of the element are usually crystalline or capable of becoming crystalline, and there are obvious disadvantages attaching to the use of potentially crystalline substances as the basis of living matter, it has been found necessary to employ the more complex carbon derivatives containing many hundreds of elemental atoms, which by reason of their high molecular complexities no longer possess, or seem capable of acquiring, a crystalline structure, but belong to the class of jelly-like or colloidal substances.

Until we can determine how a small number of carbon atoms combine one with the other, we cannot hope to obtain any insight into the manner in which the more complex natural substances are built up, or any information regarding the way in which they are utilised to bring about the changes occurring during animal and vegetable metabolism.

STRUCTURE.

The science of structural organic chemistry is only just fifty years old. It was born when the genius of van 't Hof gave to the world the clue upon which the three-dimensional formula we now use is based. It is therefore no inconsiderable achievement to have gained in so short a time a knowledge of many of the reactions and properties of the more simple complexes of carbon in combination with oxygen, nitrogen, and other elements. But much yet remains to be done before we can attack with any real hope of success the problems which the chemistry of Nature presents.

It is true that the knowledge already gained has led to the synthetic preparation of quite a number of natural products, many of which are of service in relation to human needs. Many of the alkaloids, colouring matters like indigo and alizarine, camphor, and a large number of natural products, have yielded the secrets of their structures and have been produced by laboratory methods and, where necessary, on the factory scale. But the synthesis of such compounds has not provided much insight into the mechanism leading to their production in Nature, and indeed the reason for their occurrence in the plant is not understood. They are, moreover, crystalline substances which either occur in the plant as such or are formed by the hydrolytic fission of some more complex plant materials. Their homogeneity is therefore not open to doubt, and their degradation into known fragments and the rebuilding of these fragments into the original substances, although by no means easy, is nevertheless comparatively simple when the difficulties attending the investigation of more complex natural products are taken into account. Even so, some of the simpler type, for example, strychnine, still resist the attack of the chemist.

BIOCHEMISTRY.

In its earliest days the science of organic chemistry dealt only with those compounds which were derived from natural sources, and it was regarded as certain that such substances could be produced only through the agency of life and by no other means. Since then this theory has been shown to be wrong by the preparation in the laboratory of many substances identical with those formed during the operation of life processes. Nevertheless, the more complex substances which Nature utilises in building up her animal and vegetable structures still show no signs of yielding the secrets of their constitutions, or the mechanism by which they are produced. Indeed, although we can imitate in the laboratory certain natural operations such as the hydrolysis of starch to glucose, we are still quite ignorant of the means by which glucose is converted, by the appropriate enzyme, into alcohol and carbon dioxide, neither can we imitate this process in the laboratory.

When once the chemist has passed beyond the crystalline and the distillable he enters a region full of difficulties, because he has few means either of purifying the materials with which he has to deal, or of determining their homogeneity when they have been purified. These are the real difficulties which confront the biochemist when he approaches his subject from the structural side of organic chemistry.

It is far from my object to disparage the wonderful work which has been done and is being done by physiologists and pathologists in their attack on the mechanism of normal and abnormal life processes. Their record speaks for itself. But too little is being done to approach the problems from the purely organic chemical side, and too few of the people engaged in biochemical research have an adequate knowledge of organic chemistry or the methods of the organic

[1] From the presidential address to Section B (Chemistry) of the British Association, delivered at Oxford on August 5.

chemist. The number of organic chemists who are co-operating with biologists in their attack on natural processes is too few. Indeed, the very difficult question arises here as to how best to organise methods for dealing with problems which are essential borderland problems between two great sciences.

It seems that the best method to attack problems in borderland subjects is by co-operation between two types of trained investigators. In the case of biochemistry, for example, by the provision of trained students of two kinds, one trained in physiology but with a sufficient knowledge of organic chemistry to promote sympathy with and knowledge of the chemist's point of view, and the other trained as an organic chemist with a similar knowledge of the methods and requirements of the physiologist. The former would be a trained physiologist who would devote his final year to organic chemistry, the latter an organic chemist who would devote his final year to a study of physiology. This is, of course, no new idea, but is one which is being carried out in at least one institution in Great Britain in connexion with other borderland subjects.

It is the absence of any real attempt to approach biochemical problems from the chemical side that renders it particularly desirable that the need for some such scheme should be emphasised. It is true that the fault is largely on the side of the organic chemists who, for the most part, seem appalled by the difficulties attaching to the study of natural processes. The difficulties are indeed great, but not insurmountable. We are far from gaining any insight into the meaning of life, but it is not unlikely that we shall, in the near future, obtain some information regarding the mechanism of the action of the enzyme, the important agent in the non-living transformation of living matter into chemical products. It may be that organic chemists are waiting to see how Willstätter, who has already made great progress in enzyme chemistry, will surmount the difficulties confronting him, and it may well be that this great organic chemist will introduce new methods of attack which will open up fresh fields for investigation.

PETROLEUM.

The complex hydrocarbons which form the main constituents of crude petroleum belong to a section of organic chemistry at present too little explored. Although many millions have been made through the production and sale of petroleum products it is safe to say that the percentage of profit devoted to research in oil products has been infinitesimal. It is true that in the United States large sums are given by the oil interests towards research in other subjects, but until quite recently none of these was, curiously enough, given for the purpose of improving our knowledge of the science on which the utilisation and isolation of petroleum products depends. The reason is not far to seek. The apparently inexhaustible supplies of petroleum render it unnecessary to devise means for economical working. The crudest and most wasteful methods were employed, because economy and the conservation of the natural product were not paying propositions.

This applies not only to the methods used in fractionisation, but also to those employed for the purpose of 'cracking' the higher boiling fractions into liquids of lower boiling point. For at the present moment it is the fraction up to 200° C. which is the important product, because it is the 'petrol' of the internal combustion engine. Time was, before the introduction of this particular machine, when the light fraction from crude petroleum was a drug on the market, and in many cases was actually set on fire at the refinery because no use could be found for it. In those days the chief product was the kerosene fraction which was used as lamp oil. At the present time the rapid increase in the use of the motor-car for personal and commercial transport indicates that at no distant period, if progress continues to be made in the same direction, the amount of the 'petrol' fraction will be insufficient for the world's needs. This point has already been reached in America, where approximately 70 per cent. of the world's consumption of petrol (gasoline) is effected. During 1925 the consumption of petrol in the U.S.A. approached 800,000,000 gallons a month, which is about twelve times the amount consumed in Great Britain.

The 'cracking' operation is now carried out on an enormous scale by numerous processes, all subject to patents, but differing from one another only slightly on the question of principle. All depend on the well-established fact that hydrocarbons of high molecular weight will break down into those of lower molecular weight if they are subjected to the requisite degree of temperature. Pressure appears to play an important part in the character of the product, as does also the surface action of the container or material used in the container to promote surface action. All are wasteful, because little or no research has been carried out on the true chemical nature of the cracking operation. Much permanent gas is always produced, consisting for the most part of ethylene and propylene. In the States the ethylene is allowed to go free, because its obvious utilisation in the form of ethyl alcohol is attended with difficulties, but the propylene is usually absorbed in sulphuric acid, and thus converted into *iso*propyl alcohol, useful as a solvent.

The production of these two unsaturated hydrocarbons provides a clue to the mechanism of the cracking process which is of some significance. If you break a long-chain saturated hydrocarbon, one of your products must be an unsaturated hydrocarbon, and it is evident that cracked spirit contains a considerable proportion of such unsaturated bodies. Moreover, the cracking processes at present in use do not produce aromatic hydrocarbons, and it is on the presence of a proportion of these aromatic hydrocarbons that certain special properties of petrol depend. For example, the tendency at the present time is to produce for motor-cars internal combustion engines of increased compression ratio, in order mainly to diminish the petrol consumption and thus increase mileage per gallon consumed. For some reason, which research has not yet ascertained, the use of petrol which does not contain the right quantity of aromatic hydrocarbons of the benzene type leads to 'detonation,' 'knocking,' or 'pinking' when ignited in cylinders giving more than a small compression ratio. This detriment diminishes the value of cracked spirit as such for any but low-compression engines, and many have been

the devices suggested in order to overcome this difficulty.

A vast number of substances, selected more or less at random, have been tried as 'anti-knock' materials, and as an outcome it has been found that one, namely, lead tetraethyl, possesses the property, when present in exceedingly small quantities, of preventing the 'detonation' of the explosion mixture in the cylinder. For a time lead tetraethyl (ethyl gas) fell under a ban in the States owing to a fatal accident which attended the spilling of a certain amount in one of the American factories, but it is understood that further investigation has led to a revision of the view first formed, and that considerable quantities of 'ethyl gas' are now being used. I remember visiting Wilmington in 1924, when some 500 gallons of lead tetraethyl were being made daily. Although there was naturally a strong smell of the material in the factory building, and I remained for some hours there, no ill-effects were noticed.

It is obvious that the conditions which produce 'knocking,' and the reason why certain substances are 'anti-knock' compounds, and why the presence of aromatic hydrocarbons prevents the phenomenon, must be made the subject of systematic research.

The question is also one of national importance, because in the case of high-compression engines, such as those used in aeroplanes, it is essential that a petrol should be used containing a high percentage of aromatic hydrocarbons. In war-time these aromatic compounds will be required for the manufacture of explosives, and it is quite certain that there will not be enough for both purposes.

Nevertheless, it must be remembered that it is only at the moment that the low boiling fraction of petroleum is the chief marketable product. It is probable that progress in the future will tend more and more to produce a motor-car engine of the Diesel type, or one having a carburettor capable of effectively vapourising the higher fractions of petroleum. In these circumstances it may well be that the low fraction will become the less important part of crude petroleum, and that, instead of having to resort to 'cracking,' a process of synthesis, by which the lower hydrocarbons can be converted into higher ones, will have to be adopted. As a matter of fact there are methods known by which this can be effected. Pure *iso*amylene can, for example, be converted into diamylene by interaction with stannic or aluminium chloride, and the process can be carried further, so that perfectly good lubricating oils can now be made by the polymerisation of the lower unsaturated hydrocarbons.

Polymerisation and depolymerisation are therefore the two operations which the petroleum industry must, investigate and establish on a firm scientific basis by research, so that it may be in a position to supply the public need for any particular form of engine which the engineer may evolve. Especially is it desirable to ascertain under what conditions polymerisation leads to the formation of aromatic and naphthenic hydrocarbons. Considerable attention has been directed within recent times to what may be termed in general the Bergius processes for depolymerising organic substances. The operation, which consists in heating the material under high pressure in the presence of hydrogen, was introduced in the first instance for the treatment of coal. There can be no question that great and fundamental changes are brought about in organic substances by the treatment whether a catalyst is present or not, and that a wide field for research is opened up thereby, but it is doubtful if, at the moment, general operations of this type can be regarded as commercial propositions. The plant is exceeding costly and the conditions subject to wide variations which are difficult to control. Actually, it has been ascertained that in the 'cracking' of the kerosene fraction of petroleum, hydrogen is unnecessary and can be replaced by nitrogen without affecting the character of the final product.

Little is known of the constituents of crude petroleum, or indeed of the fractions into which it can be separated after purification and distillation. Some of the simpler hydrocarbons of the pentane and hexane type have been isolated and the presence of cyclic compounds has been established. Many of them are classed under the head of 'naphthenes,' but these are of uncertain structure. No doubt many are present in the crude oil, but it is certain that others are formed during the distillation process. It is clear that much opportunity for research work offers itself here, and it is probable that small alterations in the method of distillation may cause deep-seated changes in the character of the distillate, causing it to be of greater service for particular purposes. The occurrence of hydrocarbons of the naphthalene series in petroleum products has also been clearly established. The higher fractions which constitute the valuable lubricating oils also need attention, for it is now certain that viscosity bears no relation to oiliness, that is, the capacity for acting as an efficient lubricator. The addition of small quantities of 'polar' substances of the type of fatty oils or acids confers increased oiliness on these compounds, and although we are now gradually reaching a stage when we know more about the effects of such ingredients, the field for research is still a large and important one.

The formation of free carbon occurs during both the distillation and 'cracking' process, in some cases to a very considerable extent. The utilisation of this carbon for the purposes of making electrodes is an important part of the industry, and the formation of carbon in a condition in which it can be used by the rubber tyre manufacturers is also likely to become practicable as an outcome of the thermal decomposition of hydrocarbons.

At present we know nothing about the structure of the hydrocarbons present in the lubricating oils. Indeed, it seems possible that these may not be long-chain hydrocarbons with which the organic chemist is familiar, but rather polymerised products formed from unsaturated components liable to be formed or destroyed under comparatively mild conditions. The relative ease with which the oil in the engine sump of a motor-car loses its oiliness through continued use is not characteristic of the stability usually associated with an organic hydrocarbon.

It is clear, therefore, that the need for systematic research into the character of petroleum products is urgent, and it is gratifying to note that the Anglo-Persian Oil Company has established a research laboratory at Sunbury-on-Thames, in which the

important principles underlying the industry have been and will be studied.

DYESTUFFS AND INTERMEDIATES.

Prior to the War, Germany manufactured three-fourths of the dyestuffs required for the world's markets. Of the remaining one-fourth, one-half was made from German intermediates and was therefore dependent on Germany. Switzerland, although without a domestic source of raw materials, ranked second with about 7 per cent. of the world's production. Great Britain produced about one-tenth of her requirements, and France produced in French-owned and operated plants from 10 to 15 per cent. of her consumption. In order to meet the patent requirements of France and Great Britain, German manufacturers operated plants in those countries where the final assembling operations were completed. The small dye industry of the United States was almost entirely dependent upon German intermediates. At the present time Great Britain produces 80 per cent. of the dyestuffs required for its own use, and we are therefore in a position to review the conditions which have led to this remarkable change and to consider the procedure necessary to strengthen it.

It cannot be said that any fundamental advance in the chemistry of the dyestuffs has been made since Bohn discovered indanthrene in 1901, although great advances have been made since then in the preparation of new colours belonging to this and other known series. Consequently, the research work necessary in order to establish our position as a dye-making country has been mainly along known lines, involving the extension of reactions which had already been established rather than the discovery of new ones. Nevertheless, it is no inconsiderable achievement for our research chemists to have established a position such as that indicated above in so short a space of time, for many of the preparations, the details of which could only be found in the patent literature, had to be worked out *de novo* and the correct conditions found for their adaptation to the technical scale.

It is probably along the lines of decreased cost of production that research work in the immediate future will be mostly engaged, and especially is this the case with the intermediate products from which the dyestuffs are derived. Moreover, the intermediate products are of the greatest importance for other industries, for example, the fine chemical industry, the perfumery, and the explosives industries, and any improvement in the processes for their manufacture or the production of new compounds having enhanced value from the commercial point of view is of the greatest importance to all these industries alike. The parent substances of the intermediate products are the hydrocarbons of coal-tar or the coke-oven by-products. The operations required to convert these hydrocarbons into the finished intermediates often involve many stages, any one of which depends for its cost on the purity and yield of the product. There is thus a wide field for research into the improvement of technical methods which may well occupy the attention of our dyestuffs chemists for some time to come.

On the other hand, the question of fundamental research into new processes, both for the preparation of new intermediates and new dyestuffs, must not be lost sight of. The intermediate determines the character of the dyestuff, and it is always possible that a new intermediate may be discovered which will yield a dyestuff with just that difference of shade as to catch the public fancy, and will lead to the replacement of the older dyestuff on the market. The sulphonic acids of naphthol, naphthylamines, and amino-naphthols are cases in point. These substances are used extensively for the preparation of azo dyes. There is a great number of these compounds theoretically possible, but only a few have found technical application, owing mainly to the high cost of producing the others. The high cost is nearly always caused by poverty of yield, an objection which may be at any time removed by the discovery of an improved process. The same argument holds good for the dyestuffs themselves.

It is futile to say that the vast field of organic chemistry has been thoroughly explored for the production of new types. At any moment one or other of the men or women engaged in fundamental research may repeat Bohn's discovery of 1901, and obtain a new compound which will be the forerunner of a new series of dyestuffs. It is perhaps too much to ask an industry which is struggling to hold its own to expend large sums on the prosecution of abstract research, most of which will be of no use to it, but it is not too much to expect that the industry will take every means to foster and encourage abstract research in our university institutions, and even to give some lead as to the direction in which its experience leads it to think that advances may be made. There is at present no organisation which can bring the manufacturers of dyestuffs and intermediates into touch with the work being carried on in our university laboratories, and it is possible that if at the present time a valuable discovery were to be made it would be unrecognised as such, and, following the usual course of academic research, would be published and thus lost to the country. What is required is a lead from manufacturers which will indicate the matters which they regard of importance, but which they do not consider as likely to yield results sufficiently quickly to justify them in employing their own research staff for investigating them.

This aspect is of all the more importance at the present time, when organic chemistry is entering on a new phase which will undoubtedly revolutionise many of the existing processes of manufacture. It is now recognised that the presence of a small quantity of a catalyst may either alter the course of a reaction or may lead it to proceed to completion where otherwise a totally inadequate yield would be obtained. The catalyst may either be added or the containing walls of the reaction vessel may act in this capacity. The well-known example of the oxidation of naphthalene to phthalic anhydride by vanadium pentoxide is an example of this, but similar cases are continually recurring, and it has only recently been found that the classical method for preparing ketones by the distillation of the calcium salt of the appropriate acid can be utilised in the most unexpected directions if the thorium salt instead of the calcium salt is employed.

Francis Bacon and Scientific Method.

By Dr. C. D. BROAD.

I.

FRANCIS BACON, who died on April 9, 1626, and whose tercentenary is to be celebrated at Cambridge on October 5 of the present year, was born at York Place, Strand, on January 22, 1560/61. His father was Nicholas Bacon, Lord Keeper to Queen Elizabeth, and his mother was Anne Cook, daughter of Sir Antony Cook, who had been tutor to Edward VI. Bacon went to Trinity College, Cambridge, at a very early age; he was only fifteen when he finally went down in 1575. He was sent to France by his father, who died while he was there, leaving Bacon ill provided for. He decided to follow the career of a lawyer, and was admitted to Gray's Inn on November 21, 1576. During Elizabeth's reign Bacon had much legal work to do, and received many promises of preferment, but he was not greatly rewarded either in money or in offices. Under James I. his advancement was rapid. He rose to be Lord Chancellor and Baron Verulam in 1618 and Viscount St. Albans in 1620–21.

This was the culmination of Bacon's career. On May 3, 1621, he pleaded guilty to a charge of corruption; was fined 40,000*l.*; imprisoned in the Tower during the King's pleasure: made incapable of sitting in Parliament or holding any office of State; and banished from the verge of the Court. The King soon freed Bacon and remitted his fine; but the fallen statesman retired to his estate at Gorhambury, and devoted the rest of his life to those literary, scientific, and philosophic labours which had always been his main interest. His most important philosophical and scientific works are the "De Augmentis" and the "Novum Organum." There are in addition a great many fragments and sketches which throw much additional light on his scientific and methodological theories. Bacon died a martyr to experimental science, and might well be made the patron saint of the cold storage industry. In extremely cold, snowy weather he stopped his coach near Highgate, bought a chicken, and stuffed it with snow, in order to see whether this would preserve the meat. He caught a severe cold, which was aggravated by the damp bed into which he was put at Lord Arundel's mansion, where he had stopped for the night, and he died in his sixty-sixth year.

In order to understand Bacon's dissatisfaction with the science of his time, we must try to imagine a state of affairs in which physics and chemistry were in much the same position as psychology and sociology are now. There were various sects or schools of physicists, following various masters, wrangling with each other, and producing much heat, little light, and less fruit. Existing scientists are divided by Bacon into two classes: (1) the extreme rationalists who rush to wide general principles from a few common-place and badly analysed facts, and then profess to explain everything by means of these principles; and (2) the mere empiricists, who investigate with extreme diligence but no scientific method some small region of phenomena, and then put forward theories of the universe in terms of the small corner of it with which they happen to be best acquainted. Nothing satisfactory can be reached in either of these ways. The theories of the rationalists are more plausible than those of the empiricists, but they lead to no practical results and give us no control over Nature. The empiricists (*e.g.* the alchemists) have sometimes stumbled by chance on useful practical results. But each of these is isolated from the rest, and Nature cannot be controlled practically until its structure and laws are understood theoretically. So Bacon demands that the sciences shall be built up again from better foundations and by a new method, which shall combine the careful observation and experiment of the empiricists with the generality and systematic connexion of the rationalists. Like other philosophers of his time, Bacon made the mistake of thinking that, because a good method is necessary in order to accomplish anything, it is sufficient in order to accomplish everything. He compares it to a ruler or a compass in drawing; and, like Descartes, he thinks that it will reduce all human intellects to a level.

Now Bacon holds that science has so far failed, partly because the human mind has not had an adequate, trustworthy, and properly selected set of data to work upon, and partly because it has not applied a suitable instrument of interpretation to the data which have been available. He thinks the first defect more serious than the second; for he says that important generalisations could be gained even by the present imperfect logical processes from an adequate natural history, whilst even the most perfect logical instrument would be powerless to elicit truth from the present scanty and unreliable data. In order to remedy this evil, Bacon holds that the first necessity is to prepare the mind for collecting a proper natural history and for interpreting and generalising from this history. The mind of any grown man is a highly distorting mirror, and our first business is to plane and polish it as far as may be. The factors, innate and acquired, which cause bias and error are called by Bacon "Idols." Certain of these are common to the human race, *e.g.* the tendency to ascribe to Nature the particular kind of orderliness and simplicity which is pleasing to men. These are called "Idols of the Tribe." Others vary from individual to individual; *e.g.* some men tend to dwell on resemblances and neglect differences, whilst others have the opposite bias. These are called "Idols of the Cave." Then, again, the suggestions and associations of language are a fruitful source of error; since words and phrases embody theories which are often false and observations which are often mistaken. These are called "Idols of the Market Place." Bacon admits that these three kinds of Idol can never be completely eliminated. But we can be put on our guard, so that we allow for them and thus render them harmless. Finally, there are false systems of philosophy and science erected by bad logic on flimsy foundations. These are called "Idols of the Theatre"; and there is no reason why they should not be completely removed, partly by pointing out their fallacies and their unfruitfulness, and partly by substituting good reasoning and properly attested data.

The human mind has, however, many deficiencies

as well as positive sources of error. When the latter—the Idols—have been removed, it is time to provide aids to supplement the former. The senses have two defects. In the first place, they are sensitive only for a small range of stimuli. Secondly, their deliveries are always infected by subjectivity; they tell us of things, not as they are in Nature, but as they affect a particular organism at a particular time and place. The first kind of defect can be remedied to a large extent by suitable instruments. The second can be remedied by comparison between different senses of the same observer, or the same sense of different observers. Bacon holds that the deliveries of the senses, when properly compared, criticised, and neutralised, are trustworthy, and are the only possible foundation of science.

When the mind has been thus purified and helped, it is time to give it directions for collecting a complete natural history. Bacon recognised that the actual collection of such a natural history would be a work which would take much time, trouble, and expense, and in which many men would have to co-operate. He hoped to secure such co-operation, and to confine himself to giving directions and to completing the logical principles for interpreting and generalising the facts. Unfortunately he received no help either in money or in kind, and so he was forced to collect his data for himself, a task for which he was obviously ill-fitted.

Bacon's scheme for a complete natural history was as follows. It was to consist of an account of the normal course of Nature, of abnormalities spontaneously produced in the course of Nature, and of results deliberately produced by the interference of man. Bacon attached very great importance to deliberate experiment as compared with passive observation. He also attached great weight to the observation of spontaneous abnormalities. They set us free from prejudices, and they suggest means of producing new substances and changes artificially. Bacon explicitly recognised that there is no fundamental distinction between natural and artificial products. In the history of the normal course of Nature we are not to neglect what is commonplace or to omit what is filthy. The method of selection is to be the following. Data are to be chosen, not for their intrinsic interest or for their immediate practical usefulness, but for their capacity to throw light on the structure and laws of Nature. Bacon's views on practical applications in science are admirably just. On one hand, he regards the practical control of Nature as the ultimate end of science, and ability to produce observable results as the ultimate test of any scientific theory. On the other hand, he fully recognises that Nature can be controlled practically only by being understood theoretically; and he constantly asserts that to aim directly at particular applications is fatal to pure science and short-sighted even from the point of view of practice.

Bacon gives rules for recording and arranging the data of the natural history when they have been collected. The following are the most interesting. All data that can be accurately measured should have their values recorded; where accurate measurement is impossible, upper and lower limits should be assigned. All difficult experiments must be fully and carefully described, so that others can criticise and, if necessary, repeat them. The data must be tabulated and classified from the very first. But we must recognise that at first the natural history will almost certainly contain some alleged facts which are not genuine, and that our first classifications will be partly inappropriate. If, however, the bulk of the data recorded are genuine facts, they will suffice to establish the general laws and structure of Nature; and, in the light of this, the few errors will stand out as anomalies and can be reinvestigated and corrected. Similarly, it will be necessary to return to the natural history again and again as our knowledge of the general laws and structure grows, and to reclassify the data in the light of this increased knowledge. Probably a work like Beilstein's "Dictionary of Organic Chemistry" would be a good example of what Bacon meant by a natural history. Yet of course the classification of compounds within this dictionary depends entirely on chemical theory, whilst Bacon wanted his natural history to be as free from theory as possible. The solution of this apparent contradiction is that the natural history and the theories induced from it act reciprocally and successively on each other. The first and crudest form of the natural history involves the minimun of theory and gives rise to the crudest inductions. The natural history is now corrected and reclassified in terms of these inductions. It thus imbibes an additional dose of theory, and becomes the basis for more accurate inductions which in turn react on itself.

(To be continued.)

Antarctic Weather.

THE recent publication of Dr. Simpson's interesting Halley Lecture of 1923 focusses attention once more on the little-known causes which are responsible for the weather of the Antarctic continent. In his lecture Dr. Simpson dealt particularly with the meteorological conditions as they affected adversely Capt. Scott's journey to and from the South Pole, and justified Scott's own view that the conditions on the last stage of the return journey were such as could not have been foreseen. This impossibility of forecasting weather conditions is of course shared by the Antarctic continent with many other regions of the earth, but there is some reason for believing that the contrasts in weather conditions from year to year and from day to day are very pronounced, at least in the region of South Victoria Land, to which area these remarks chiefly refer.

A visitor's first sight of the still active volcano forming the summit of the ice-clad Ross Island is indeed prophetic of the contrasts he will later experience; he will be no less surprised to discover that the continent, roughly circular and of radius some 1200 miles, is almost entirely covered with ice and snow, though it could, so far as precipitation is concerned, be classed almost as a desert. The general surface circulation is anticyclonic, the air flowing outward from the continent with an easterly component due to the earth's rotation. Superposed on the normal distribution of wind velocities

appropriate to the anticyclone is a fairly frequent and high south-easterly wind. These blizzards are inclined to commence more suddenly in winter than in summer, and to occur more frequently during the darker months. On the floating Ross Barrier the yearly excess of precipitation over loss from the surface is only some 8 in. of solid ice, on the average. On the plateau, the net gain to the surface is probably a good deal less than this, the gain being balanced approximately by the downward flow of ice in glaciers of various types. The ice covering differs from that in other regions of the globe in that it does not melt appreciably on land and often pushes a floating 'tongue' for many miles into the sea before a point is reached where melting can set a limit to its advance. Practically the whole of the small snowfall must be formed during blizzards; it is also during blizzards that evaporation from an ice surface is a maximum, at least in the winter months.

Though possibly not in the most logical manner, this leads us to consideration of the blizzard of the western Ross Barrier—that blight of English expeditions. On account of its geographical position and the lower temperature of the Barrier, the pressure over it is higher than over the Ross Sea. This causes a preponderance of surface air-flow from the south and east, on the western side of the Barrier; any increase of this pressure difference—for example, in the form of a moving pressure wave—causes a blizzard. Simpson has indeed showed that blizzards occurred in McMurdo Sound, which lies at the north-west corner of the Barrier, when the pressure difference between that place and Amundsen's headquarters, at the north-east corner, increased; high northerly and light southerly winds, or calms, occurring when the pressure difference decreased. Even when no snow is being formed, the air during a blizzard is filled with vast quantities of loose snow scooped up from the surface, and, at the same time, the temperature generally rises. These characteristics and the gustiness of the blizzard suggest a thorough mixing of the cold surface air with warmer air above it. Blizzards may be of short duration or may last a week or longer; that during which Scott and his party perished lasted for at least ten days. The position of a party storm-bound for many days in a tiny tent is not particularly comfortable, especially when the sun is low, and one can readily imagine the earnest—even fierce—and interminable discussions which accompany the blizzard: Is a wind of 60 miles an hour and a temperature of $-30°$ F. worse or better than a wind of 50 miles and a temperature of $-40°$ F.? How much cream goes to the making of cream cheese? Is it better to sleep with the fur side of the sleeping bag inside, or with the skin side inside?

The western barrier blizzard occurs most frequently in the winter and the adjacent months. To appreciate the reason for this, it is necessary to consider the intensity of radiation to and from the surface, bearing in mind that air receives or loses heat chiefly by contact with the surface. On the snow-covered Barrier, the surface is peculiarly sensitive to radiation on account of the low specific heat and low heat conductivity of the loose snow covering, in comparison with the corresponding constants for the sea which bounds it on the north. Over the sea, convection is operative, and there is a normal temperature gradient in the air above it. The same is true over the Barrier when the inward directed radiation is sufficiently intense, the surface temperature being, however, naturally unable to rise above freezing point. When outward directed radiation predominates, the snow surface rapidly cools and an inverse temperature gradient is established in the air above, provided the horizontal air flow is not too great. This results in a large daily amplitude of temperature on the Barrier—a variation which is almost exactly in phase with the sun's altitude. In appropriate conditions, a mean amplitude of 20° F., corresponding to a variation in the sun's altitude from 10° to 30° above the horizon, has been measured, a range which equals the mean daily amplitude in India, where the sun nearly reaches the zenith and is below the horizon for almost twelve hours.

Due to the same causes, the yearly variation of temperature lags only eight days behind the sun. For the summer 1911–1912 the mean temperature on the plateau for the midsummer month was $-9°$ F., with a mean temperature of $-19°$ F. for the following month. These figures are suggestive of what is likely to occur on the plateau in the depth of winter when the temperatures on the Ross Barrier, which is almost at sea-level, fall at least to the minus seventies. Except in summer, the mean temperature of the Barrier is fixed largely by the frequency of the southerly blizzards, each of which causes a rise in temperature. The low Barrier temperatures, which played so great a part in the disaster to Scott's party, were such as could be expected to occur occasionally; what was entirely unexpected was the length of the cold spell, or, in other words, the unusual paucity of blizzards in late February and March. When the blizzard did come, it was of unusual duration and came at a critical time, when the party was within eleven miles of One Ton Depôt.

March and April are probably critical months, since the formation of a permanent winter ice covering in McMurdo Sound seems to be conditioned largely by its ability to reach a sufficient thickness between blizzards, before the winter weather sets in.

Travel on the Barrier at a time when the sun is setting, or has set for the winter, is indeed an unpleasant business, and considerable advantage is gained by choosing a time for the commencement of a long journey so that Christmas falls practically in the middle of the period. Apart from the necessity of avoiding the bad weather of the autumn, one should strive by this means to avoid the bad sledging surfaces associated with low temperatures. We have no quantitative information about the relative friction at temperatures about and far below 0° F., or in fine and coarse-grained snow, but the differences are known to be very important, and the great wear of the sledge runners is quite sufficient indication of the increased friction at really low temperatures. On cold, freshly-fallen snow of a 'floury' consistency the effort of hauling is so great that one has the feeling that the friction is a friction, not between snow and runner, but between adjacent snow grains.

Much more data are required before the weather of the Antarctic can be known in more than its broad outlines—data which can only be gathered by concerted

action and by the permanent occupation of temporary observatories. The present poverty of the country is such that no well-found expedition is likely to be launched in the near future, but the time will come when further information will be urgently required, and this will be the time for insisting on the importance of such conditions as will obtain the fullest scientific value for money expended. It is hoped that the Scott Polar Research Institute, the formal inauguration of which has recently taken place at Cambridge, will have some influence in determining questions of this nature. C. S. W.

Obituary.

PROF. F. W. GAMBLE, F.R.S.

A DISTINGUISHED English zoologist, a remarkably fine teacher and a man of a singular charm of character, has been lost to science by the death, on September 14, of Prof. Frederick William Gamble, Mason professor of zoology and comparative anatomy in the University of Birmingham. He was born in Manchester on July 13, 1869, and was educated at the Manchester Grammar School and at the Owens College. At the College he came under the influence of the late Prof. A. Milnes Marshall, and catching his enthusiasm for the study of animal morphology, devoted himself to zoological studies. After taking his degree with first-class honours in the newly established Victoria University and gaining the Bishop Berkeley research fellowship, he went abroad and studied for a time in the University of Leipzig. The first two papers from his pen, one on our rare British Nudibranchs, published in 1892, and the other on the British marine Turbellaria, published in 1893, were descriptive and systematic in character, but already they showed evidence of the tendency of his mind towards the experimental side of the subject.

After a short period as a junior demonstrator, Gamble was made lecturer and senior demonstrator in zoology in the University of Manchester, and in 1896 he completed his account of the flatworms and Mesozoa for the "Cambridge Natural History," a most interesting and valuable contribution to that excellent text-book. It was about this time that the lug-worm (Arenicola) was introduced as a type in the schedule for the first M.B. examination of the Victoria University; and finding from laboratory experience that the current accounts of the structure of this worm were inadequate and in many respects inaccurate, Gamble and his colleague J. H. Ashworth prepared and published in the *Quarterly Journal of Microscopical Science* a very careful and elaborate description of its anatomy. This study led to the important discoveries by Ashworth, at a later date, of the structure and function of the giant nerve cells and nerve fibres of the Polychæta.

While the work on Arenicola was still in progress, Gamble's interest was attracted to the colour changes in the 'Phantom' shrimp *Hippolyte varians*, and, working now in partnership with a colleague in the botanical department, Mr. (now Sir Frederick) Keeble, a series of experiments were made at the fisheries' station at Piel which led to very interesting and remarkable results. The discovery of a blue nocturnal phase in all the colour varieties of this shrimp was in itself a novel and startling fact, but when the researches were extended to the higher forms of Crustacea, many other very important systematic and physiological results were obtained. In 1903 another paper by the same authors, working on the coast of France, appeared in the *Quarterly Journal of Microscopical Science*, on the bionomics and physiology of the remarkable turbellarian worm *Convoluta roscoffensis*, in which it was proved that the green corpuscles of the Convoluta represent a phase in the life-history of a flagellate organism allied to the genus Carteria, and that this organism infects the eggs after they are laid. It is not an exaggeration to say that this study in symbiosis has become one of the important classics of the subject. It is frequently referred to by later writers as the chief authoritative statement on the physiological relationship of host and guest.

It is not possible in this place to refer in detail to other scientific work Gamble did when this partnership was dissolved. It was characterised by the same love of the experimental method, accurate observation, and cautious deduction that was shown in his earlier writings.

With all his love for scientific research Gamble combined all the great qualities of a conscientious and explicit teacher. He spared no pains to make his lectures and demonstrations effective, with the result that he earned the respect and gratitude of a large number of his pupils and colleagues. In the two admirable little books which he published, "Animal Life" and "The Animal World," he has left some indication of the way in which he presented the problems of biology to an unscientific audience; and his account of the Radiolaria in Lankester's "Treatise on Zoology" shows his power of mastering the literature of a large subject and presenting the substance of it in an intelligible way to the more advanced student.

By the death of Gamble many of us have lost a most sincere and devoted friend. His quiet, modest manner, his constant readiness to help his colleagues and his pupils, and his unblemished character, endeared him to a wide circle of friends and acquaintances. He was elected a fellow of the Royal Society in 1907 and appointed professor of zoology in the University of Birmingham in 1909. He was president of Section D of the British Association at the Toronto meeting in 1924, where he delivered a very interesting address dealing principally with the question of the metabolic gradients.

Gamble married, in 1904, Ellen, daughter of the late Rev. J. M. Bamford, of Arnside, who survives him. He left no children.

WE regret to announce the following deaths:

Prof. Rudolf Eucken, from 1874 until 1920 professor of philosophy in the University of Jena, and author of many works on philosophy, on September 14, at eighty years of age.

Dr. Paul Kammerer, of the Biologische Versuchsanstalt, Vienna, known for his experimental work on the inheritance of acquired characters in amphibia, on September 23, aged forty-five years.

News and Views.

THE report of the Government Chemist upon the work of the Government Laboratory for the year ended March 31, 1926 (London: H.M. Stationery Office, 1926; 1*s.* 6*d.* net), though mainly a statistical document, is a standing witness to the value of this adjunct to the Government services. Unlike their medieval predecessors, Sir Robert Robertson and his merry men are not called upon to produce gold from base metal, to read the stars and to cast horoscopes; their task is the more prosaic but far more practical one of safeguarding the revenue and, to a certain extent, the health of the country, by means of chemical tests. Their work, however, extends beyond this, for in addition to serving the Board of Customs and Excise, the Board of Trade and the Ministry of Health, they do much chemical work for other Government departments, such as the Ministry of Agriculture and Fisheries, the Air Ministry, the Office of Works, the War Office, the Post Office, and the Inland Revenue. Not content, apparently, with these primary duties, the comparatively small staff of the Government Laboratory undertakes occasional research work of no mean importance, and provides representation on a number of scientific committees. Chemical analysis is, however, its main activity, and the number of samples analysed during a year, no less than their diversity, inspires us with a feeling of profound respect, if not of awe. During the year 1925-26, no fewer than 445,606 samples were examined, of which more than 110,000 related to beer and brewing materials, 106,305 to wines, 48,587 to spirits and spirituous preparations, 72,289 to tobacco, 61,003 to sugar and sugar products, 39,391 to tea, and 13,128 to cocoa and chocolate. The number of samples of imported beer, cocoa-goods, and imported spirits and spirituous preparations was considerably in excess of the number analysed in 1924-25.

THE work of the Government Laboratory indicates in no uncertain way the trades that are especially marked out to bear the burden of taxation, and it also reflects important changes in legislation. Thus in the year 1924-25 no samples of silk were examined in the Laboratory, but last year, following the imposition of duties, 12,237 samples were taken and tested, of which 10,313 were from imported materials, 1803 from exports, and 121 from home factories. Developments, industrial and fiscal, in the Irish Free State have been responsible for recent fluctuations in the number of tobacco samples examined. The Safeguarding of Industries Act necessitated the examination last year of 9645 samples of imported goods, whilst the Dyestuffs Act accounted for 195 samples, as compared with 535 in the previous year. Although mainly of interest to the analytical chemist, the report contains many items that will appeal to the student of affairs, and the layman's perusal of it leaves the impression that on the score of impurities and adulterations, the public have little reason to complain. From the large number of miscellaneous samples examined for the Post Office, it is interesting to note that, although 'gold thread' figures in the list, there is no reference to 'red tape'; analyses of lubricating oil for H.M. Stationery Office suggest a welcome acceleration of motion in that department; and the recovery of radium from disused compass-dials, gun-sights, etc., for the Treasury evokes memories of a war, and of a Damocletian weapon in the form of an axe that never fell.

A BRIEF Reuter message from Batavia in the daily press of September 27 announces the discovery by Prof. Heberlein of what is said to be a complete skull of the type *Pithecanthropus erectus*, the well-known Java skull. The discovery was made at Trinil, the village near which Dubois in 1892 found the skull-cap, thigh bone, and two teeth, to which the name *Pithecanthropus erectus* was given and about the human character of which so much controversy has since raged. Should later detailed information confirm the character of the new find, its importance will amply reward the patience, time, and money which have been expended, since Dubois' discovery was made known, on searching the neighbourhood for further relics of this earliest known and most primitive of the human types. Dr. Aleš Hrdlička, the American anthropologist, on his return last year from an anthropological tour of the sites on which relics of early man have been found, pointed out the importance of an early investigation in Java, where he had seen in the hands of natives an abundance of relics of man, apparently of considerable antiquity, which were being lost to science. It is therefore gratifying to note the announcement that the American Museum of Natural History intends to raise funds to carry on the work of excavation.

THE sixth (interim) report of the Sea Action Committee of the Institution of Civil Engineers is dated October 1925, and deals with researches carried out in 1924 or early in 1925. Its publication by the Stationery Office in September 1926 cannot therefore be called premature. The report contains summary reports on the periodical examinations of the steel test-pieces exposed at various harbours, but it is pointed out that "no really definite results can be expected until the bars are taken up for final examination." The experiments on painted specimens are also at an inconclusive stage, but the results are fairly consistent in showing that some of the paints are decidedly better than others. The biological work carried out for the Committee consists in series of experiments on the toxicity of various compounds to Teredo larvæ and to adult Limnoria. It is concluded that "substances that are toxic to Teredo do not necessarily confer any very high degree of protection against Limnoria." No comment is made on the discrepancy between this result and that obtained by the American Committee, the report of which, published in 1924 and summarised at the end of the present one, states that "the toxicity of the various compounds was approximately the same" for Limnoria and for the Teredinid Bankia. Prof. Barger reports that experiments by Dr. C. M. Yonge at Plymouth have

shown that organic arsenic compounds of the type of D. M. (phenarsazine) are the most effective in poisoning the larvæ of Teredo. Tests on adult Limnoria at Edinburgh by Dr. F. D. White proved that it was not specially susceptible to organic arsenic compounds, the most effective substance being fluorenone, which, however, is too expensive for practical use. Dr. Yonge found that the poisons had no repellent effect on the Teredo larvæ, which settled as readily on wood impregnated with D. M. as on untreated wood, although in the former case they were speedily killed by the poison.

THE paper by Dr. Huber-Stockar, formerly chairman of the electrical department of the Swiss Federated Railways on the Electrification of Railways, which was read to the World Power Conference at Basle, is of interest at the present time. Dr. Huber-Stockar points out that when a railway is once electrified it never returns to steam traction. At first sight it is difficult to understand why so many railway companies are hesitating whether to adopt electric traction or not. The delay is due partly to economic considerations. Electrification involves expenditure, and this expenditure is not justified unless the traffic increases. Every new capital expenditure makes the railway more sensitive to a decrease in traffic. Electrification on a modest scale has not much effect on the prosperity of the railway. The hesitation of railway companies is also partly due to the difficulty in deciding which system is the best. State owned railways are as much interested in economic considerations as privately owned railways. In Europe a number of countries have experienced beneficial effects from electric traction which have justified its adoption. Favourable factors for changing to electric traction are cheap electric power and expensive coal and manual labour. The conditions are also favourable when the traffic is heavy and the gradients are long and steep. Dr. Huber-Stockar concludes that no definite and easily applied rules can be given for determining whether a railway is ready for electrification or not. It would be a great help to engineers if details of installations and working results were always given in similar forms, so that they could be readily compared.

THE excavations at Beisan of the Palestine Expedition of the University Museum, Philadelphia, which were resumed on August 24, have already produced finds of importance in throwing light on the extension of Cretan influence in this direction. In the *Times* of September 23, Mr. Alan Rowe, field director of the Expedition, records the discovery of cult objects, one a cylinder terminating in a pig's head, which is compared with and closely resembles a Cypriote vase, a basalt model of a chair of Minoan type, and a model of a table, also of Minoan type. The chair, although Cretan in form, bears Egyptian emblems—a winged Set animal, a vulture with outstretched wings, and the *ded* pillar emblem with arms and hands holding the Sign of Life. These finds, taken in conjunction with those of 1925, which, however, were of later date, point to a strong Cypro-Mycenæan influence in the religion of Beisan from 1375 B.C. onwards, of which the final phase was the Philistine domination ended by David about 1000 B.C. A bronze axe-head with a blade at one end and four curved prongs at the other, is similar to an axe-head held by a king figured on the gate of the Hittite capital in Anatolia. This would accord with the fact that about the time this temple of Amenophis IV. was being built the Hittites were advancing in northern Syria. The discovery of faience objects bearing the cartouche of Amenophis III. below the level of the floor of the temple confirms the attribution of this building to Amenophis IV. (1375-1358 B.C.).

AT the recent meeting of the British Association in Oxford, a registering balloon ascent was made by the Meteorological Office from the quandrangle of Keble College, in the presence of the guests assembled for the Meteorological Luncheon held on August 10. The balloon and meteorograph fell at Caxton, near Cambridge, a distance of 94 km., N.E. by E. The balloon reached a height of 20·1 km. before bursting. The meteorograph employed was a light barothermograph without clock, but it is possible to infer from the known approximate vertical velocity of the balloon that the total time of flight from ground to ground again was about 1½ hours. This indicates an average horizontal velocity of about 18 m. per second. The balloon was seen to enter a cloud of mammato cumulus form at a height of about 1½ km.; the record shows a small lapse rate of 4° per km. just below that height. From this point upward to 3·0 km. the atmosphere was in a slightly unstable condition with regard to saturated air; then there occurred traces of a reduced lapse rate, while above that again slight instability prevailed up to 7 km. It is probable that 3 km. marked the upper limit of the clouds seen from the ground. The stratosphere was found at 9·9 km., with a temperature of 231° Abs., and above that not more than 2° change of temperature, plus or minus, occurred at any point up to the maximum reached. The ascent was made in the south-westerly current to the south east of a depression centred south-east of Iceland, with a gradient wind of about 8 m. per second.

A FUND for research fellowships, to be known as the "Eric Knight Jordan Research Fellowships in Geology," has lately been established by Dr. and Mrs. David Starr Jordan as a memorial to their son, who died on March 10 last. This fund is to be administered by the Stanford University, of which Dr. Jordan was the first president. The founders attach two conditions to the gift: first, that their son's name shall be perpetuated in the foundation; and secondly, that the principal sum shall be forever kept inviolate, only the interest thereon being used. The founders as an initial step have contributed a sum of about 1000*l*., but expect to add to this later on, and invite friends of their son to contribute also E. K. Jordan in his all too short life (1903-1926) had shown great promise. No less than eleven important

papers stand to his name, all published in the last six years. Beginning with one on recent mollusca, followed by a temporary digression into the subject of Hawaiian fishes, the remainder are concerned with the tertiary and quaternary molluscan faunas of localities in Lower California and Mexico, or expeditions in connexion therewith.

PROFS. H. BENNDORF and V. F. HESS are at present engaged in writing a comprehensive treatise on "Atmospheric Electricity and Allied Phenomena," to be published next year. As is well known, the funds available for the libraries of the Austrian universities are far from adequate, and it is extremely difficult to maintain scientific journals, especially the bulletins and proceedings of scientific institutions and societies of foreign countries. Profs. Benndorf and Hess write asking physicists and meteorologists in all English-speaking countries to send them reprints of their publications. Papers are required on atmospheric electricity dealing with the electric field of the earth and atmosphere, atmospheric ionisation, electricity of thunderstorms, electric properties of rain and snow, radioactivity of the earth and atmosphere, rays of cosmic origin, electric currents in the atmosphere, the aurora, theories of the origin of electro-atmospheric phenomena, and propagation of electric waves round the earth. Any reprints on these subjects would be gratefully received; they should be addressed to Prof. Benndorf or Prof. Hess, Physikalisches Institut, Universität, Graz (Steiermark), Austria.

DURING the past summer Prof. G. F. Sleggs, professor of biology at the newly established Memorial University College of Newfoundland and oceanographer to the Newfoundland Government, a former graduate of the Oceanography Department of the University of Liverpool, has carried out biological and hydrographical research in Bonavista Bay, Trinity Bay, Conception Bay, and other important Newfoundland fishery grounds. Samples of water have been obtained from a wide area and from accurately known depths for a study of plankton and temperature variations. A drift bottle experiment has also been carried out, a satisfactory proportion of the bottles having already been recovered. The work is in co-operation with the North American Committee on Fishery Investigations and is the first of its kind to be officially supported by the Newfoundland Government.

AMONG many brightly written and well illustrated articles in the *Scientific American* for September is one on the decreasing level of the great lakes From a diagram, showing the variations in level of Lakes Huron and Michigan from 1860 to the present year, it would appear that apart from minor fluctuations a general lowering of level set in about 1890, after which the level has never reached previous maxima and has generally stood well below previous minima. Since 1909 the level, with one or two exceptions, seems to have been steadily falling. It is now about two feet lower than it was in 1860. The Chicago drainage canal, which was opened in 1900, has a flow of 8800 cubic feet a second, while other canals and artificial outflows from Michigan, Huron, and Erie account for 57,000 cubic feet a second. It is, however, pointed out that during the period 1917–1925, while the lakes stood at their lowest level, the rainfall deficiency over the lakes and their drainage area was at least two inches a year, and in some areas in certain years rose to six inches. Thus it is by no means certain that canal construction has been entirely to blame in robbing the lakes of water, though, if the decrease continues, the construction of weirs will become necessary.

IN view of the recent discussion at the British Association, attention may be directed to a brief historical review of the question of the species concept by Fridthjof Okland in *Naturen* (1926, pp. 75-87). From this he draws the following conclusion : " Even if we realise how uncertain the species concept is, biologists can and must continue to work with some such delimitation of forms. At the same time the obvious hopelessness of finding any biological concept of the species that shall be universally applicable gives distinct proof that the limits between forms are often more apparent than real. Our classification does not always give a true picture of relationships and connexions in living Nature." On which one is impelled to ask : Can it, and should it ?

THE twenty-fourth annual report of the Rhodesia Museum, Bulawayo, for 1924, records the appointment of Mr. A. Frost to the post of geologist, vacant since 1915. Mr. Frost arrived soon after the discoveries of platinum ore in the Transvaal and found his time almost entirely occupied in reporting on samples submitted by prospectors. A special platinum exhibit was arranged, illustrated by maps and sections. A platinum panning, supplied by Mr. Milligan, of the Anglo-French Exploration Co., is available for prospectors to see and 'tail out' for themselves. It is to be hoped that some of the many who receive assistance will become members of the Museum, which is so poor that it does not possess even a rock-cutting apparatus.

THE Meteorological Department of the Government of India issued during the early part of August a forecast of the probable amount of rainfall during August and September, together with a memorandum on the rainfall experienced in June and July. The monsoon was very weak in June but normally active in July. The June rains were generally in defect, but in July there was a marked improvement. The inferences from the data most likely to have influence on the rains of August and September, show that the monsoon rainfall of the two months is likely to be normal in north-west India and normal or in excess in the Peninsula. Forecasts which are required by the Indian Government were issued by Mr. J. H. Field, Director-General of Observatories.

THE Atlantic weather, which has been brought to general notice more than usual of late by the disastrous hurricane in Florida and the West Indies, is thoroughly discussed in the *Marine Observer* published by the Meteorological Office, Air Ministry.

Research Items.

ANCIENT BRONZE FROM THE TRANSVAAL.—At the meeting of the South African Association for the Advancement of Science held at Pretoria in July last, Mr. Percy Wagner presented a communication on the making of bronze by the ancient inhabitants of the Transvaal, which is published in the *South African Mining and Engineering Journal* of July 26. Tin mining and smelting were practised by an unknown people in the Transvaal long before the advent of the whites. Some years ago a lump of bronze was found alongside a furnace on a farm, Blaauwbank No. 433, about 40 miles west of Warmbaths. The bronze was remarkable in that it included 3 per cent. nickel and 2 per cent. arsenic. Some regarded this bronze as an accidental product due to the reduction of a composite ore; but a recent discovery has placed it beyond question that the ancient miners deliberately set out to make bronze. Recently on the same farm, Blaauwbank No. 433, have been discovered near a dry watercourse, thirty distinct smelting furnaces, with hand-cobbed tin and copper ore alongside. 'Slugs' and 'frills' of bronze were found in the furnaces. In regard to the presence of nickel in the bronze, there is at Blaauwbank a nickel lode carrying at the outcrop masses of apple green 'nickel-bloom' which remotely resembles malachite. The accidental introduction of this material may have led to its continued inclusion intentionally when its special qualities had been appreciated. The point is one of considerable archæological interest, as it is stated that no other ancient mines are known that could have furnished in one locality the ores for producing a nickeliferous bronze, and a nickel-bronze was known and in use in early Mesopotamia and Egypt.

THE FAMILY 'TRINITY.'—In *Man* for September, Prof. Radcliffe-Brown puts forward an interesting theory to account for the relations of father, mother, and child in the primitive family. It has been pointed out that the natives of Murua (New Guinea) regard the incidence of childbirth as in the nature of a welding of personalities—a trinity of father, mother, and child. But this same conception is found among a great many primitive peoples. In the Andamans, for example, the family does not really exist as a properly constituted group until the birth of the first child—the relationship between husband and wife is not simply created by marriage. It is illustrated by teknonymy, the custom whereby one of the spouses addresses the other as "mother of," "father of" the child. The imposition of a special taboo points in the same direction. It differentiates the family as a group. It is only the first child that counts, the later born children being regarded as multiples of a single personality. This principle operates also in the polygynous family, where either the wives are, like the children, multiples of a single personality, especially if they are sisters, or the husband is separated into a number of units, each with a wife and her children—the form typically taken by the polygynous family in Africa. The other method, however, may be adopted there also, when a man marries two sisters, or where a wife is childless and another wife is obtained to bear children. The same principle applies to polyandry, but only when the husbands are brothers.

THE TABANIDÆ OF THE CANADIAN PRAIRIE.—The biology of the blood-sucking flies belonging to the family Tabanidæ forms the subject of a recent paper by Prof. A. E. Cameron in the *Bulletin of Entomological Research* for July 1926 (vol. 17, Part I.). Hitherto most of what is known concerning these insects in North America has emanated from the United States, and information concerning the Canadian forms is very meagre. The genus most abundant in species is Tabanus, its most prevalent member being *T. septentrionis*. Of the genus Hæmatopota there appears to be but a single representative, *H. americana*, while the most abundant species of Chrysops is *C. mœrens*. Previous to the settlement of western Canada, the principal hosts of Tabanidæ were the larger game animals. The moose, deer and elk are still to be found in the northern regions where the white settler has not penetrated, and, along with the barren-ground caribou, these animals are the chief native hosts of prairie Tabanidæ to-day. In cultivated districts they attack live-stock and human beings indiscriminately. The theory that Tabanidæ are the insect-transmitters of infectious anæmia of horses appears to be very uncertain and requires critical investigation, as the disease may be rife on one farm, while on adjacent farms, which enjoy apparently similar environment, the animals may be devoid of any symptoms of the complaint. Tabanidæ are well known to be strong fliers, and if they do convey the disease it would appear that not all horses are equally susceptible to infection. Prof. Cameron discusses the technique of rearing the larvæ of these insects, and describes and very clearly figures both the larvæ and pupæ of a number of species.

NEW PLANT ILLUSTRATIONS.—In *Curtis's Botanical Magazine*, vol. 151, part iii., Dr. Stapf figures and describes nine new Asiatic plants now in cultivation, namely, *Actinidia kolomikta*, *Rhododendron saluenense*, *Jasminum Beesianum* (which bears beautiful glossy black berries in cultivation in England), *Polygonum campanulatum*, *Pyracantha atalantioides* figured in flower and *P. yunnanensis* in fruit, *Primula siamensis*, *Berberis lycioides* which has the additional attraction for the cultivator that its decorative 'barberries' make a delicious jam, and *Fritillaria Oliveri*. In addition, a Spiranthes is described from the Argentine, a beautiful Cordyline from New Zealand, a Mammillaria from Mexico and a Mesembrianthemum from South Africa, but this distribution of the new records of cultivated plants shows the preponderating influence of new introductions from Asia in our gardens at present.

BURR-KNOTS ON APPLE AND CROWN GALL.—Certain varieties of apples have on their stems, generally at nodes, tumour-like swellings which sooner or later pass over into a crowded mass of wart-like projections. Some of the apple stocks most frequently used in England bear these 'burr knots,' and such stocks have been forbidden entry into the United States under the assumption that these structures were a form of a pathological condition known as 'hairy-root,' which has been found to be associated with the crown-gall organism *Bacterium tumefaciens*. Probably all British workers will, however, endorse the conclusions of R. G. Hutton, H. Wormald and A. W. Witt, in the *Journal of Pomology and Horticultural Science* (vol. 5, No. 3, July 1926), that these structures indicate the position of dormant, stem-borne root initials, and that if placed under moist conditions they will readily give rise to roots. One American worker, C. F. Swingle, has recently published a similar view, and the British workers publish a useful bibliography of earlier references to these structures, which, however, omits the important paper by Dr. A. W.

Borthwick (*Notes from Royal Bot. Gard., Edinburgh*, vol. 16, 1905), in which valuable anatomical data are supplied. Dr. Borthwick's paper supplied practically conclusive evidence that these structures were really root initials, but in view of the American point of view, it is good to have this later confirmation that all attempts to isolate a pathogenic organism from burr-knots have given negative results.

STATISTICS OF FIELD EXPERIMENTS IN AGRICULTURE.—The growing importance of field experiments in agriculture has led to the development of technique for eliminating errors of experimentation, and R. A. Fisher (*Journ. Minis. Agric.* 33) has investigated statistically the relative value of different methods of arranging field plots. A valid estimate of error can be obtained by finding the standard error, the square root of the variance, and a method of replication has been devised whereby this estimate can be obtained from the actual yields of the trial year. Great care is necessary that the arrangement of unlike plots shall be such as to provide a valid estimate of error, and a random arrangement appears to be the most suitable. For simple trials in which every possible comparison is of equal importance, the Latin square provides the most efficient arrangement, one Latin square being selected at random out of the total number possible. For more complex experiments in which comparisons involving single factors—*e.g.* with and without phosphate—are required, replication of randomised blocks is necessary in order that no possible interaction of the factors may be disregarded. With this method the conclusions drawn from the single-factor comparisons will be given, by the variation of non-essential conditions, a very much wider inductive basis than could be obtained by simpler methods without extensive repetitions of the experiment.

GRAVITY DETERMINATIONS AT SEA.—In 1923 Dr. F. A. Vening Meinesz made a submarine voyage from Holland to Java by way of the Mediterranean and the Indian Ocean. Gravity observations were made at thirty-one points, and the results of their isostatic reduction (carried out by the U.S. Coast and Geodetic Survey) were presented at the recent annual meeting of the American Geophysical Union. The average anomaly for all the stations with regard to sign is 0·012 dyne by the Bowie formula. It is of special interest that for ten stations in the Indian Ocean far from land the average anomaly is 0·009. Thus isostatic equilibrium beneath the Indian Ocean is as perfect as it is under the continental regions that have so far been investigated. Dr. Meinesz made additional submarine observations between Holland and Port Said in 1925, and these are now being reduced in America. At present Dr. Meinesz is continuing his work in a submarine voyage to Java via the Atlantic, the Panama Canal and the Pacific. Special attention is being devoted to the continental shelves and the oceanic deeps.

MAGNETIC SURVEY OF FRANCE.—An account of the latest magnetic survey of France, begun in 1921, is given by A Baldit in *La Nature*, August 21, 1926; it is hoped to complete the survey this year. Earlier surveys of France were made by Lamont (in 1856–7, with 44 stations), Perry (33 stations, 1868–9), Marié-Davy (20 stations, 1875), and Moureaux. The latter made two surveys, one including 80 stations (1884–1885), the second, extending over eight years, 1888–95, being much more detailed, and including 617 stations. In regard to the density of the network of stations, the latter was the first survey of France approaching modern standards for a civilised country. It revealed many hitherto unexpected irregularities in the isomagnetic lines, some of which could be correlated with geological features of the country. The present survey is still more detailed, being intended to include 1440 stations; these are not uniformly distributed, being specially dense where the magnetic features of the country are of particular interest. Six observers have been engaged in the work since 1922. The instruments used are not new, and are of standard type, the magnetometer being of Mascart's design, and the inclinometer of d'Abbadie's. The accuracy anticipated is to 1′-2′ for declination, 2′ in dip, and about 20 γ in horizontal force. The period of the survey is one of magnetic calm, and the accidental errors due to disturbance are therefore minimised.

ATLANTIC OCEANOGRAPHY.—A summary of the important oceanographical work of the German *Meteor* expedition of 1925 is given by Dr. H. R. Mill in the *Geographical Journal* for July. The object of the expedition was to survey the ocean depths, including physical and chemical work, of the South Atlantic between lat. 20° S. and the Antarctic circle. The most important work began in June 1925 with the first cross-section of the Atlantic along the parallel of 40° S. from South America to Africa. Profile II. was westward along the parallel of 29° S. Profile III. was eastward on the parallel of 48° S. Then followed Profile IV. westward along the 35th parallel, and Profile V. eastward along the 55th parallel with a dip southward to lat. 64° S., where a sounding of 4380 fathoms was obtained somewhere to the east of South Georgia—the exact position is not yet published. Finally Profile VI. was run west along the Tropic of Capricorn. Echo soundings were checked from time to time with wire soundings. Bottom samples, serial temperatures, and salinity observations were taken throughout the voyage. The upper air was investigated with kites and pilot balloons. The full results of this expedition will throw much light on oceanographical problems in the Southern Ocean.

ELECTRIC LAMP FIRE-DAMP DETECTOR.—It is nearly fifty years since Mr E. H Liveing first designed a method for measuring fire-damp in mines by sending an electric current through two spirals of platinum wire over one of which the mine air was passed: the increased luminosity produced by the combustion of the methane-air mixture on the heated wire gave a measure of the methane present in the air. The apparatus in skilful hands would certainly measure fire-damp, but its value lay rather in its promise than its practical utility. The Liveing principle has been the foundation on which many inventors have built, and has lately been embodied in the electric-lamp detector of Messrs. C S. W Grice and A. G. Gulliford. In the new detector the current of the lamp accumulator can be switched through a small length of fine platinum wire in a chamber to which the mine air has access through a wire mesh. The length of fine wire—3 mm.—between its metal clamps is so adjusted that the wire fuses when the methane reaches 3 per cent. of the atmosphere: below this percentage the wire glows brightly and indicates the presence of gas. It is evident that the utility of the invention will depend on how far the conductivity of the wire and the voltage of the accumulator can be maintained constant under working conditions.

SWEDISH RAINFALL.—In the note in NATURE of August 28, p. 318, on the Swedish rainfall statistics for 1925, the fact was overlooked that the means for each month and for the year are compared with the figures for 1925, which adds to the value of the volume.

The Alloys of Aluminium and Silicon.

THE very great interest at present being taken in the aluminium alloys containing from about 10 per cent. to 13 per cent. of silicon, is shown by the fact that no less than three of the papers presented to the Institute of Metals at the recent meeting at Liège dealt with this material.

Both from the practical point of view, regarding the material as one of considerable promise for the production of light alloy castings, and from the theoretical, these alloys are of more than usual interest. It has been known for some time that the structure may be greatly affected by the addition to the molten metal of small amounts of various 'modifying' reagents. Many theories concerning the reason for this change of structure have been propounded, but, hitherto, no completely satisfactory hypothesis has been available. Figs. 1 and 2, reproduced by courtesy of the Institute of Metals, illustrate the change in structure of the 10 per cent. alloy brought about by the addition, at 750° C., of 5 per cent. of sodium hydroxide. Fig. 1 represents the material in the ordinary chill cast state, and Fig. 2 the same after the 'modifying' treatment. The mechanical properties also are greatly improved when the alloy possesses the second type of structure.

Fig. 1.—9·86 per cent. Si, 0·45 per cent. Fe. Chill cast. Unetched. × 200.

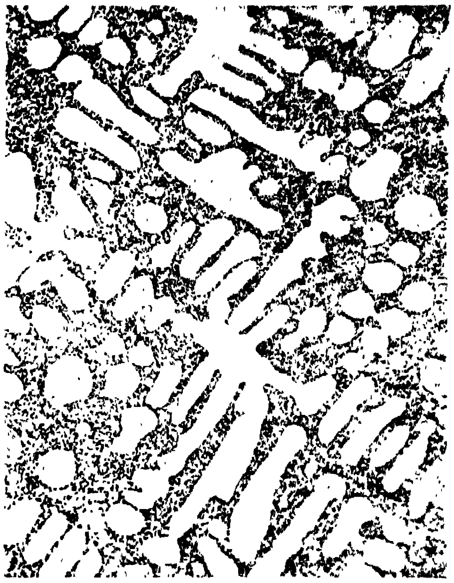

Fig. 2.—9·86 per cent. Si, 0·45 per cent. Fe. Same alloy as Fig. 1, but modified with 5 per cent. NaOH at 750° C. Chill cast. Etch HF. × 200.

Of the three papers now before us, that by Dr. A. G. C. Gwyer and Mr. H. W. L. Phillips (with an appendix by Dr. Stockdale and Mr. I. Wilkinson which is concerned with the mechanical properties of the alloys) is the most important The properties of the material in the 'normal' condition are not very remarkable, but the addition of a small amount of a suitable metal or salt to the melt before it is poured endows the casting with far superior strength and ductility.

In the normal state these alloys consist of a simple eutectiferous system, with small limits of solid solubility at each end. The thermal-equilibrium diagram has been redetermined, and the eutectic point placed at 11·7 per cent. of silicon and at a temperature of 577° C. After 'modificatior' the eutectic contains an appreciably greater amount of silicon and is formed at a lower temperature, both the composition and the temperature being dependent on the rate of cooling and the treatment of the metal. Further, when the molten metal is stirred or remelted after 'modification,' or left in the molten state for an undue length of time after the addition of the modifying material, the normal structure and properties are obtained.

There are clear indications, therefore, that the 'modified' metal is in an unstable state. The authors mentioned now offer a new explanation of their own, which appears to approach far more nearly to the truth than anything which has yet been suggested.

This theory may be briefly stated as follows: When the aluminium-silicon alloy is raised to a temperature considerably higher than its melting point, it is probable that the silicon and aluminium are in true solution. When solid the greater portion of the silicon is present, dispersed in crystals of a size readily visible under the microscope. A small quantity, of the order of 0·5 per cent. at room temperature, remains in solid solution in the aluminium, but this may be disregarded at the moment. In solidifying, the silicon and aluminium pass from atomic dispersion to the crystalline form. At some stage during the process, therefore, the silicon and aluminium aggregates will be of colloidal dimensions. It is well known that the colloidal state is an unstable one, and that colloid particles tend to coalesce. Their rate of growth may be accelerated or diminished by the addition of protective agents.

Having regard to all the facts which have come to light, it appears to the authors that the most satisfactory explanation of the behaviour of 'modifying agents' is to assume that they function as colloid protectors. They do not, of course, confer complete protection upon the colloidal silicon and aluminium, but simply retard their aggregation. From the changes in the crystalline form of the constituents brought about by the process of 'modification,' it is probable that the protector itself is a colloid. It does not, however, appear that the assumption is

justified that when sodium compounds are used for 'modifying,' the protector is necessarily metallic sodium. As a result of this action, the formation of the normal eutectic is inhibited, and aluminium continues to be precipitated from the metal until the super-solubility line is reached.

It is also shown that the protection of the modified structure can be obtained without the use of the ordinary reagents provided that the rate of cooling is sufficiently rapid.

From the theory that certain substances hinder the aggregation of the colloid particles, it should be possible to discover also other substances capable of accelerating this aggregation. The compound $FeAl_3$ is such a substance, and it has been experimentally substantiated that the presence of iron in melts of these silicon-aluminium alloys is detrimental.

A diagram has been drawn up for the 'modified' alloys indicating the manner in which under-cooling alters the normal process of solidification. The amount of the substances added to effect the 'modification' has been considered, and with sodium hydroxide, and for an alloy of about 12 per cent. of silicon, it is put at about 5 per cent. of the weight of the metal. Excess results in a deterioration of the mechanical properties.

The time which is allowed to elapse between the addition of the castings is also of importance, and, for the usual composition of alloy, should be about half an hour.

Since the general theory propounded is independent of any special constituent, it should be sufficiently general to apply to systems other than that immediately under consideration. This is shown to be the case, and exactly analogous results have been obtained in the systems copper-aluminium, aluminium-nickel, aluminium-manganese, lead-antimony, and copper-antimony.

The importance of the colloidal state in alloys at the moment of solidification, and of under-cooling, is thus shown to be far greater than has hitherto been generally appreciated. F. C. T.

The Twelfth International Physiological Congress in Stockholm.

EACH international congress, as a rule, discloses some special interest in one or another field of physiological science, as well as serving as a sure guide to the virility of the science in general. Contrasted with the last congress, held three years ago in Edinburgh, the present congress had no one central interest comparable to that excited by the isolation of insulin, but the fine attendance of the foremost representatives, with a considerable number of the younger workers, from all the continental European countries, was a welcome evidence of the general recovery of physiology from the devastating effects of the War, and of the steady and persistent advance in almost every branch of this science.

The congress in Stockholm was as beautifully arranged as in Edinburgh, and as regards the welcome and hospitality offered there is no need to say more than that it could not have been bettered. The scientific programme of the congress opened with an address by Sir Frederick Gowland Hopkins on "The Mechanisms of Biological Oxidations," in which he outlined the position attained by workers in this field, with especial reference to the work done in his own laboratory at Cambridge.

The routine work of the congress was divided into four sections which were grouped according to subjects, facilitating the attendance by each member at the discussions on those papers in which he was particularly interested.

Great interest was aroused by a number of papers dealing with the fundamental processes of life, as, for example, the communications of the recent important researches of Adrian upon the afferent impulses conducted by the single nerve fibre, and of Hill and Downing upon the measurement of heat production in nerve. An interesting summary was given by Kato (Tokyo) of his theory of decrementless conduction in the narcotised region of nerve, in which, as is well known, he is opposed to the findings of Keith Lucas and Adrian. The problem was the subject of a lively debate, and is probably now near to solution. Muscle physiology was represented by Embden, by Hill, and by Meyerhof.

Another point of great interest was the question with regard to tissue metabolism, mainly represented by Dale's school, in relation to insulin and to such problems as the development of rigor.

In the realm of the central nervous system, an interesting communication was made by Samojloff (Kasan) upon the nature of spinal inhibition. His experiments tend to support the theory of a liberation of some chemical substance affecting the synopses or the cellular structures in the spinal cord. Magnus (Utrecht) made a further contribution to the subject of local and segmental reflexes in the decerebrated animal.

Metabolism was represented by Lusk and Benedict, Boothby, Knoop, Mendel, Noyons, and de Barenne. A noteworthy tendency lay in the simplification of technique, and the applicability of the new methods to clinical practice. A summary was given by Mann (Rochester, Minn.) of his work on the dehepatised animal. Interest in the question of vitamins seems recently to have diminished, very few communications being made.

The study of digestion has now definitely shifted out of the hands of Pavlov's school to America, from whence the pupils of Carlsson, and particularly Ivy, brought communications dealing with the phases of gastric and pancreatic secretion.

Circulation was represented from America by Wiggers (Cleveland), who discussed the fractionate nature of ventricular contraction. The British school was represented by Anrep, who gave papers upon the central and reflex regulation of the coronary circulation (mainly in regard to the innervation of the coronary blood vessels), and upon the electrical measurement of coronary circulation during the single cardiac cycle. Heymans (Ghent) communicated the results obtained with his method of cerebral perfusion as applied to the study of the respiratory and cardio-inhibitory centres. Frédéricq (Liège) summarised the results of his recent work upon chronaxie, especially in relation to the influence of the vagus and sympathetic cardiac nerves.

Prof. Loewi (Graz), in one of the most interesting papers of the congress, gave an account of the various factors affecting the rate of destruction of the chemical substance determining the inhibitory action of the vagus upon the heart. The work of this school would seem to bring us one step nearer to comprehension of the ultimate mechanism of peripheral inhibition.

An important contribution to the problem of hæmophilia was made by Howell (Baltimore), who brings evidence that the determining factor in this condition lies in an unusual stability of the blood platelets. In a second communication, Howell discussed the chemical nature of the anti-coagulant

substance heparin, which is so largely and successfully replacing hirudin in the experimental laboratories of the United States and Great Britain.

With regard to the chemistry of blood, Nicloux (Strasbourg), although unfortunately unable to be present in person, contributed a new spectroscopic method for the determination of small quantities of carbon monoxide in gas mixtures, applying his method to the determination of minimal quantities of it in blood. In a further paper this author presented a new determination of the oxygen content of methæmoglobin, fixing it at half the oxygen content of oxyhæmoglobin of the same blood.

In the present congress demonstrations played what might perhaps be called a secondary part. Many, such as those of Adrian, Kato, and Hill, were in demonstration of communications. Especially interesting in this group was a demonstration by Brinkman (Groningen) of his method of registering the attainment of pH equilibrium in H_2CO_3-bicarbonate buffer solutions. Barcroft gave a summary of his recent work on the spleen, supplemented by a demonstration. This seems, at last, to find some definite and important physiological function for an organ which has baffled physiological thought for centuries. Lim (Peking) gave a demonstration of a dog with transplanted stomach. Of especial interest also was a demonstration by Y. Henderson (New Haven) of his method of measuring the circulation by inhalation of ethyl iodide This seems to be the simplest and most tangible method up to the present, and most probably will find a great future application.

America, as in eleven successive congresses previously, sent a strong contingent of workers, and as was only as fair as it was unanimous, the twelfth congress accepted the invitation of the American Physiological Society that the thirteenth congress be held in America in 1929.

It is, perhaps, of especial interest to mention also the good attendance from Russia, showing that the worst period in that country is approaching an end. Dr. Orbeli (Leningrad), who was present, did not, unfortunately, submit any summary of the results of his experiments upon the sympathetic innervation of voluntary muscle, a problem on which we know him to have been engaged for several years. Prof. I. P. Pavlov, the *doyen* of the congress, showed no sign of diminished activity in spite of his advancing years. There were no communications from his laboratory, although he informs us that a full description of his work on the cerebral cortex is being published in English towards the end of the present year.

The thanks and appreciation of all the members of the congress to their colleagues and hosts in Sweden was expressed by Profs. Gley, von Frey, and Starling at the final meeting of the congress at Upsala, and also previously and more lightly by the same representative speakers at the banquet given to the members of the congress by the City of Stockholm.

The Geological Search for Oil.

ONCE more the ubiquitous problem of the origin of petroleum is forced on our attention, this time as a practical matter rather than as a philosophical thesis. Dr. Murray Stuart writes a paper in the recent issue of the *Journal of the Institution of Petroleum Technologists* in which 'working hypotheses' in the geologist's search for oil form the main theme, the principal argument being that all exploration for petroleum is handicapped at the outset by the fact that little, if anything, is known concerning its origin. We appreciate the laws governing migration and accumulation of oil; we contemplate favourable geologic structures, providing the strata involved are oil-bearing, which are located with remarkable precision; but unless the oil manifests itself by seepage or in some indirect manner, there is little to guide the search. To this extent, it may be noted, the geology of petroleum differs from the geology of, for example, metalliferous ore deposits.

One of the earliest and best known working hypotheses in oil-geology is that attributable to David White, whereby the degree of progressive devolatilisation (or metamorphism) of coal is interpreted as a measure of the chances of obtaining oil or gas in commercial quantity in associated deposits, the percentage of fixed carbon (pure coal basis) being the determining factor. White's law has found ample vindication in the West Virginia oil-fields, but it is not of universal application, as pointed out by Wade in a recent paper on "The Search for Oil in Australia"; the author, however, seeks to amend the law to the extent of excluding the idea of subsequent 'metamorphism' in favour of carbon ratio variation being interpretable in terms of normal processes of sedimentary deposition. He visualises his carbonaceous material as part of a sheet of sediment in which transition from conglomerate ". . . through sand and shale to oil-bearing shale, . . . through something equivalent to Torbanite into more or less pure carbonaceous material . . ." is perceptible; carbon ratio variations are thus functions of original influences (mother substance, environment, etc.), not of subsequent change in the course of geologic time. From this point of view is deduced the hypothesis that, assuming the carbon ratio of a fresh-water or estuarine coal seam to be favourable (*i.e.* 50 to 55), the seam will probably pass through torbanite into oil shale when traced in the direction from which the material composing the seam was initially derived. In the case of coals deposited under marine conditions, lateral variation into petroleum or into oil-shale (depending on the nature of the organic material incorporated in the sediment) is probable. A further hypothesis states that ". . . when formations containing abundant fossil-wood occur the underlying marine formations may contain liquid petroleum," and has been reasoned by the author in previously published papers.

The occurrence of oil in dolomitised limestones of lagoon formation furnishes the author with a contrasted, though in some respects parallel, line of argument; he examines this environment from a biochemical point of view, directing attention to the rôle of foraminifera and other protozoa, and also bacteria, in promoting essential mother-substance, whence he formulates the hypothesis that "all dolomitised limestones of lagoon formation are worthy of thorough investigation, provided that they prove, on microscopic examination, to be foraminiferal."

What we may term the 'coal-to-conglomerate' hypothesis of the author raises problems at least as controversial as those of the origin of petroleum itself, though there is considerable novelty, if not practical import, in the views he puts forward. For the "many examples known in the world of coal seams and lignite seams passing laterally into either oil-shales or oil deposits" there are as many in which no coal-oil association is apparent. The tracing of a coal seam into an oil-shale seam in existing economic circumstances would be little reward to the geologist

bent on locating commercial oil-pools; but the chances of lateral variation from coal to petroleum would seem, according to the author's reasoning, to be somewhat localised. On the other hand, where coal, lignite, or torbanite is in evidence in deposits suspected or proved to contain oil, the hypothesis clearly merits the test: only by this method and in several different cases will its validity, hence its practical value, be established.

University and Educational Intelligence.

CAMBRIDGE.—The John Winbolt Prize has been awarded to H. Bateman, Trinity College, and R. J. Smith, St. John's College, for a joint dissertation on a theoretical investigation of some elastic problems in thin rectangular plates.

EDINBURGH.—In the Royal Botanic Garden, on Tuesday, September 21, the Right Hon. Sir Herbert Maxwell unveiled a tablet to the memory of the late Sir Isaac Bayley Balfour, who was Regius Keeper of the Garden from 1888 until 1922.

THE Wigan and District Mining and Technical College sends us a Calendar giving, in 142 pages, particulars of courses, some of them leading up to the final degree examinations of the University of London, in mining, mechanical and electrical engineering, chemistry, physics, mathematics, building trades, cotton technology, commerce, art, and art crafts. In 1925 six students obtained University of London degrees. Among other specialities is a two-years' Post Office engineering course.

THE London School of Economics and Political Science announces in its summary programme for 1926–27 a series of important public lectures by eminent authorities, open to the public without fee or ticket These include, in addition to single lectures by Profs. Laski and de Paula and Mr. William Cash, a series of three by Prof. Toynbee on international history since the War, six by Prof. Salvemini on Italian communes in the thirteenth century, ten on office machinery, and twelve on accounting in public offices.

THE Battersea Polytechnic's prospectuses for 1926–27 offer full day and evening courses in preparation for the University of London's intermediate and final degree examinations in science, engineering, and music. In consultation with the Incorporated National Association of British and Irish Millers, the London Flour Millers' Association, and the Board of Education, a two-year day course in science and engineering with special reference to the flour milling industry has been organised. Courses for health visitors and sanitary inspectors and in arts and crafts are provided. A separate prospectus deals with the Polytechnic's Domestic Science Training College. Another of London's Technical Colleges from which we have lately received a prospectus is the Cordwainers'. This provides both day and evening courses in the technology of boot and shoe manufacture and leather goods manufacture.

THE East London College announces in its calendar for 1926–27 the institution of a fund for the encouragement of original investigation by the staff and students, and an important addition to its resources for such purposes in the form of a bequest by the late Sir Sidney Lee of 5000*l*. for bursaries for post-graduation work in English literature. Three research studentships of the value of 50*l*. each for one year are awardable annually in July to students completing a three-years' course at the College. Special and advanced lectures announced include: a course of six on short electric waves in wireless, by J. H. Morrell, and six (for graduates) on biology of fresh-water algæ, by Prof. Fritch and Dr. Carter. In its recently constituted department of dramatic study and research there will be a weekly seminar for collective work on a dictionary of British drama. In aeronautical engineering a three-years' course is arranged, and students attending the last two years of this are able to take aeronautics instead of hydraulics in the new subject, 'Mechanics of Fluids,' in the B.Sc. (Engineering) degree examination. The College Council has recently purchased the freehold of a house in South Woodford for use as a hall of residence for men students. One for women students on the borders of Epping Forest with accommodation for thirty-two has already been opened.

THE Northern Polytechnic, Holloway (formerly Northern Polytechnic Institute), gives, in its prospectus for 1926–27, particulars of its important Department of Chemistry and Rubber Technology. It is the only institution listed under the heading of rubber technology in the Universities Bureau's summary of specialist studies in the universities and university colleges of Great Britain and Ireland. The courses are carried on in collaboration with the Institution of the Rubber Industry and provide suitable preparation for students proposing to enter for the examinations for the associate diplomas (A.I.R.I.) awarded by that body. An influential committee, representative of all sections of the industry, co-operates with the governors, and the workshops contain a full range of modern experimental rubber-plant. In addition to the advanced courses there is a Rubber Trades School, for boys of 14 or 15 years of age. The technical chemistry three-years' courses are designed for prospective analytical and works chemists. They include chemical technology, glass-working, chemical engineering, and (a two-years' course) plumbing. A series of important special public lectures have been arranged for the coming session, beginning with one by Raymond Unwin on October 14 on town planning.

THE Municipal College of Technology, Manchester, has resumed publication of its *Journal*. Volume 12, just issued, records investigations undertaken by members of the College between 1919 and 1924. It contains original articles on: losses in resistance connectors in single-phase commutating motors (Miles Walker), the discharging capacity of side weirs (G. S. Coleman and Dempster Smith), the aromatic character of the glyoxaline nucleus (F. L. Pyman), ferrous materials and corrosion (E. L. Rhead), values of the smallest zeros of harmonic functions (J. Prescott and H. V. Lowry), a null method for ionisation potentials (L. S. Palmer and W. Hubball), and a direct-reading refractometer (A. Adamson). The prospectus of the College for 1926–27 shows that since 1919–20 from ten to thirteen research scholarships have been awarded by it each year. The scholarships are open to graduates of any university in the British Empire and other persons possessing special qualifications for research. In awarding three of them, preference is given to Manchester ratepayers and their sons and daughters. Courses of advanced study and research are offered in mechanical, electrical, municipal, and sanitary engineering (including sea outfall and coast defence works), applied chemistry (including textile fibres, paper manufacture, metallurgy, rubber, brewing and allied industries, coal tar and dyestuffs, photography and photographic processes), textile industries, applied physics, and mining engineering.

Contemporary Birthdays.

October 5, 1861. Sir Thomas L. Heath, K.C.B., K.C.V.O., F.R.S.
October 7, 1842. Sir Philip Magnus, Bart.
October 8, 1850. Prof. Henry Louis le Chatelier, For. Mem. R.S.
October 8, 1857. Sir Richard C. Garton, G.B.E.
October 9, 1879. Prof Max T. F. von Laue.
October 9, 1863 Prof. Albert Charles Seward, F.R.S.

Sir THOMAS HEATH, who was born in Lincolnshire, was educated at Caister Grammar School and Clifton College, passing thence to Trinity College, Cambridge, where he graduated 12th wrangler, whilst also acquiring distinction in classical studies. Entering the public service, he was early attached to H.M. Treasury, fulfilling successively the highest offices. Since 1919 he has been Comptroller-General, National Debt Office. Among many dissertations and works, he is the author of "A History of Greek Mathematics" (2 vols., 1921). Sir Thomas is an honorary fellow of Trinity College, Cambridge, and Hon. D.Sc. Oxford.

Sir PHILIP MAGNUS, to whom very hearty congratulations are due on the approaching anniversary of his eighty-fourth birthday, was educated at University College School, graduating thence at the University of London. Organising director and secretary of the City and Guilds of London Institute from 1880 until 1888, he was afterwards and for nearly thirty years the able and zealous secretary of its Technology Department.

Prof. LE CHATELIER's name is associated with important discoveries in several branches of chemistry. In conjunction with Mallard he conducted elaborate investigations on the ignition and explosion of gaseous mixtures, in which principles of fundamental importance were established. His thermo-electric couple inaugurated a new period in the measurement of high temperatures. One of the pioneers of micro-metallurgy, he was among the first to introduce exact methods into the science of industrial silicates. Prof. le Chatelier was elected a foreign member of the Royal Society in 1913, and allotted the distinction of its Davy medal in 1916, in respect of his eminence as a chemist.

Sir RICHARD GARTON was educated at Owens College, Manchester, and the University of Marburg. As honorary secretary of the British Empire Cancer Campaign he has carried out work of widespread importance.

Prof. MAX VON LAUE, Nobel laureate, 1915, was born at Pfaffendorf, near Coblentz. His studies were conducted at the Universities of Strasbourg, Munich and Berlin. In 1912 he occupied a chair in the University of Zurich, and was afterwards at Frankfort. Since 1919 he has been professor of theoretical physics in the University of Berlin. Prof. Max von Laue was allotted the Nobel prize in physics for 1915, for his discovery of the diffraction of Rontgen rays in crystals.

Prof. SEWARD, Master of Downing College, Cambridge, professor of botany in and vice-chancellor of the University, was educated at Lancaster Grammar School and St. John's College, Cambridge. The Royal Society awarded Prof. Seward a Royal Medal last year for his fruitful studies in palæobotany, which have proved of direct stratigraphical value to geologists, enabling the principles and facts of one science to aid, and even solve, the problems of another.

Societies and Academies.

PARIS.

Academy of Sciences, August 30.—Bigourdan: The regularity of the diurnal movement and the possibility of verifying it by means of observatory clocks (see also NATURE, September 18, p. 425).—Boris **Delaunay**: The theory of parallelohedra.—G. **Polya**: The linear functional operations exchangeable with the derivation and the zeros of the sums of exponentials.—Mlle. N. **Bary**: The analytical representation of a class of continuous functions.—A. **Kovanko**: The integration of suites of functions capable of summation.—Kyrille **Popoff**: The convergence of series and celestial mechanics.—**Krawtchouk**: The method of N. Kriloff for the approximate integration of the equations of mathematical physics.—N. **Bogoliouboff** and N. **Kriloff**: The justification of Rayleigh's principle by the order of the error committed at the nth approximation.—Jacques **Bourcart**: An attempt at the morphological interpretation of the Bouches de Cattaro.—Lucien **Daniel**: Researches on the grafting of garlic and cabbage.—Antonin **Němec**: Chemical methods for determining if agricultural soils are in need of nitrogenous or potash manures. Details of the analytical methods and limits of nitrate and potash suitable for sugar beet, barley, and oats.—Raymond **Hamet**: The inversion of the normal action of adrenaline.—E. **Ducloux** and Mlle. G. **Cordier**: The virus of sheep scab treated with various aldehydes.

CAPE TOWN.

Royal Society of South Africa, August 18.—L. P. **Bosman**: The nature of the co-enzyme of lipase. The lipase extract (from sheep's pancreas) is dialysed against distilled water and the lipolytic actions of the dialysate and the 'inside' liquid on ethyl butyrate are studied. The inside liquid loses approximately 50 per cent. of its hydrolytic power. The dialysate, while having no hydrolytic power, when coupled with the inside liquid, restores the lipolytic power of the original extract. The dialysate was investigated and the so-called co-enzyme was found to be inorganic salts.—W. **Rose** and J. **Hewitt**: Description of a new species of Xenopus from the Cape Flats. The new species, *Xenopus gilli*, differs from *X. laevis* in that tentacles are not apparent and that there is in the mouth an organ which is either a posteriorly attached tongue or a deflated air-sac.—J. H. **Power**: Notes on the habits and life histories of South African Anura with descriptions of the tadpoles.—C. von **Bonde**: The vascular system of the Plagiostomi, with special reference to the common dogfish (*Squalus acutipinnis*, Regan). The author has previously worked out the morphology of the vascular system of the South African dogfish *S. acutipinnis* and it is now compared with the structure typical of the Plagiostomi in general. The absence of vascular loops round the gill-arches together with the absence of a precardiac extension of the dorsal aorta presents an interesting feature. The arterial circulation of the cephalic region also shows a distinctive difference from the normal distribution of the carotid arteries in the Plagiostomi.—Neville S. **Pillans**: The African genera and species of Restionaceae.—H. G. **Fourcade**: A new method of aerial surveying.

ROME.

Royal National Academy of the Lincei: Communications received during the holidays.—T. **Levi-Civita**: Einsteinian motions in second approximation.—Ferruccio **Zambonini** and S. **Restaino**: Double sulphates of the rare earth and alkali metals (vi.). Cerous

potassium sulphates. In addition to the double salts already described, this system forms the compound, $Ce_2(SO_4)_3$, 4·5 K_2SO_4, which is stable in the presence of solutions containing from about 5 per cent. to 1·2 per cent. of potassium sulphate.—G. **Bruni** and A. **Ferrari**: Crystalline structure of certain bivalent chlorides. Anhydrous magnesium, manganous and cadmium chlorides are found to be of rhombohedric structure with the respective axial ratios, 2·45, 2·34, and 2·20. Zinc chloride appears to exhibit a rhombohedric or hexagonal structure, the dimensions of its structure indicating its structural similarity to magnesium chloride.—Silvio **Minetti**: Investigation of the singularity of $f(z)=\sum_{n=0}^{n=\infty} a_n z^n$, where $a_n=g(n)$ for n a positive integer with $g(n)$ wholly transcendental.—Mauro **Picone**: The isolated singularity of harmonic functions in two or more variables.—Oscar **Zariski**: Conformable representation of the area bounded by a lemniscate on a circle.—Luigi **Fantappié**: The polydromy of linear analytic functionals.—A. M. **Bedarida**: A new rectilinear congruency.—Harry **Levy**: Einsteinian motions of a disgregate medium with spherical symmetry.—Arnaldo **Belluigi**: Evaluation of the damping in seismographic pendulums.—Rita **Brunetti**: Theory of the polarisation of independent X-rays.—G. **Natta** and A. **Reina**: Oxides and hydroxides of cobalt: Crystalline structure of cobaltous oxide and hydroxide. The results of X-ray analysis show that cobaltous oxide belongs crystallographically to the monometric system and has an elementary cell of side a 4·22 Å.U. of the sodium chloride type, containing four molecules. The precipitated and crystalline forms of cobaltous hydroxides are structurally identical and are of the uniaxial rhombohedric type.—Raoul **Poggi** and Angiolo **Polverini**: Destruction of filter-paper by alternate oxidising agents applied to quantitative analysis.—Adolfo **Quilico**: Röntgenographic investigation of metallic hydrides: copper hydrides. The so-called hydrides obtained by reducing cupric oxide by means of hydrogen prove to be either pure copper or copper containing occluded hydrogen in proportion insufficient to modify appreciably the crystal lattice. The products formed in the reaction between hypophosphorous acid and copper sulphate vary with the temperature employed and consist either of amorphous copper containing occluded hydrogen or of a mixture of this with cuprous oxide.—C. **Sandonnini**: Heats of mixing of water with acetic acid and with isopropyl alcohol.—Emanuale **Quercigh**: The nature of stibiobismuthinite. This mineral, found in Nacozari, Mexico, consists of an isomorphous mixture of bismuthinite and antimonite, with or without inclusions of sulphur.—C. **Acqua**: The virus of the polyhedry of the silkworm in relation to modern theories on the filterable virus.

of historical materialism pure and simple. Here again we have a restatement of a point of view so much repeated and debated that it has grown stale for the sociologist. Yet the author, judging from his quotations, is unaware of the existence of Marx, Loria, H. Cunow, and of such of their opponents as Benedetto Croce, Schmoller, and others.

Against the charges of social Darwinism and extreme Marxism the author might shelter himself behind a number of chapters in which he extols altruism and righteousness, parental love and filial piety, the obedience to law and general good temper. Mr. Machin does not even forget the amenities of life, sports and amusements, music-halls and moving pictures, which all form the virtues of the evolutionary metaphysician. Only to religion does he remain decidedly unfriendly and unfair. "The office of civil government, and more particularly of religion, is then essentially negative. . . . Progress, the advancement of individual and national prosperity is not due to religion" (p. 246). Many similar unfriendly sentiments might be adduced from Mr. Machin's chapter on law and religion.

These many virtues and ethical commandments of evolutionism—such as military truculence, Rotarian graspingness, parental love, righteousness, and love of amusement—are, however, not welded into any consistent scheme. At best it is made plausible that they are not inconsistent with the loosely conceived Darwinism. This might be considered satisfactory if we agreed with the author to regard Darwinism as a form of religion. Regarded as a mere scientific method or system of thought, Darwinism, or the theory of natural selection, cannot yield such a multitude of virtues.

Here we come to the really important question concerning the book. Apart from its metaphysical claims —with which it is quite impossible to come to any understanding—the book has a serious and methodologically interesting aim. One of its purposes is to apply the principle of natural selection to the development of culture and to illuminate several aspects of human civilisation in this manner.

To the average sociologist the promise of applying Darwinism to the study of culture sounds as would to the physicist another device for circumventing the first law of thermodynamics by a new plan for establishing perpetual motion. Natural selection, in the sense in which it is used by biologists, does not act on individuals of the human species, because culture stands between man and the selective action of Nature. In the very process of procreation man shows a radical difference as compared with the animal, in that he can and does control fertility and is able to protect the offspring beyond any limits which animals can reach. Mr. Machin, in fact, has seen this point and treated it more fully and intelligently in several of his chapters than most sociologists and anthropologists have done. Beyond parental care, 'mutual aid' is, as Kropotkin has shown, the rule in humanity rather than the 'struggle for existence.' The human individual, again, does not merely rely on anatomical endowment—he has the whole of material culture at his disposal. He is not adapted to his environment merely by his physiological processes and instincts—he has developed knowledge, belief, and tradition. In brief, the animal under conditions of Nature, and man under conditions of culture, show different forms of mating, of co-operation, of practical dealing with environment, in short, of adaptation. Cultural process is not identical with natural evolution, and biological principles cannot be directly applied to the study of man. This is the reason why even such brilliant attempts as those of Bagehot, of Gumplowicz, or of Enrico Ferri have not led very far, and anthropology from Bastian and Tylor up to Frazer and Westermarck has not attempted to apply natural selection to the comparative study of human society. There is, in fact, a considerable methodological literature on the subject of the delimitation between natural and cultural science to mention only such names as Dilthey, Paul Barth, H. Rickert—and the new attack of the so-called historical school against anthropological evolutionism has justifiably pointed out the dangers of borrowing a method, a terminology, and a conceptual apparatus by one science from another.

Of all this Mr. Machin is apparently unaware. His anthropological quotations do not reach very far beyond Herbert Spencer, who is decidedly not sufficient as a source book and intellectual arsenal of anthropology and sociology. Of this it is impossible to make a valid charge against the present book, for Mr. Machin frankly calls himself a layman in the preface and admits that "this essay is based, in the main, on the works of the two giants of evolution theory Darwin and Spencer." Nor is it possible to contradict him on this point, for the present book contains no original research, no addition to method, and no really new principles. Perhaps the one exception to this is the discussion of the difference between the regulation of animal and human fertility in the second section of the book. This discussion, however, has no direct bearing on the main anthropological part of his contribution.

There is one aspect, however, under which this book is of considerable importance in spite of its serious shortcomings; and that is the reason why it has been necessary to criticise it more fully instead of damning it with faint praise. Although any attempt to apply

the principle of natural selection to the evolution of human culture must, in the opinion of the reviewer, prove unsuccessful, such an attempt raises once more the capital problem of anthropology. Mr. Machin's book reminds us again that man has evolved from lower animal species and that this cannot be denied by any one except the crazy fundamentalist. Human culture again, has evolved from the state of Nature, from a zero level, so to speak. Both these facts bring up the problem: What is the action of natural conditions upon man? What is the difference between human relations to the environment and animal adjustment, what is the difference, in short, between evolution in biology and evolution in culture? The anthropologist of to-day is satisfied with pointing out, negatively, that the cultural process differs from the biological one. This is sufficient reason not to mix them up, but it is not a sufficient reason not to compare them. Only comparison can bring out the essential similarities as well as the differences in either process. Most modern anthropologists of the so-called historical school have been busy pooh-poohing the concept of human evolution and the study of the origins of institutions and the causes of progress.

All these questions are constantly raised by the argument of the book reviewed. Some of the arguments may have to be rejected, but they will have to be replaced, for Mr. Machin has the great gift of seeing the problem and formulating it clearly--a gift of more value in science than the facility to solve irrelevant and imaginary questions. The author is handicapped by his out-of-date reading, by his adhesion to his authorities, and by a lack of first-hand acquaintance with his material. But in honesty of thought, lucidity of exposition, and clarity of style the book is often excellent, and through these virtues it is especially fitted to suggest the real problems to the anthropologist. It is a work which no student of man should omit to read. Science does not thrive by mere avoidance of errors, but by resolute grappling with real problems. From this point of view Mr. Machin's book is a more valuable contribution to anthropology than many modern works which startle us with revelations about the 'diffusion' of culture from Egypt, Atlantis, Yucatan, or some other Garden of Eden. Anthropology will become a useful science only after it has realised once more that the problems of evolution of culture cannot be shirked any more than the problems of evolution of species. If Mr. Machin's book helps in combating anthropological fundamentalism—the bitter opposition to evolutionary thought within the science of man—it will have fulfilled its mission, even though we must reject it as the "new Gospel."

B. MALINOWSKI.

Aids for the Spectroscopist.

(1) *Tabelle der Hauptlinien der Linienspektra aller Elemente nach Wellenlänge geordnet.* Von Prof. H. Kayser. Pp. vii + 198. (Berlin: Julius Springer, 1926.) 24 gold marks.

(2) *Atlas de spectres d'arc: tableaux d'analyse pour les recherches spectrochimiques.* Par Dr. Jacques Bardet. Pp. 55 + 54 planches. (Paris: Gaston Doin et Cie, 1926.) 240 francs.

ONE of the outstanding features of recent progress in experimental physics is the remarkable development of research in spectroscopy. This is largely due to the efforts of theoretical workers who, although the precise physical meaning of their assumptions cannot always be assigned, have nevertheless achieved amazing success in constructing semi-empirical rules for the analysis of spectra. The generality and extremely suggestive character of these rules have inspired fresh investigations of the spectra of the majority of the elements, with the result, among others, that lists of spectrum lines which were once regarded as complete are being augmented to a surprising extent and at an unprecedented rate.

Such an accumulation of data, provided they be accurate, is an unqualified blessing, but its attainment is not unattended by considerable danger. Rapidity of progress does not always allow the application of the rigid and impartial criticism of every detail of the experiment which alone can ensure freedom from error. If, for example, a group of, say, seven lines is predicted in a spectrum, and the experimenter who has already obtained six of them ultimately finds the seventh, and weakest, on a well-exposed plate, the new line runs some risk of missing the stringent test for impurities which is its due. On the other hand, if an unexpected line, or one of uncertain behaviour, appears in a spectrum, it may be rejected as a possible impurity on the 'safety first' principle (a principle, by the way, which in practice often means 'safety only'), and the existence of an important line thereby lost sight of. We have known of recent examples of these and other sacrifices to the ideal of early publication which, in the long run, delay rather than advance progress.

(1) In order to minimise such dangers as these, Prof. Kayser, to whom spectroscopy already owes so much, has placed the scientific world under yet another debt of gratitude by the preparation of the first of the books before us. The table of 'Hauptlinien' at the end of volume 6 of his monumental 'Handbuch der Spektroscopie" (1913) has long been familiar to every spectroscopist, and in the new volume he has adopted the same general method of presentation as was employed therein. The progress of the last thirteen

years, however, has made some changes of detail necessary. The wave-lengths are now given only in international angstroms, Rowland's scale having become obsolescent. The values recorded are the weighted means of all the observations available, and are given only to such a degree of accuracy as the compiler considers trustworthy. The limits of wave-length included have been extended at both ends of the scale, and the table includes fainter lines than the earlier list, so that the total number of lines (now about 19,000) is almost doubled. In the Schumann region, owing to the fact that, of necessity, only the stronger lines are at present observable, all the recorded lines are included. Another modification of the original table is the indication of the degree of ionisation (where it is known) of the element to which a line belongs. Thus, λ 5889·965 is no longer recorded as Na, but as NaI. About 15 per cent. of the stronger lines can at present be so classified.

It is needless to point out the value of such a book as this, or to comment on the excellent manner of its production. It is obviously indispensable to every experimental spectroscopist.

(2) The atlas of M. Bardet is designed to encourage and facilitate the use of spectrum analysis by chemists. It comprises 48 principal plates and a few supplementary ones intended to illustrate special features of the process. Each plate of the main set shows the prismatic spectrum of iron as seen in the microscope, with an adjacent scale of angstroms. Above this spectrum vertical lines are drawn at the positions occupied by the lines of the various elements (the chemical symbol, approximate wave-length and intensity being placed against each line for identification), and it is intended that the experimenter, having photographed the spectrum of the material to be examined in contact with that of iron, shall compare his negative with the atlas and so identify the unknown lines. The 48 plates are divided into six series, in each of which the iron spectrum over the range λ 3500-λ 2500 is shown in 8 plates. In the first series the adjacent lines include all the lines of the elements with fairly simple spectra, and the most characteristic lines of the remaining elements, as they appear in the spectrum of the arc. The remaining series show, in greater completeness, the positions of the lines of the more complicated spectra, each series being devoted to a particular group of elements. In this way overcrowding of lines is satisfactorily avoided.

The iron spectra, though originally drawn by hand, are faithfully copied, and simulate the appearance of photographs remarkably well. The wave-lengths are taken from the tables of Exner and Haschek, and are given in terms of Rowland's scale. The method of using the atlas (in which full use is made of the *raies ultimes* of de Gramont), together with instructions relating to the whole process of spectrum analysis, is given in detail in an accompanying brochure, which contains also a preface by M. Urbain in which the neglect of spectrum analysis by chemists is discussed and deplored.

Both in design and in execution the work is excellent, and the accompanying notes testify to the wide experience of the author in this branch of study. The production should prove of great value not only to chemists but also to all who have occasion to use spectrum analysis. The author is to be congratulated on meeting an obvious need so effectively, and it may be confidently predicted that his work will be widely used. When, however, M. Urbain, in the preface, claims that M. Bardet " est probablement le seul homme au monde qui, d'un rapide coup d'œil jeté sur un spectre, puisse énumérer immédiatement les principaux corps qui l'ont produit," he is presumably thinking only of chemists. There are spectroscopists of much longer experience than M. Bardet who acquired this faculty many years ago. H. D.

Rubber: Natural or Synthetic?

Synthetic Rubber. By Dr. S. P. Schotz. Pp. 144. (London: Ernest Benn, Ltd., 1926.) 21s. net.

THE meaning of the title of this book, although sufficiently clear to satisfy the general public, is, from a scientific point of view, entirely unsatisfactory. The author evidently feels this when in the first few lines he writes:

"Even samples of natural rubber probably differ widely in details of constitution. To attempt to reproduce a synthetic rubber of exactly the same constitution as a specific natural rubber would be difficult and futile. Fortunately it is possible by synthetic means to obtain substances which are constituted similarly to natural caoutchouc as far as the linking of the various hydrocarbon groupings is concerned, having similar physical properties and offering the same resistance to chemical reagents and mechanical influences. The whole development of this coming industry is tending in that direction."

It is therefore clear that the word 'rubber' is applied to a number of substances or, rather, mixtures of substances which possess certain physical properties in common which are more or less standardised.

Natural vegetable products are rarely found in a chemically pure state: if the substance is a solid of relatively low molecular weight, it is usually capable of being obtained in a state of purity by some method of crystallisation. If the vegetable product is a liquid, it can frequently, but not always, be purified by

fractional distillation either under ordinary conditions or under reduced pressure. When the substance is a colloid of high and unknown molecular weight, the above-mentioned methods of purification are not available. It is true that, in the case of most natural caoutchoucs, the greater part, if not all, of the comparatively small amount of 'impurities' it contains can be removed by selective solvents, leaving a residue of presumably pure matter which on analysis gives figures corresponding to the general formula $(C_5H_8)_n$. On subjecting this matter, or the unpurified caoutchouc, to destructive distillation, various hydrocarbons are produced mostly possessing the same percentage composition, but of lower molecular weights than the original substance, and amongst them the key substance to the synthesis of caoutchouc is found. This is the simple hydrocarbon, isoprene, C_5H_8, boiling at about 33°-34° C.

Isoprene was first obtained by Himly in the year 1835 by the destructive distillation of rubber, and was later examined by a number of chemists, but its structure was first determined by Sir William Tilden as being β-methyl butadiene:

$$\begin{array}{c}CH_2=\underset{\displaystyle CH_3}{\underset{|}{C}}-\underset{\displaystyle H}{\underset{|}{C}}=CH_2\end{array}$$

Tilden obtained isoprene by the destructive distillation of both caoutchouc and turpentine, and satisfied himself that the light hydrocarbons obtained from both sources were identical. He further found that, on keeping for a short time, the very mobile isoprene became viscid and, after a period of some years, produced a white solid which had most of the properties of india-rubber. He also examined the catalytic action of a large number of substances on isoprene and came to the conclusion that isoprene was the parent substance of caoutchouc. Other chemists afterwards worked upon the production of isoprene, but almost entirely from a scientific point of view, and the possibility of a commercial synthesis of rubber was not seriously considered until about 1910, when the shortage of rubber and its rise in price to about 10*s*. per pound caused a large amount of work to be undertaken to see whether rubber could be produced commercially.

The problem was attacked seriously both in Great Britain and in Germany. Messrs. Strange and Graham organised a group of research workers in the former, and in the latter the like work was undertaken by the Farbenfabriken vorm. F. Beyer and, to a lesser extent, by the Badische Anilin- u. Soda-Fabrik.

At first the work in both countries consisted chiefly in exploring any possible routes by which isoprene could be produced cheaply. The most obvious method, namely, the cracking of turpentine, was soon abandoned, as the yield of isoprene was too small to be remunerative. Of organic compounds containing 5 atoms of carbon, the most promising seemed to be normal pentane, isopentane, and isoamyl alcohol, occurring in fusel oil.

Normal pentane itself is not, theoretically, a good starting-point, as it contains a straight chain of 5 carbon atoms and, unless isomerisation took place during the series of reactions, only an isomer of isoprene could be obtained. The isopentane route was also explored, but was not persevered with owing to the difficulty of obtaining the raw material in sufficient quantity at that time. Isoamyl alcohol was found to be a good raw material, but it could not be obtained either in sufficient amount or at a suitable price.

The English workers then attempted to get increased quantities of isoamyl alcohol by a fermentation process and, with the help of Prof. Fernbach of the Pasteur Institute, a bacterium was isolated which, acting upon starchy material, produced not isoamyl alcohol but normal butyl alcohol and acetone in a yield of nearly 50 per cent. of the starch taken. Meanwhile the German chemists seem to have reached more or less the same conclusion as their English rivals.

It was known by this time that hydrocarbons possessing the conjugated double linking

$$\diagdown C=C-C=C\langle$$

were capable of being polymerised into rubber-like substances. As substances of this type containing 5 carbon atoms were not easily obtainable, the German work concentrated upon members of this group containing 4 and 6 atoms of carbon. The 4-carbon substance, C_4H_6, known as butadiene, divinyl, or erythrene, was obtainable in various ways, but no completely satisfactory raw material was obtainable and the Fernbach bacillus was not available to them. They therefore concentrated chiefly upon the 6-carbon member β-γ-dimethyl butadiene or di-isopropenyl. This substance could be obtained fairly readily from acetone, which was reduced to pinacone, from which di-isopropenyl was obtained without difficulty.

The English group, now having plentiful supplies of *n*-butyl alcohol, worked almost exclusively upon the best method of converting this substance into butadiene, which was by now known to polymerise into a substance having similar properties to the polymer produced from isoprene. The raw materials and methods of producing the hydrocarbons C_4H_6 and C_6H_{10} having been provisionally settled, work now concentrated upon methods of polymerising these into rubber-like substances. Here both groups, almost simultaneously, hit upon the same method, namely, by means of metallic sodium,

but the English group, owing to a priority of a few days in the date of the patent specification, succeeded in upholding their patent rights both in Great Britain and in Germany.

It appeared afterwards from the work of Harries on the ozonides of rubbers that so-called sodium rubbers were not identical with the rubbers obtained by simple heat polymerisation. They had, however, remarkably good properties as regards elasticity, etc., and Harries in a paper in the *Annalen* looked upon sodium butadiene rubber as being the best synthetic rubber produced. These rubbers were capable of being vulcanised like natural rubber, which improved their properties considerably, but the 6-carbon rubber, although made on a considerable scale in Germany during the War, did not possess the elasticity of its lower C_4 homologue and was very prone to undergo destruction by oxidation in air. On the other hand, a sample of sodium butadiene rubber recently examined after keeping for a period of thirteen to fourteen years was found to possess its original properties practically unimpaired.

The important question arises: Will synthetic rubber ever supplant the natural substance? This in the opinion of the writer of the present article is entirely a matter of price. Rubber can be produced on well-managed estates at about 8*d.* per pound. At the present artificial price of 1*s.* 8*d.* per pound synthetic rubber is bound to come shortly, and the probable source will be American petroleum.

Reverting to Dr. Schotz's book: it gives a clear and not too technical account of the art of making synthetic rubber as known to-day. It is fairly free from mistakes, but some have been noticed. On p. 58 bauxite is classed as a hydrated iron compound. On p. 64 1 : 3 dimethyl butadiene should be 2 : 3. The book is somewhat marred by the introduction of plates, dealing with machinery for rubber manufacture, which have no connexion with the subject matter. On the whole, a very readable and interesting account is given of a very technical subject.

Our Bookshelf

British Museum (Natural History). Catalogue of the Machæridia (Turrilepas and its Allies) in the Department of Geology. By T. H. Withers. Pp. xv + 99 + 8 plates. (London: British Museum (Natural History), 1926.) 7*s.* 6*d.*

ON account of their sabre- or blade-shaped form, the name Machæridia is proposed for the group of Palæozoic fossils which comprises the genera Lepidocoleus, Turrilepas, Deltacoleus, and Plumulites. These genera are undoubtedly related to one another, but their systematic position has long been a matter of dispute. Although regarded by some authors as Mollusca (Polyplacophora), Cystidea, Annelida, or Trilobita, they have usually been referred to the Cirripedia; and several writers have looked on them as the ancestors of the stalked barnacles of later times. This view, which is based largely on a comparison with the Chalk form Stramentum (Loricula), is shown by Withers to be untenable, since that genus is now known to be an aberrant type representing a specialised side-line of development from the scalpelliform barnacles, and further, none of the Palæozoic genera can be proved to be Cirripedia, the earliest undoubted representative of that group being found in the Rhætic beds.

In the Machæridia the shell apparently covered the whole of the soft parts of the animal; it consists of either two or four columns of plates and could open along the whole of the sharp edge, and the plates along the thick margin show muscle-scars indicating the presence of a series of transverse muscles. The fact that the plates in some genera consist of crystalline calcite and show a reticulate structure suggests relationship with the Echinoderma, while the imbrication of the plates and the character of their ornamentation may indicate a connexion with the Cystidea. In his preface to the volume, Dr. F. A. Bather shows that he is inclined to accept this view of the affinities of the Machæridia, and suggests that the Heterostelea and Machæridia are among the earliest offshoots of the echinoderm stem and differ from all other classes of echinoderms in not having had pentamerism and the other echinoderm features impressed on them during an ancestral period of fixation.

Although bearing the modest title of "Catalogue," this work is really of the nature of a monograph and deals in a thorough manner with all the species known. The eight plates are excellently reproduced in collotype from photographs by H. G. Herring.

The Wonder and the Glory of the Stars. By Dr. George Forbes. Pp. 221 + 16 plates. (London: Ernest Benn, Ltd., 1926.) 8*s.* 6*d.* net.

WE have much enjoyed reading Prof. Forbes's book, which consists largely of a selection of his numerous lectures delivered during the last twenty-two years and of related essays. The title is a true indication of the author's wish to convey something of his own enthusiasm for the wonders of the night sky accessible to all who care to look for them. Prof. Forbes has long been associated with astronomy, and he has watched its widening horizon from the early days of stellar spectroscopy and astronomical photography. A personal touch is conveyed to the reader by occasional reminiscences of men and events, including an account of a night spent by the author in 1871 at the Vatican Observatory with Secchi and his spectroscope, and impressions of meetings of the Royal Astronomical Society in 1926 which enter into the theme of the last chapter entitled "Fairy Tales by Astronomers."

As already indicated, the book lays no claim to being an elementary text-book of astronomy, but comprises a series of self-contained, yet interdependent articles, the popular nature of which is fully indicated by most of the titles—" Surprise Visitors among the

Stars," "Tornadoes in the Sun," "Stars and their Wireless Messages," etc. By this method of treatment, the reader who scans the pages from cover to cover in an evening or two must necessarily encounter some unavoidable repetition of salient facts. On the other hand, a few points of general interest have been omitted. No mention is made, for example, of the *cyclical* change of the shape of the sun's corona. The description of Cepheid variables might well have contained a few sentences concerning their use in the determination of stellar distances. Again, in the chapter on "Greenwich Observatory" a brief reference is due to the instrument which produced the original of Plate VI., as being typical of another branch of routine work carried on for more than fifty years. It may be added that the type is scarcely large enough for a popular work. There are very few misprints, but the index is defective in a few places. The illustrations are a pleasing feature and include several of the most recent astronomical photographs, the reproduction of which is above the average standard for books of this kind.

A Manual of Elementary Zoology. By Dr. L. A. Borradaile. (Oxford Medical Publications.) Fifth edition. Pp. xvi + 670 + 16 plates. (London: Oxford University Press, 1926.) 16*s.* net.

DR. BORRADAILE'S "Manual" is well known to all teachers of zoology, and, to judge from the frequency with which new editions appear, it must also be well appreciated by students. In these circumstances praise is superfluous and interest centres on the changes which the new edition shows. The most important of these are in the accounts of the movement of Amœba and of the relation of individuality to metabolic gradient, while the introductory chapter, the chapter on reproduction and sex, and that on the animal in the world, have been rewritten—and much improved.

A good deal of new matter has crept into the book since its first appearance, with the inevitable result that the medical student meets in it much that does not concern him, while the pure zoologist finds some rather serious omissions and some cases of too extreme condensation. There is no mention, for example, of Helix, Peripatus, or Ciona, and the reviewer's experience of the chapters on evolution and embryology is that they are too compressed to be of great value to the student. No two authors, however, would solve the problem of what to omit in the same way. On the whole, Dr. Borradaile's choice is a wise one; he maintains a balance between morphology and philosophy which makes his book a scholarly treatise, and one that can be unreservedly recommended.

Elements of Photogravure, Photo Printing from Copper Plates: Screen Photogravure simply explained, with full Working Instructions and an Explanatory Chapter on Modern Rotary Gravure Printing. By Colin N. Bennett. (Lockwood's Manuals.) Pp. viii + 129. (London: Crosby Lockwood and Son, 1926.) 5*s.* net.

MR. BENNETT describes in clear and simple language every step of the process of the making of photogravure prints by the screen plate process, leaving the original dust-grain process with little more than a bare mention as out-of-date. He begins with the getting of the necessary apparatus and materials, and estimates the prime cost to one who has the usual photographic necessities at from 10*l.* to 15*l.* This includes a copperplate printing press. The book appears to provide an answer to every question that a photographer, whether amateur or professional, might wish to ask during his first attempts at the process, even as to where the various items may be purchased. In order to render the volume more complete, the final chapter is devoted to the "Elements of Rotary Gravure," and on the last page Mr. Bennett says that he "does not hesitate to name rotary gravure as the best all-round solution of two and three colour photo-printing." Flat plate gravure is not well adapted for the superposition of two or more impressions, because the damping of the paper renders registration difficult on account of its expansion thereby, and because the capacity of the paper to pick up copper plate ink is much diminished after its first pull through the press.

Biology. By O. H. Latter. ("Science for All" Series.) Pp. vii + 197. (London: John Murray, 1926.) 3*s.* 6*d.*

THIS book may be confidently recommended wherever biology is taught as a subject of general education. Mr. Latter's long experience of biological teaching is an assurance that from the wide field of possible topics his choice will be a wise one, and his book is, in fact, a notable success. Its chapters are linked by the principles of the dependence of living things on one another, and their adaptations to their surroundings. Since it is assumed that time will not be available for general practical work, each chapter ends with a suggestion of suitable demonstrations, which need no special equipment beyond a few microscopes. Two features of the book will make it particularly helpful to its readers—its clear diagrams and Mr. Latter's practice of giving the Latin or Greek derivation of all technical words. He thereby removes, as nearly as possible, one of the chief difficulties of a young biologist—that of mastering the terms in which the science is described.

Grundzüge der mathematischen Erdkunde. Von Prof. Dr. Georg Wegemann. (Sammlung Borntraeger, Band 9.) Pp. 184. (Berlin: Gebrüder Borntraeger, 1926.) 6·60 gold marks.

PROF. WEGEMANN'S book is a compendium of astronomical and geodetic knowledge. It is mainly descriptive, with abundant numerical data; formulæ are quoted but not proved. Time measurement, including many systems not prevalent in modern Europe, the form and motions of the earth, astronomical errors of observation, and the nature of the principal perturbations of the moon's motion, are a few of the varied topics treated.

An Introduction to the Calculus. By Clement V. Durell and R. M. Wright. (Cambridge Mathematical Series.) Pp. vii + 91 + xi. (London: G. Bell and Sons, Ltd., 1926.) 2*s.* 6*d.*

THIS is a reprint, with slight modifications, of the section on calculus in Part 2 of the authors' "Elementary Algebra." The course meets the requirements of the School Certificate Examination conducted by the Oxford and Cambridge Joint Board.

Letters to the Editor.

The Kerr Effect in Wireless Transmission.

MR. HOLLINGWORTH'S observations (NATURE, Sept. 18, p. 409) on the polarisation of long wireless waves by day and by night are of great interest in connexion with the attempts which have been made to explain the diurnal variation of atmospheric influences on wireless transmission.

According to the original theory of diurnal variation proposed by Dr. Eccles (*Proc. Roy. Soc.*, A, vol. 87, p. 79, 1912), atmospheric deviation of wireless waves is produced during the day by ionic refraction in a somewhat diffuse layer in the middle atmosphere, while at night true reflection of all wave-lengths takes place from the sharp boundary of the Heaviside layer in the upper atmosphere. According to this theory, the difference between the 'reflection coefficients' of the day and night layers is due to the difference in the degree of variation of ionic content of the under boundaries of the layers.

More recently (NATURE, March 7, 1925; *Electrician*, April 3, 1925) a somewhat different theory has been found useful in linking the mass of evidence relating to geophysical influences on wireless transmission which has accumulated during the last few years. According to this view, the increase of signal strength at night, which is noticeable particularly on the shorter waves, is attributed not to an increase in ionic gradient but to a general lifting of the layer after sunset The reduction in the collisional 'friction' of the electrons in the layer, due to the increased height and lower pressure, makes deviation with reduced absorption possible In this connexion it seems clear that the difference between reflection and refraction is determined by the ratio of the thickness of the transitional layer to the wave-length, and, since a transitional layer of several kilometres is contemplated both by day and by night, we may generalise roughly and say that long wireless waves are deviated by reflection and short waves by refraction. The gradient of conductivity (which is determined not only by the gradient of ionic content, but also by the gradient of τ, the time between two collisions of an electron with the gas molecules) is sufficiently high to deviate long waves within a wave-length, while the shorter waves are deviated by ionic refraction brought about by a diminution of the refractive index Experimental evidence is steadily accumulating which shows that in the latter case ionic refraction without absorption is only brought about, as Sir Joseph Larmor first predicted on theoretical grounds, when the frequency of the waves is higher than the frequency of the electron collisions with gas molecules.

In linking up these ideas with the magneto-ionic theory, in which the effect of the earth's magnetic field on the motion of the electrons is taken into account, a Kerr effect was predicted (*Proc. Camb. Phil. Soc.*, vol. 22, Part 5, p. 675, 1925) for long waves when reflected by the ionised layer at night. Mr. Hollingworth's observations on long waves seem to show that such an effect is appreciable. Considered in conjunction with Dr. Smith-Rose and Mr. Barfield's observations with the Adcock system, they also constitute another confirmation of Mr. T. L. Eckersley's theory of the nature of directional errors.

A consideration of the magneto-ionic formulæ for the conductivity and dielectric constant of ionised gas shows that, in cases of reflection, there is a certain critical height in the atmosphere above which the conductivity in the direction of the earth's lines of magnetic force is appreciably different from that in a direction at right angles. This is the height at which the frequency of the electron collisions with gas molecules is equal to the angular frequency with which the electrons normally spiral round the lines of magnetic force. Taking the earth's field as 0·5 gauss, the critical value of τ is found to be equal to 10^{-7}. Estimates of both mean free paths and air pressures at different heights in the atmosphere, as given by different writers, vary somewhat, but from the available data we may, using the above value of τ, put the critical height somewhere about 70 km. to 80 km. When the waves are deviated below this height, practically no abnormal polarisation is produced, but when deviated above, both Kerr and Faraday effects will be produced according to the wave-length. The fact that the Kerr effect is found at night and not by day indicates that the ionised layer passes from or below this critical region to a height appreciably above it at sunset. Current determinations of the height of the layer for these wave-lengths by day and by night support this conclusion.

Early Egypt and the Caucasus.

As the careful summary of the meeting on this subject at Oxford (NATURE, September 25, p. 463) stops short before my reply to the difficulties there raised, I trust that I may be allowed to complete the report. We must consider the reasons for retaining the view of the dependence of the Fayum on the Nile flow, which has been held by engineers, geologists, and historians during the last fifty years—much of history depends on the conclusions.

The essential question is to choose between the received view (*a*) that the Fayum lake gradually rose by the rise of Nile level up to 205 or 220 feet over the present lake, and was suddenly dried up by restricting the inflow, under the Ptolemies; or the new view (*b*) that there was a high lake in the early human period, which was gradually dried down to the present size. The complete drying up would not take more than twenty-five years.

For the view (*a*) there are six reasons. Physically there is (1) an open channel from the Nile, the mud in which is at least as low as the Nile was at 5000 B.C., and it is unlikely that this would become blocked when a large mass of water was flowing to and fro every year. (2) It would be impossible to maintain a lake at high level unless fed by the Nile, the adjacent deep basin of Wady Rayan has not had any historical lake, because there is no Nile inflow. Historically we see (3) there are an early cooking-pot, fire, and flints *in situ* at 170 feet level, while the water in Greek times must have been up to over 200 feet, by a site being called the "crocodile island," so the lake level was rising and not falling (4) There is no trace of human work anywhere below the Nile level of its own age, which points to the lake covering the ground up to Nile level. (5) There are four structures of stone, all at the same level, which cannot be reasonably explained except as quays of late origin, and these are at 215 feet level, showing the late lake to have been far above the early flint work. (6) Direct evidence is that of Herodotus; he states

that the water flowed for half the year out of the lake to the Nile, and he names the different amount of tax on fisheries during the inflow and outflow. These reasons for the old view (*a*) seem to outweigh the interpretation of traces of the lake levels, after 2000 years of denudation which are adduced for the new view (*b*).

The geologists made objections, which were unfortunately irrelevant, as to the relation of Badarian to Solutrean culture; for it would be useless to expect that different branches from one culture, travelling 3000 miles apart under very different conditions, should retain the same details.

Permit me to add a parallel to the view of there having been an Asiatic centre of distribution for the Solutrean, Badarian, and some western neolithic culture. In the thirteenth century there were European settlers in Greenland, who were later exterminated by advancing cold, and savage Eskimos, much as Solutreans were exterminated in Europe. In the seventeenth century the same race settled in Greenland again and in New England. An American archæologist in future might say that no resemblance could be seen between these invasions, the clothing of the first age was different from that of the second, the architecture and arms of the second age were unknown in the first. Yet we know, from fuller detail, that they were of one race and one culture. Differences do not count in such a question; resemblances are the trustworthy facts.

There were five independent subjects noticed at the above meeting, each of which has to be judged on its own evidence, and the settlement of one subject will not prove or disprove any of the others, though they are closely connected in results.

FLINDERS PETRIE.

Variability of Species.

THE writers have, on one hand, been examining the variability of thirty-five species of Lepidoptera, chiefly common British moths, and, on the other hand, studying the variation to be expected theoretically in a population exhibiting inheritance wholly on Mendelian lines, with the corresponding appropriate mutation frequencies, under the influence of natural selection. The conclusions at which they have respectively arrived show a sufficiently striking agreement to suggest a theory which may be generally applicable to the natural variability of wild species.

The actual variance exhibited is regarded as having been arrived at as an equilibrium condition between the action of mutations tending to increase variability, and of selections tending to diminish it. If in such an equilibrium the mutation rates, and also the selection rates, were the same for all species, then the variance would be proportional to the population of the species. We know of no reason for supposing that the mutation rates are different for species differing in abundance, but it is *a priori* probable that in abundant species individual survival is less fortuitous, and more selective, than in rare species; while it is easily demonstrable that in species in which a higher proportion of the total variance is ascribable to genetic causes, the effective selection will be more intense than in species in which the variance is to a larger extent ascribable to environmental variations. On these grounds we should expect the more abundant species to be, in fact, the more variable, though to an extent which can only be ascertained by observations.

Charles Darwin ("Origin of Species," Chap. ii.), in studying the causes of variability, attempted a statistical investigation of material relating to a large number of different species of plants. He was, perhaps unfortunately, dissuaded from publishing his actual tabulations, but gained the concurrence of Hooker to the general conclusions that "wide ranging, much diffused, and common species vary most." Darwin was concerned to show that it was not merely that wide ranging forms give rise to local varieties in reaction to different inorganic and organic environments, but also that, "in any limited country, the species which are most common, that is, abound most in individuals, and the species which are most widely diffused within their own country (and this is a different consideration from wide range, and to a certain extent from commonness), oftenest give rise to varieties sufficiently well marked to have been recorded in botanical works."

The accompanying observations concern not "well marked varieties," but individual variation in a continuously variable character, namely, depth of pigment of the ground colour of the forewing, the variability found being that exhibited in each case in a single locality. As is shown in Fig. 1, the average variance of the abundant species is almost double of that of those species which are comparatively uncommon;

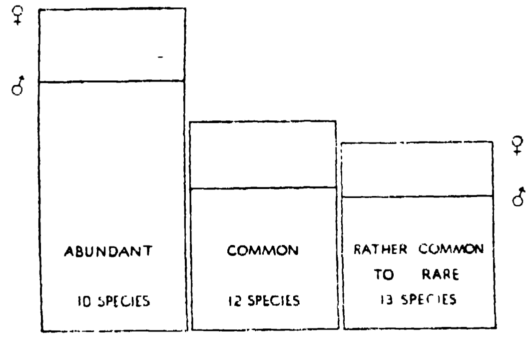

FIG. 1.

the values for males and females are shown by the lower and upper lines, the agreement of which gives some indication of the statistical trustworthiness of the results.

The data thus supply a complete confirmation of the conclusion arrived at on purely theoretical grounds; moreover, the fact that Darwin's observation with respect to "well marked variations" should be equally applicable to continuous variation would be unintelligible if, as is sometimes assumed, continuous variation had some origin distinct from the familiar Mendelian mutations.

Finally, the female moth is distinctly the more variable, the difference being nearly constant at about 38 per cent. for all degrees of abundance; this fact supplies a confirmation of theoretical anticipations of an unlooked-for kind. It has been argued (*e.g.* G. Dahlberg, "Twin Births, etc.," p. 231) that the sex with the greater number of sex chromosomes should therefore show the greater variability; a closer examination shows that this consequence will follow only if the dominant gene is, in the population concerned, generally less numerous than the recessive. (It should be noticed that this does not imply that the dominant genotype is generally the less numerous.) Our previous investigations (Fisher, 1922, *Proc. Roy. Soc. Edin.*, 42, 321) have, however, shown that in any character subject even to small selective influences the recessive gene will nearly always be the rarer. Consequently the heterogametic sex, which is the female in moths, should be the more variable, since a single recessive factor exercises its full effect

in an XY chromosome pair, though in all other cases it requires also a recessive partner. Numerically, on the simplest assumptions, we should expect the variability due to the sex chromosome in the heterogametic sex to be increased by about 9·86 per cent., while that of the homogametic sex should be diminished by 27·47 per cent. The difference is 51 5 per cent. of the smaller value, and on comparing this with our observed difference of 38 per cent. it will be seen that either additional causes must be sought for the striking excess of female variation, or the greater part of the variation present must be ascribed to the sex chromosome, which is unlikely.

Whatever may be the explanation of this great apparent activity of the sex chromosome, the two main inferences from the statistical study of the effect of Mendelian factors under selection, (1) that variability in any one locality is greater for the more numerous species, (2) that it is greater in the heterogametic sex, have both been unmistakably verified in the body of material which we have examined.

E. B. FORD.

Wadham College, Oxford.

The Atomicity of Electricity as a Quantum Theory Law.

IN the five-dimensional theory of the connexion between electromagnetism and gravitation first proposed by Th. Kaluza (*Sitzungsberichte d. Berl. Akad.*, 1921, S. 766, see also O. Klein, *Zs. fur Phys.*, 37, 875, 1926), the equations of motion of an electrified particle may be shown to be the equations of geodetics belonging to the following line element:

$$d\sigma = \sqrt{(dx^0 + \beta\phi_i dx^i)^2 + g_{ik}dx^i dx^k}, \qquad (1)$$

where x^1, x^2, x^3, x^4 are the co-ordinates of ordinary space time with the line element $g_{ik}dx^i dx^k$, while x^0 is a fifth co-ordinate, and the ϕ_i are the four co-variant components of the electromagnetic potential vector. If the constant β is given the value

$$\beta = \sqrt{2\kappa}, \qquad (2)$$

κ being the Einstein gravitational constant, the 14 field equations of the Einstein theory may, moreover, be simply expressed by means of the curvature tensor belonging to this line element.

Let now $d\tau$ be the differential of proper time belonging to a particle of mass m and charge e; then the Lagrange function L for the geodetics representing the motion of the particle may be given the form

$$L = \tfrac{1}{2}m\left(\frac{d\sigma}{d\tau}\right)^2. \qquad (3)$$

Defining momenta in the ordinary way by putting

$$p_i = \frac{\partial L}{\partial(dx^i/d\tau)} \qquad (i = 0, 1, 2, 3, 4), \qquad (4)$$

p_0 is seen to be constant along a geodetic, since x^0 does not appear in L. In addition to the equation expressing this constancy, the system belonging to (3) contains four equations which indeed become identical with the equations of motion of the particle if we put

$$p_0 = \frac{e}{\beta c}. \qquad (5)$$

With this choice of p_0 the momenta p_1, p_2, p_3, p_4 are further seen to agree with the ordinary definition of the momenta of an electrified particle.

Now the charge e, so far as our knowledge goes, is always a whole multiple of the electronic charge, so that we may write

$$p_0 = \frac{N\epsilon}{\beta c}, \qquad (6)$$

ϵ being the electronic charge and N a whole number, positive or negative. This formula suggests that the atomicity of electricity may be interpreted as a quantum theory law. In fact, if the five-dimensional space is assumed to be closed in the direction of x^0 with a period l, and if we apply the formalism of quantum mechanics to our geodetics, we shall expect p_0 to be governed by the following rule:

$$p_0 = N\frac{h}{l}, \qquad (7)$$

N being now a quantum number, which may be positive or negative according to the sense of motion in the direction of the fifth dimension, and h the constant of Planck. Comparing (7) with (6), and making use of the value (2) of β, we get for the period l:

$$l = \frac{hc\sqrt{2\kappa}}{e} = 0{\cdot}8 \times 10^{-30}\ \text{cm}. \qquad (8)$$

The small value of this length together with the periodicity in the fifth dimension may perhaps be taken as a support of the theory of Kaluza in the sense that they may explain the non-appearance of the fifth dimension in ordinary experiments as the result of averaging over the fifth dimension.

In a former paper (*Zs. für Phys*, *l.c.*) the writer has shown that the differential equation underlying the new quantum mechanics of Schrödinger can be derived from a wave equation of a five dimensional space, in which h does not appear originally, but is introduced in connexion with a periodicity in x^0. Although incomplete, this result, together with the considerations given here, suggests that the origin of Planck's quantum may be sought just in this periodicity in the fifth dimension

The Rôle of the Cerebellum in the Co-ordination of Animal Movement.

THE intracerebellar nuclei, forming, as they do, important stations on the course of the cerebellar reflex arcs, naturally invite inquiry as to the kind of influence they exert on the muscles. Our observations have been made on the cat, decerebrated in deep anæsthesia according to Sherrington's original technique, the plane of transection of the neuraxis passing just in front of the superior colliculus and in front of the infundibulum, thus leaving intact the *nucleus ruber*. Horizontal slices were then removed from the cerebellum on one or both sides, so as to expose for stimulation the dorsal surfaces of the nuclei Measures were taken to arrest the bleeding and to maintain the proper temperature. The approximate position of the nucleus in question having been determined by measurements, the section of cerebellum in this neighbourhood was then carefully explored with minimal currents applied by a unipolar electrode The following is a brief résumé of our results obtained by stimulation of the several nuclei.

Faradisation of the outer side of the *nucleus dentatus*.—This yielded repeated flexions at the elbow of the ipsilateral foreleg, when the limb was already somewhat flexed owing to the cerebellar removal; the limb was also abducted. Results of this kind were obtained by Horsley and Clarke. The contralateral foreleg, previously in slight extension, showed adduction with palmar flexion of paw. The

hindlegs already extended became more rigid in extensor tone.

At times the ipsilateral foreleg passed from flexion into extension on stimulation of the dentate nucleus; or if originally extended the effect of stimulation was to diminish the tonus. Similarly the hindlegs sometimes showed an inhibition of their tonic rigidity. The tail has been seen to point opposite to the stimulation, whilst the body was curved with the concavity contralateral.

Faradisation of the *nucleus emboliformis*.—This elicited in the ipsilateral foreleg, when previously slightly flexed, more marked flexion at elbow and paw together with adduction. The contralateral foreleg already rigidly extended showed diminished tonus. The ipsilateral hindleg showed inhibition of extensor tonus, the contralateral hindleg increased extensor tonus. The ipsilateral foreleg when originally extended showed inhibition of tonus. The tail was elevated and rotated rapidly. The eyeballs were rotated on the visual axes, the upper parts turning towards the stimulation.

Faradisation of the *nucleus fastigii*.—Manifestations consisted in strong flexion of both forelegs, already somewhat flexed in consequence of the cerebellar ablation; the toes were spread apart. The ipsilateral hindleg was flexed, the toes being separated.

Obviously, from these results, stimulation of the nuclei may yield either an increase or a diminution of tonus, the outcome apparently depending on the functional state, whether of activity or depression, of the infracerebellar centres. It is known that certain regions of the cerebellar cortex yield on stimulation inhibition of muscular tone, and, since these regions are linked with the internal nuclei, the inhibition elicitable from these latter becomes intelligible; thus support is furnished for a doctrine of cerebellar function recently enunciated by one of us, namely, that control of postural tone by the cerebellum may be either in the direction of augmentation or of inhibition (*Physiol. Rev.*, 6, 124, 1926).

The Action of Silica on Electrolytes.

IN a letter to NATURE (January 2, p. 17, 1926), Dr. Joseph suggests that I have modified my point of view. I am rather more confirmed in it. There are really two points at issue between Dr. Joseph and myself. (1) Dr. Joseph holds the view that our usual conception of ionic equilibrium in heterogeneous systems is sufficient to account for the liberation of acids when hydrated silica reacts with electrolytes (*J.C.S.*, 1923, **123**, 2022; 1925, **127**, 2813). We consider the reaction to be an example of an equilibrium between ions in the double layer and those in solution. As stated in my previous letters to NATURE, we believe that the surface primarily adsorbs anions. (2) Consequently the adsorption of acid by hydrated silica is also to be expected.

I shall take up the second point first. Dr. Joseph denies the existence of what we call 'primary' adsorption. This adsorption is to be calculated after taking into account the diluting effect of water of hydration (*Phil. Mag.*, vi. 44, 1922, p. 337). From the data given in my letter in NATURE of January 31, 1925, it would appear that the water of hydration cannot account for a diminution in concentration of about 90 per cent. The amount of primary adsorption is small and is found to be of the order of 10^{-4} gram moles of hydrochloric acid per gram mole of silicon dioxide. The failure of Dr. Joseph to confirm our results is to be ascribed to his having used 1 gram of silica and 100 c.c. of solution.

The smallness of the amount of adsorption is not against our point of view, as the adsorption of other anions is likely to be less than that of hydroxyl ions. We have observed that the total amount of acids that can be liberated from these samples of silica by repeated washing with saturated solution of potassium chloride is 6×10^{-4} gram equivalents of acid per gram mole of silica (*Quarterly J. Indian Chem. Soc.*, vol. 2, 1925, 211).

We shall now deal with the first point. In his second paper (*loc. cit.*), Dr. Joseph observes that calcium silicate is more insoluble than the corresponding barium salt. Dr. Joseph also states that solubility relationships explain the observations regarding the interaction between silica and neutral electrolytes. On this basis it is to be expected that under identical conditions calcium should, in contact with silica, liberate hydrogen ions at a higher concentration than barium chloride. On the other hand, from theoretical considerations of the effect of these cations on the electric charge of the surface of hydrated silica, barium should have a greater effect than calcium, and consequently barium should liberate hydrogen ions at a greater concentration. This is what we have observed, and I think the observation cannot be explained from Dr. Joseph's point of view based on considerations of solubility as usually applied to such reactions.

We have also observed that at higher concentrations individual differences between different cations decrease. Here also solubility relationships fail even if we consider the formation of some sort of solid solution. Besides silica there are other systems, *e.g.* manganese oxides, which behave similarly.

The British Patent Office.

IT is to be hoped that the arguments in the leading article in NATURE of September 18, for reforms in the patent system which would increase the chance of an issued patent being valid, will have effect.

It is undoubted that the value of a patent would be increased if the British Patent Office were given greater powers by the enlargement of the field of the investigation made as to novelty and by allowing the Patent Office to pronounce on the question of quantum of subject matter. The Patent Office examiners in Germany, for example, have this power, so why not those in England? It is common experience that the investigation as to novelty now made by the Patent Office examiners is, within the limited powers granted to them, more efficiently carried out than in any other country. One difficulty in the way of allowing the Patent Office to give a definite decision on validity is not so great as it appears. It is very doubtful whether 'prior user' alone is often the determining factor in deciding the invalidity of a patent. In most cases the relevant process or article has been described also in a patent specification or in text books or periodicals of the art. It is to be noted that in Holland, where the powers of the Patent Office examiners are great and their attitude towards claims strict, the validity of a patent is guaranteed after five years' freedom from successful attack.

It would help to inspire confidence in the worth of

a patent, even under the present system, if the examiners in the Patent Office were to be more strict in their requirements as to the clear and precise definition of an invention and the distinguishing of it from the prior art. At present a patent agent can usually form a correct opinion from reading a specification as to its scope, but the ordinary manufacturer, however 'skilled in the art' he may be, must frequently find himself at a loss. It requires no fresh legislative powers for the Patent Office to require an applicant to state unequivocally what is the monopoly claimed in terms which, whilst appealing rather to a craftsman than a lawyer, would yet be precise enough to satisfy the latter.

This defect is probably due to the attitude of 'leave-it-to-the-Courts' which is a relic of the days before the Act of 1902 came into force, and would tend to disappear if it were established that the greatest possible assurance of the validity of a granted patent were to be striven for, and that only in the very last resort should patent matters come before the Court.

Apocryphal Medical Science.

OUR attention has been directed to a book called "Microbe Hunters" recently published by Messrs. Harcourt, Bruce and Company, New York, and alleged to have been written by one Paul de Kruif—a gentleman whose name is quite unknown to us. The work evidently aims at being a kind of popular history or rather romance regarding medical discovery, and mentions us among others. We should like an opportunity to say, for the information of readers of NATURE, that the author's statements about ourselves and our researches are almost entirely apocryphal; that they are not supported by reference to the original literature; that they are largely imaginative or spurious; and that his knowledge of the subjects with which we have been concerned is obviously incomplete.

We have been legally advised that some of his assertions regarding ourselves are libellous according to British laws; but in America we have no means of protection except a public denial of the truth of his allegations, and we therefore trust that we may be allowed to publish such a denial, as emphatically as we may, in the columns of NATURE.

Dr. Cuthbert Christy's signature does not appear on this letter, as he is in Africa; before sailing, however, he left us the following statement: "With regard to Chapter IX. of Paul de Kruif's book 'Microbe Hunters' I beg to emphatically state that it contains statements which are totally erroneous, misleading and some of them libellous. As an example I will quote paragraph 2, page 264, which reads: 'The third member' (namely, myself) 'became disgusted with the ignorance and failures of his two colleagues and went off prospecting for rubber. . . .' This paragraph is absolutely untrue and libellous. It suffices to say that I have always given credit to Castellani for his discovery of the trypanosome as the etiological agent of Sleeping Sickness—see for instance my letter to the *Morning Post*, August 22, 1923. As regards my abandoning my colleagues and going off prospecting for rubber, this is entirely libellous. I never abandoned my colleagues and, as a matter of fact, I did not get interested in rubber until 1906, which was three years after the labours of the First Sleeping Sickness Commission were completed."

ALDO CASTELLANI.
GEORGE C. LOW.
DAVID NABARRO.
RONALD ROSS.

Kammerer's Alytes.

As I have been both misquoted and misrepresented by Prof. MacBride in a recent letter to NATURE (August 21, p. 264), I may be permitted to say a word in my own defence. My remarks on Kammerer's Alytes at the British Association were to the effect that the sections sent by Dr. Kammerer to America showed only asperities, not distinctive glands characteristic of the nuptial pads of other Salientia. The glands in his sections of the controls were the same size as those in his experimentals. Asperities may be formed on different parts of the body in one or both sexes of different species of frogs, and in some cases are apparently not correlated with a sex hormone. In the case of Kammerer's results, the question concerned the inheritance of spines, not of complete pads. Prof. MacBride seems to believe there has been some confusion in my mind on this subject.

In regard to the only specimen in existence of Kammerer's experimentals exhibiting merely a "clumsy attempt at 'faked' restoration," made "after its return to Vienna," we have Kammerer's own word that the blackened areas were present in the specimen when it went to England (Przibram, 1926, NATURE, August 7, p. 210), and moreover these areas are the only "nuptial pads" which show up in the photograph made in Cambridge (Kammerer, 1924, "The Inheritance of Acquired Characteristics," New York, Fig. 9) or in the one made in Vienna (Kammerer, 1919, *Arch. f. Entwicklungsmech.* 45. plates x-xi). Further, these blackened areas deceived two able biologists in Vienna who examined the specimen in my presence.

The question of Proteus is, of course, entirely irrelevant. The young Proteus possesses eyes, and the mere fact that certain individuals due to an irregularity of development, whether or not casually connected with an abnormal environment, should have continued the development of these structures, has no bearing on either the question of the inheritance of acquired characters or of Kammerer's experiments with Alytes.

Variation of Penetrating Radiation on the Jungfrau.

OUR new researches on the penetrating radiation in the region of the Jungfrau have now reached a partial conclusion. As is well-known, the existence of this radiation was proved by balloon observations in the years 1909 1914, and, in particular, their extraordinary hardness, which pointed to a cosmic source, was then established by Kolhörster. Afterwards, Nernst in 1921 suggested that their origin lies in recently formed matter. Our researches in 1923–1924 did, in fact, give indications of a sidereal periodicity of intensity of the radiation. These variations can now be closely followed with our more sensitive instruments. It appears that the radiation reaches maximum intensity when certain celestial regions culminate, for example, the Milky Way, and specially the regions of Andromeda and of Hercules. This is explicable as a consequence of the minimum length of the path of rays from these regions through our atmosphere at culmination. The measurements were made at different stations on the Jungfrau up to heights of 14,000 feet, and on the Mönch peak at 13,500 feet above sea-level. Glacier ice was in general used as screening material.

September 14.

Function and Design.[1]

By Prof. J. B. LEATHES, F.R.S.

AMONG natural sciences physiology takes a place which in one respect is different from that taken by any other. It studies the phenomena of life, but more particularly the ways in which these phenomena are related to the maintenance of life. Anatomy and morphology are concerned with the forms of living organisms and their structure; biological chemistry, as distinct from physiology, with the composition of the material in which the phenomena of life are exhibited. The province of physiology, in studying the functions of these forms and of this material, is to ascertain the contributions that they make to the organisation of the living mechanism, and learn how they minister to the maintenance of its life. Function implies ministration; structure for physiology implies adaptation to function, what, in a word, may be termed design.

Ultimate analysis of the phenomena with which physiology deals leads to the fundamental distinction between matter in which life is manifested and matter in which it is not. Life is exhibited only in aqueous systems, containing unstable, perishable combinations of carbon with hydrogen, nitrogen, sulphur, phosphorus and oxygen, in the presence of certain inorganic ions, those which are present in the sea, the native environment originally of all forms of life. The inalienable property that such matter exhibits when alive, and that matter which is not alive does not, is that these unstable organic combinations are for ever reforming themselves out of simpler combinations that do not exhibit this property, and do so at a rate which averages at least not less than that at which they break down. This power of self-reformation, spontaneous regeneration, operates not only when living organisms, cells or communities of cells are growing or reproducing their kind: the very maintenance of living existence requires by definition that it should persist. In the absence of water, the living process may sometimes apparently be suspended for a time, as it may be if the surrounding watery medium is immobilised by cold; it is a question whether this is anything more than a retardation to a rate of change that is imperceptible by the ordinary methods of observation, and a question how long such suspended animation is possible where it is possible at all.

Chemical analogies for this power of spontaneous regeneration, if such exist, can only exist in part: in the present state of our comprehension of it, certainly, it is hazardous to try to trace them. The attempt so commonly made to trace one between the growth of living matter and the growth of crystals in a saturated solution, it is safe to say, is in so many respects on the wrong lines that it is merely misleading.

Let us for a moment consider what this spontaneous regeneration implies. Of the various chemical components of protoplasm, proteins are generally considered the most important, often the only important, ones. The elucidation of the chemical principles upon which the structure of proteins rests, which took place about the beginning of this century, was, like the neurone hypothesis of the structure of the nervous system, an advance the magnitude of which only those, perhaps, can appreciate who began the study of physiology well back in an earlier one. For a time it seemed in each case that the problem was solved and all that was to follow was simple. Those were great days.

The best-known varieties of proteins, when detached and uprooted from the place where they grew, consist of chains of about a hundred, sometimes nearly two hundred, links. Each link is an amino acid coupled by its acid group to the amino group of one neighbour and by its amino group to the acid group of its other neighbour, a molecule of water being lost at each linkage. There are not more than about twenty different amino acids, so that some of them must occur several times in the chain; in some kinds of protein one amino acid may occupy thirty or forty of the hundred places in the chain. In any such isolated protein it is probable that the order as well as the proportion in which each amino acid occurs in the molecule is fixed, and it is this specific order and proportion that accounts for the specific character and properties of the protein. What could be simpler? Only yesterday all was so obscure.

It is not recorded that in the rush of this advance any one stopped to reflect what number of formations such a protein might still possibly have. Supposing it were a chain of only fifty links, a very simple case; if all the links were different, the number of possible permutations is denoted by the innocent-looking symbol $|\underline{50}$. If, instead of all being different, one kind of link recurred ten times, the number would be reduced to $|\underline{50} / |\underline{10}$. If, in addition, there were four that recurred four times and ten that recurred twice, it would be further reduced to

$$|\underline{50} / |\underline{10} \times (|\underline{4})^4 \times (|\underline{2})^{10}.$$

It would now consist of a chain of only fifty links, of which there were only nineteen different kinds, and the number of different arrangements of its parts would be about 10^{48}. Astronomy deals with big figures. Light, it is said, takes 300,000 years to travel from one end of the Milky Way to the other; this distance expressed in Ångström units, 10,000,000 of which go to a millimetre, would be less than 10^{32}. So far are we from knowing the structure of protein molecules! So far are we from knowing what variations in disposition of the parts in such a molecule may not occur without our being within a measurable distance of detecting them! For if the number of possible varieties of a protein the molecular weight of which is known, and known to be exceptionally small, which contains the several amino acids in a known proportion, is so great as this, the number that is possible when that proportion may be changed is practically incalculable, each change in proportion being capable of a number of new arrangements that could be calculated, as was done for our hypothetical case.

Now it is possible that the analogy of crystal formation may be applied to the reproduction of the characteristic order in which the linkings occur, and that the parts out of which a new chain is to be formed may

[1] From the presidential address to Section I (Physiology) of the British Association delivered at Oxford on August 5.

be collected and brought into position alongside of the corresponding parts of an existing chain by forces that are similar to those that determine the latticed relations of atoms in a crystal. But something more than this is required to account for the linking up of these links by the loss of water, and still more for the fashioning of the links themselves. We have to suppose that it is by selective emphasis of certain otherwise unemphasised but possible arrangements of atoms or groups of atoms, evidence for the occurrence of which under similar conditions in the absence of life is generally not obtainable. Specific catalysed syntheses must cooperate with the forces that merely sort out and place in proper order the assembled parts, and must fashion for them the particular links that they need at each step. Specific catalytic agents playing an important part in cell chemistry are familiar in the enzymes found in digestive secretions and also locked away within the cells themselves.

In the chemical make-up of protoplasm, proteins, the most abundant component, are not the only ones that are necessary. Pre-eminent among the others are the nucleic acids. When we consider what has been learnt of the behaviour and of the chemical composition of the nuclear chromosomes, and that according to Steudel's reckoning the nucleic acids form 40 per cent. of the solid components of these chromosomes, into which are packed from the beginning all that pre-ordains, if not our fate and fortunes, at least our bodily characteristics down to the colour of our eyelashes, it becomes a question whether the virtues of nucleic acids may not rival those of amino acid chains in their vital importance. From Steudel's figures it can be reckoned that there are about half a million molecules of nucleic acid in a single sperm cell of the species with which he was working.

In addition to nucleic acids there are also strange compounds of higher fatty acids containing suspiciously significant groups, identical in their general character with those found also in nucleic acid, namely, phosphoric acid, organic bases and sugar; and besides these there are the mysterious sterols. All of these are frankly insoluble in water, and yet have in some part of their composition features that make them not indifferent to water or even to the molecules and ions that exist in true solution, in the liquid state, within the cell. The physical condition of these insoluble substances in the aqueous system of the cell is still little understood. All that can be said with certainty is that they must modify its homogeneity even more than the long floating chains of amino acids, however much these may be linked together one with another. If the characteristic behaviour of living matter is rightly regarded as due to the order that it introduces into the movements and spatial relationships of foreign molecules in its vicinity, then these insoluble components may well be expected to play a leading rôle by forming films and surfaces that permeate its texture and delimit its parts.

If this analysis is approved and the distinctive property of living matter, the power of self-regeneration, depends upon the power of limiting the movements and directing and controlling the spatial relations of surrounding molecules so as to modify their chemical behaviour, it is the exercise of this same power that leads to the formation of substances such as starch, glycogen and fats; and in so far as such substances contribute to the regeneration of the living matter, the power of forming them contributes to its survival. Where energy is necessary for such synthetic rearrangements of adjacent matter, it may be derived from the radiant energy of the sun or from the combination of oxygen with adjacent organic matter.

This faculty of regeneration implies the power of introducing order into the chaotic movements of adjacent matter in conformity with patterns that it possesses. It is a faculty resident in material that is capable of incalculable variation. The number of permutations of its parts that are possible without affecting the results of such analysis as is practicable defies calculation. Some of these permutations confer synthetic powers which others do not. When they appear, are they not what biologists call, for short, mutations? But when they appear, if they retain the power of self-regeneration, and if they minister to its maintenance, they will *ipso facto* survive. For whatever promotes persistence of this power must itself survive.

A disposition of matter in molecules or aggregates, unstable and incalculably variable, that has and retains the power of determining the disposition of matter not yet so disposed, in such a way as to conform to its own disposition or to patterns which help it to exercise this power, is all that must be premised for the whole of evolution to follow. Variations that do not or cease to contribute to the retention of this power do not survive. The condition of survival is ministration to self-regeneration, that is, to the maintenance of life.

Before the days of vertebrates, in pre-Silurian time, an unstable variation occurred in certain types in the disposition of atoms and organic combinations of atoms that was mainly protein in character, a protein to the making of which little short of 200 amino acid links must contribute. Coupled to this protein, which probably is not the same in all species of animals in which it is found, is another group containing iron that is probably always the same. This group is of remarkable nature, and is closely related to one that occurs in the far older substance chlorophyll. This complex substance hæmoglobin had the power of attaching to itself two atoms of oxygen for each atom of iron that it contained in such a way that it could be readily detached and made available for effecting oxidations. Such was the service that this variation rendered that it is safe to say that without it there could be no vertebrate creation. It is this service that has made it possible for it to survive to this day, when in the human species alone it is being produced at the rate of about 10,000 tons a day. The story of the service of chlorophyll would, of course, be more remarkable than this.

Natural selection applies to the survival of the chemical forms of living matter as it does to complex living organisms. These forms, infinitely protean in their variety, survive and persist in so far and so long as they minister to its self regeneration. It is the principle of survival by service. Function alone gives permanence to structure.

Why is it that what may be termed official physiology takes so little cognisance of the doctrine of evolution?

These branches of biological study appear to follow courses so exactly parallel that they never meet.

The doctrine of evolution digs down into the foundations of scientific philosophy. If a physiologist addressing physiologists ventures to say anything on this subject of supreme appeal to all biologists, it must be in exaltation of the work of those who have approached it from the morphological side, and it may be in hopeful anticipation of the ultimate share in the elucidation of some of its problems to be borne by physiology.

On the part that function plays in the determination of structure it is to be supposed that physiology will ultimately, at any rate, have something more to say. May I submit to the consideration of physiologists certain points in the physiological development of the machinery of the body where, unless I am mistaken, it is possible to detect the operation of function in determining the design of the machine?

The properties and behaviour of cells result from the properties of the material composing them. When a muscle cell contracts this is, in general terms, a reversible rearrangement of its parts in response to some alteration in the distribution of forces within or about it due to a disturbance from without. Such reversible reaction to adequate disturbance is a property common in the material of which living cells are composed.

In addition to this reversible type of reaction there are irreversible reactions, characteristic of other kinds of cells, and it is what we call connective-tissue cells that I would consider here. There are several kinds of connective-tissue cells, but they are alike in that they produce and discharge into their vicinity material of a characteristic composition: in some of the commonest this material is chemically collagen, the substance out of which gelatine can be obtained. In course of time these cells come to be embedded in the material which they deposit about themselves and so form one kind of connective tissue. Cells capable of behaving in this way are found, however, which have not yet exercised their faculty; these fibroblasts are then undifferentiated wandering cells that have found no abiding place in the community in which they have their birth. What it is that makes them settle down and start producing the material in which they come to be embedded has never yet been determined. But the most striking structures to which they give rise are the tendons and aponeuroses that make the muscles fast to the bones, and the ligaments that bind the bones to one another. The material that they deposit is composed of inextensible fibres that lie, in the case of tendons at any rate, so exactly and exclusively in the line of the resultant of the tension set up in the muscle to which they attach themselves, that it is difficult to believe that the disturbance which starts them producing their characteristic secretion is anything else than the pull exerted on them by the muscle fibres to which they are attached: the recurring external disturbances that produce reversible states of tension in the muscle, indirectly producing in them an irreversible reaction, which consists in the discharge of material that by its inextensibility can transmit the tension along the line of the force that provokes its deposition.

In their simplest form, cells of this kind deposit the wavy fibres in areolar tissue which, when straightened out under the action of a displacing force, set a limit by their inextensibility to the dislocation of the part first affected, and so distribute the action of the displacing force over surrounding areas. It is interesting to note that the origin of cells of this kind has been traced to the mesothelium cells that line tissue spaces and serous cavities, the clefts that make the gliding displacements of parts over one another possible. The deposition of fibrous material seems here, as in the tendons and ligaments, to be the result of reaction to the recurring disturbances set up by displacements, such, for example, as those of the lungs, the alimentary tract, the heart and pulsating vessels, and the deposition occurs in the line of strains set up by the displacing forces. The service rendered by this behaviour of the cells is that the fibres which they deposit, in virtue of their inextensibility, limit the extent of displacement at any one point by distributing it to surrounding parts.

The other component of areolar tissue, the elastic fibres, is similarly produced by other cells. These fibres take a straight course between their attachments; displacements in the line of their deposition are rendered possible by their stretching, and are recovered from by their elasticity.

The contribution made by such cells to the fabric of the body appears to result from the recurring operation of disturbances, to which they react by depositing fibres along the lines of disturbance.

More striking are the properties of cells upon which the formation of the skeleton depends. The cells that make bone not only secrete fibrous collagen, but they also encrust the fibres with insoluble lime salts, and it has long been subject of comment that the rigid bone that results always comes to lie in the line of prevailing strains and stresses. The analysis of the structure, for example, of the head and neck of the human femur, by Wolff and others who have followed him, shows how strictly this is true. Calculations prove that no particle of bone lies anywhere but where the strains dictate. We can predict with certainty, it seems, that it will be found that bone cells are composed of material that in reacting to physical forces directs, in constant relation to the line of action of those forces, the deposition of the substances which make up this connective tissue. Bone can only arise where strains and stresses set up this reaction, and the greater the strain or stress the denser the deposit. When a bone is fractured many bone cells are dislodged, and in the abundance of nutriment that ruptured vessels supply, these cells, released from their imprisonment, multiply. At first the force of gravity and the twitching of muscles acting on the soft semi-fluid tissues between the broken ends of the bone supply stimuli that are indeterminate in direction, and such reaction as occurs results only in the formation of loosely ordered calcareous fibres: but even this soft callus gives some degree of rigidity, sufficient to restrict the strains gradually to more and more clearly defined lines along which in proportion a stronger reaction can take place.

Once it is established that bone corpuscles react to strain and stress by discharging collagen, the intimate spatial disposition of which, as well as of the lime salts with which it comes to be encrusted, is determined by the directing forces to which it is exposed; and once it is recognised that the law of spontaneous regeneration requires that this reaction will persist in proportion to the prevalence of these forces, not only must the gradual replacement of callus by appropriate permanent

bone necessarily follow, bone in which no particle persists except it be in the line of constantly recurring stress and strain, but it will also necessarily follow that the position of every spicule of bone in the skeleton, cancellous or compact, is the expression of a physiological reaction to the forces of gravity and muscular tension.

The evolution of the machinery of the connective tissues seems to be not entirely the result of natural selection and the survival of individuals in which this machinery chanced to be of appropriate design. The appearance in early vertebrates of the material that is characteristic of the bone corpuscle seems to have ensured that skeletons would take a shape determined by the direction of the forces to which these corpuscles were exposed, and that the formation of this skeleton is as much a reaction to recurring stimuli as are the reflexes, composite movements and postures characteristic for the species.

This conception of the way in which the vertebrate connective tissues take their shape transfers a large share of the development of the bodily form back into the nervous system, in which the machinery is stored that directs and determines the habitual movements and postures that in reaction to external disturbances are specific. A physiological account of the evolution of the nervous system, one certainly that is based on the chemical constitution and chemical behaviour of its component parts, must seem almost infinitely remote from practical investigation. But the work of Pavlov has made one thing clear: that by a physiological reaction in it, machinery may come into existence which did not exist before. The repeated occurrence of a disturbance at times that are uniformly related to the normal operation of existing machinery results in the acquirement of a new reaction which must require machinery that is new. It is rendered probable, if not proved, that this new machinery is situated in what may be called the growing point of the central nervous system, the cortex of the cerebral hemispheres, the part where all is not 'cut and dry,' where cells retain more of the properties of the developing neuroblasts, the properties that enable them to grow out through the embryonic tissues along courses that make it certain that the maturing organism will behave in a manner true to type. In the formation of a conditioned reflex, two events are made to occur in the cerebral cortex at times which are uniformly related to one another; one of these events, from the constitution of the nervous system, necessarily results in a certain activity of some muscle or gland, the other has been hitherto in no way related to such a result; after many repetitions of the association of these events, it is found that that one which previously had never resulted in this particular activity, comes to have this result as certainly as the other.

But if and when it is possible to trace the origin of structures to functional reactions of cells, and to reactions that depend upon the chemical properties of the cell substance; and if and when this is possible not only in the connective tissues, but also in the nervous system, the functions of which have so controlling an influence on the operation of every part of the body; until it becomes clear that the results of changes in such influence reappear in succeeding generations, the study of functions can have no bearing upon the ultimate problem of biology, the evolutional history of life upon the earth. Pavlov communicated to the International Congress of Physiology in 1923 some results of experiments that he had done upon this subject which, when confirmed, should 'electrify the atmosphere.' Conditioned reflexes that are established only after many—eighty or a hundred—repetitions of the associated stimulus, in each succeeding generation require fewer and fewer repetitions, and in the fourth may be established after only four. In April of this year he wrote to say that owing to other work he had not been able to give the necessary time to confirmation of these results. We are content to wait.

In the great question whether characteristics developed in the life of an individual have any influence on descendants, experimental evidence must come slowly. In what is called parallel induction a step has been taken which is probably of greater importance than is generally conceded. External influences that affect the bodily characteristics of an organism affect also the germplasm in such a way that these characteristics appear in the first, and even, in a less degree, in the second generation born after the external influences have ceased to operate. While such experiments furnish evidence only of a temporary change in the properties of the germplasm, one that may be put down to the lodgment in it of unassimilated foreign matter that is gradually eliminated, the fact that the eternal germplasm has been shown to be subject to temporal influences must not be belittled. A true mutation is not eternal. Our descendants may be able to dispense with hæmoglobin. The hereditary melanism that in certain moths, it is said, can be induced by food infected with manganese, is, perhaps, something more than such parallel induction.

Physiological inquiry is a stream that has many sources; its waters gather from quarters far removed from one another. A marvellous meeting took place in the early years of this century when the forgotten experiments of Mendel came to the surface again, and found corroboration in the cytological studies that from about the same time had pursued their slow obstructed way above ground in the endeavour to elucidate the changes in the nucleus of maturing germ cells. In a resting germ cell the chromosomes form an even number, characteristic for the species; they consist of half that number of pairs of homologues, one of each pair descended from the paternal element in the last zygosis, the other from the maternal. At one of the cell divisions by which the germ cell gives rise to the mature gamete, with half the characteristic number of chromosomes, there occurs a segregation of the two members of each pair so that they pass into different gametes—the exact cytological equivalent of Mendelian segregation of allelomorphic pairs of characters. To-day the study of genetics and of the 'topographical anatomy of the chromosomes,' with its 'groupings' and 'crossings over,' seems to require chemical assistance. It may be that in the lifetime of some of us those confluent streams of thought and experiment are to be joined by yet another that rises in the vast, remote and, as it must appear to some, muddy swamps of physiological chemistry; and it then, forgetting its 'foiled, circuitous wanderings,' will form with them a 'majestic river, brimming and bright and large.'

Francis Bacon and Scientific Method.[1]

By Dr. C. D. BROAD.

II.

THE natural history, selected, arranged, and recorded by the rules described in the previous article, forms the basis on which scientific knowledge must be built. Bacon's next task was to construct a logical instrument by which a knowledge of general laws can be erected on this basis. Plainly the kind of reasoning which is needed is inductive. But Bacon objected both to the order and the form of reasoning which he found in current inductive arguments. Those who use them jump directly from particular facts to extremely sweeping generalisations, and they then deduce propositions of medium generality from these generalisations by means of syllogistic reasoning. Now Bacon's view is that there should be a very gradual ascent from particulars through principles of slowly increasing generality to the widest generalisations. Conversely, there should be a very gradual descent from the widest generalisations through principles of slowly decreasing generality to new particular facts. In the ascending scale each stage covers all the facts below it and extends very slightly beyond them. We then deduce observable, but not hitherto observed, consequences from the hypothesis and see whether they are true. If they are found to be so we can accept the hypothesis and go on to generalise it a little further. Thus the descending scale serves to test the stages in the ascending scale.

Bacon's objection to the form of reasoning employed in current induction was that it made no use of negative instances. It simply argued in the form: "All *observed* S's have been P, therefore *all* S's will be P." Now Bacon's view is that the cause of a given effect cannot be discovered by direct and positive means. It can be discovered only by gradually eliminating alternative possible causes until we are left with a single survivor, which can then be accepted with confidence as *the* cause. In order to discover the cause of a given kind of phenomenon, three sets of tables were to be formed, namely: (1) cases where this phenomenon is present; (2) cases where it is absent; (3) cases where it varies in degree. Now Bacon takes it as axiomatic that what he calls the 'formal cause' of a phenomenon is such that (1) it cannot be absent when the phenomenon is present; (2) it cannot be present when the phenomenon is absent; and (3) it cannot be constant when the phenomenon varies, or conversely. He knows then that the cause must be present in all the cases in the first table. He need not consider, therefore, any factor which is absent from any of these cases. Again, he need not consider any factor that is present in the cases in the second table, for the cause must be absent from all of them. Lastly, he can reject any factor which is constant throughout the cases in the third table. By this method of rejection, and by it alone, Bacon thought it possible to discover with certainty the causes of given effects.

This is Bacon's method in the barest outline. What kind of fact did he hope to discover by it? He tells us that the ultimate aim of theoretical science is to discover 'the forms (or formal causes) of simple natures,' and that the ultimate aim of applied science is to use this knowledge to 'induce on bodies the form of any nature that we may desire it to have.' He draws a sharp distinction between the 'formal cause,' on one hand, and the 'material' and 'efficient' cause, on the other. He assigns the study of material and efficient cause to 'Physics,' and their practical use to 'Mechanics'; whilst he assigns the study of formal causes to 'Metaphysics,' and their practical employment to what he calls 'Natural Magic.' But he recognises that he is here using 'Metaphysics' in an unusual sense. The meaning of all this is the following. By a 'simple nature' Bacon means some perceptible generic physical property, such as colour, temperature, etc. By the 'form' or 'formal cause' of a simple nature he means that which this property is in things themselves apart from their relation to sensitive organisms. Thus, violent and irregular molecular motion would be the 'form' of the 'simple nature' called 'temperature.' Again, periodic variation of electro-magnetic intensity would be the 'form' of the 'simple nature' called 'colour'; and so on. So the Metaphysics of Forms is what we should call Microscopic Theoretical Physics. The propositions of 'Physics,' in Bacon's sense of the word, are what we should call 'empirical laws,' *e.g.* 'if amber be rubbed with flannel it becomes electrified.' Here the 'material cause' is amber and flannel, whilst the 'efficient cause' is the process of rubbing the two together.

Now of course we may know of various practical methods of inducing heat or electricity on bodies when we know nothing of the form of heat or the form of electricity But Bacon sees that so long as we have merely this rule-of-thumb kind of knowledge our practical control over Nature will be very limited. If, on the other hand, we know the form of a given nature we know that *any* means of inducing this form will induce this nature, and that nothing else will do so. Thus by knowledge of forms, and by that alone, we may be able to produce profound modifications at will in the properties of bodies. This is what Bacon means by 'Natural Magic'; and the syntheses of new substances in organic chemistry would be an example of what he had in mind.

Bacon holds that there is a part of physics and mechanics which is closely connected with metaphysics and natural magic, and constitutes the transition from the former to the latter. This he calls the study of the 'Latent Structure' and the 'Latent Processes' of bodies. He recognises that bodies have an inner microscopic structure too small for our unaided senses to perceive, and that many of their perceptible characteristics depend upon this. He also recognises that what we call the efficient causes of given effects are only isolated outstanding features in processes which are continuous and in the main imperceptible. If we are to understand and control Nature we must turn our attention from the gross structure and changes of bodies to their minute components and processes. Bacon particularly insists that, whilst both of these

[1] Continued from p. 488.

subjects have been neglected, the latter has been more neglected than the former; and yet the dynamical aspect of Nature is even more important than its statical aspect.

It will be interesting at this point to consider Bacon's views about mathematics, for they exhibit his peculiar weakness and strength in a clear light. It is evident that Bacon was no mathematician. He has no theory of mathematical reasoning; he seems to be contemptuous of pure mathematics; and he was evidently unacquainted with the progress which was being made by both pure and applied mathematics in his time. It is noteworthy that in his remarks about Plato, with whom he is not altogether unsympathetic, he never thinks of Plato and his school as mathematicians but always as theologians and moralists. Yet Bacon does repeatedly say that physics cannot progress far without mathematics; and some of his strictures on the excessive worship of mathematics in science are the negative side of an important positive demand. Thus he complains that optics and astronomy have fallen wholly into the hands of mathematicians. When this complaint is investigated it is found to mean that Bacon wants something more than mere geometrical optics and mere descriptions of the courses of the heavenly bodies. He wants a *physical* optics and a *physical* atronomy, which shall deal with the *nature* of light and the *substance* of the stars and planets. His own attempts to supply this want are of very little value, but the demand is a sound one.

Although Bacon held that the proper course for scientific reasoning to take is a gradual ascent from particulars to general laws and a gradual descent from these general laws to new particulars, he was prepared to admit as a subsidiary process the direct passage from one particular to other partly analogous particulars. This he calls *Instructed Experience* (*Experientia Litterata*). He distinguishes various forms of this, of which the following are the most interesting: (1) Varying an old experiment, either by applying it to different but partly analogous materials, or by applying different but partly analogous processes to the old materials, or by varying the quantities or intensities of the factors in the old experiment. (2) Repeating the original process on the product of the previous experiment, as in redistillation. Bacon is careful to point out that we must never assume that an increase in any factor will produce a corresponding increase in the effect, or that the repetition of a process upon its product will increase the effect. (3) Extending a process from Nature to art, from one art to another, or from one part of an art to another part of it. Bacon says that new and useful processes are most likely to be discovered when one or a few men learn to compare the processes of a number of different mechanical arts. (4) Inverting one or more of the factors in an experiment; *e.g.* substituting great cold for great heat. (5) Making one factor gradually more or less intense until the characteristic effect just ceases to take place. (6) Coupling together two cause-factors, each of which has already been tried separately. Here again Bacon carefully points out that we have no right to assume that, because a in the absence of b gives α, and b in the absence of a gives β, therefore ab will give $\alpha\beta$. We may conclude this point of Bacon's doctrine with two highly characteristic quotations: "Though a successful experiment be more agreeable, an unsuccessful one is often no less instructive"; and "Experiments of Light" (*i.e.* those which throw light on the laws of Nature) "are more to be sought after than Experiments of Fruit" (*i.e.* those which lead to results that are of immediate practical use).

I will conclude by mentioning the seven cases in which the senses have to be aided and the kind of help which Bacon suggests. (1) If the object be very distant it must be joined to something which is perceptible at a distance, *e.g.* something that gives a flash or a noise. (2) If it be enclosed in an opaque envelope it must be judged by processes at the surface (*e.g.* feeling the pulse) or by what comes out from it (*e.g.* examination of urine). (3) It may be unable to affect the senses because of its intrinsic nature (*e.g.* colourless gases), or (4) because of its minuteness. The latter difficulty can be avoided by causing it to produce some effect of sensible magnitude (*e.g.* using an air-thermometer to indicate small changes of temperature). (5) Motion may be too slow or too swift to be perceived. In the former case it can be magnified by pointers and similar devices. Bacon does not know how to deal with the latter case. (6) The intensity may be too great for the senses to bear. In this case Bacon recommends the use of reflectors or semi-opaque screens. (7) The senses may be very rapidly exhausted. This happens only with taste and smell. Bacon suggests no remedy for this; but he says that where our senses fail us altogether we may use those of animals (*e.g.* dogs for scent).

Much of the merit of Bacon consists in minute detail, and is lost in a rapid sketch like the present. I think we may sum up his strength and weakness as follows. He was not a great scientist, either practically or theoretically. But he saw many of the essential factors in successful scientific procedure with great clearness, and stated them with admirable force. His method is admittedly incomplete; and no method could accomplish all that he expected of it. The nearest approach to a complete method would be a synthesis of the methods of Bacon and Descartes. But we must go far before we shall find another such combination of wide generalisation, strong common sense, balanced enthusiasm, and pointed eloquence as we find in Bacon.

The Tropical Cyclone.

By E. V. NEWNHAM.

THE cyclone season of the northern tropics is drawing to a close. The accounts of widespread damage to property and loss of life, both in the Gulf of Mexico and in the Far East, that have appeared recently in the newspapers, show that the storms that have already occurred will make this season a memorable one. It is not intended here to deal with these recent events, but rather to present the salient facts about the tropical cyclones of both hemispheres, and to indicate the extent to which these phenomena are understood at the present time.

Like all meteorological phenomena, tropical cyclones

show great individual variations from the general type; nevertheless, their general characteristics are sharply defined. In size they occupy an intermediate position between the two other kinds of atmospheric vortex that give rise to winds of hurricane strength, namely, the large cyclonic depression of temperate and high latitudes and the small but excessively violent tornado of the American and Australian type. In all three vortices the pressure of the air is greatly reduced towards the centre, but it is only in the case of the tornado that the pressure becomes too low to be recorded by the ordinary barometer.

The typical tropical cyclone consists of a nearly circular symmetrical whirl, clockwise in the southern hemisphere, counter-clockwise in the northern hemisphere, with a diameter varying from 100 to 600 miles, about a central 'eye,' where the air is nearly calm. The wind is strongest along the margin of the 'eye,' which averages about 14 miles in diameter, and in this region often greatly exceeds a hundred miles an hour. Within the 'eye' the weather is usually fair, but in the zone of strong winds torrential rains occur. The movements of the clouds are in general centrifugal, particularly as regards the higher clouds. The place of origin is in general over the hotter parts of the ocean between latitudes 8° and 12° on both sides of the equator, generally near the equatorial margin of the trade winds bordering the doldrums, or belt of equatorial calms and light winds, but in the case of the storms in the Bay of Bengal and the Arabian Sea, in the region of variable winds and squalls that occur at the transitions between the north-east monsoon of the winter and the south-west monsoon of the summer.

Tropical cyclones form in three zones:

(1) The south-western part of the North Atlantic, around the West Indies.

(2) From the Arabian Sea eastwards so far as the China Seas and western part of the North Pacific.

(3) From around Madagascar eastwards to the Paumotu Islands.

There is, as a rule, one definite season extending over several months and reaching a maximum a little before the autumn equinox, when the ocean is generally at its warmest. Individual seasons differ greatly as regards the number and intensity of the storms that occur, and a connexion has been claimed by some writers between the character of the season and the number and size of the spots on the sun, but a clear relationship for the whole area affected by cyclones has not been established so far.

Cyclones move slowly along paths which also show great variation, but a dominant tendency towards motion along a certain type of curved path, sometimes described as parabolic or hyperbolic, is apparent in all parts of the world where a large mass of land is not so situated as to prevent the storm from passing through its normal life-history.[1] The motion during the first few days is compounded of an east to west drift, and a slight poleward drift, but somewhere between latitudes 20° and 30° (north or south) the motion becomes directly poleward and then inclines towards the east, becoming north-easterly on leaving the northern tropics and south-easterly on leaving the southern tropics. It should be noted that within the tropics the movement is clearly not in accordance with the prevailing winds of the region through which the storm is passing, and is more often than not almost directly opposed to those winds,[2] but on leaving the tropics, when the storm begins to lose its tropical characteristics and take on those of the ordinary temperate 'depression,' the motion, in the case of the cyclones of the North Atlantic and the China Seas, appears as a rule to be that of the prevailing winds, between about latitudes 30° and 50° N.

To return to the important subject of their place and time of origin: whatever the process may be whereby a cyclone begins to form in a region of light and variable winds, there can be little doubt that their whirling motion is due to the deflective force of the earth's rotation. Now this force varies as the sine of the latitude, and is therefore inappreciable for some degrees north and south of the equator; this fact explains why cyclones seldom originate within 8° of the equator. The reason why the time of maximum frequency is normally just before the autumn equinox appears to be that one of the necessary conditions for the formation of a cyclone is a discontinuity between distinct wind systems, and this will be found at a suitable distance from the equator when the equatorial belt of calms (the doldrums) is nearly at its farthest from the equator, *i.e.* not long after the summer solstice, the maximum being retarded somewhat because the greatest warmth of the ocean is normally attained about two months after the solstice. In the case of the Indian cyclones there is a double maximum, one in early summer and the other in autumn; in this case, the controlling factor is clearly the presence or absence of the necessary discontinuity of wind, the warmth of the sea appearing to play little part in fixing the cyclone season.

The above general description of tropical cyclones is based mainly upon a recent memoir of the British Meteorological Office,[3] which is in turn based upon all available contributions to the literature of the subject up to 1920. In the introduction to this work, Sir Napier Shaw attempts to explain the life-history of a tropical cyclone from its birth, as a result of the convection in suitable circumstances of hot moist air, to its death, when, having been transformed into a cyclonic depression of temperate latitudes, it is surrounded by cold dry air on reaching the polar regions. The convectional stage is developed in a very ingenious manner: a number of small convectional 'bubbles' are assumed to unite into a single large 'bubble'; air is withdrawn over a certain area and is 'evicted' in the upper atmosphere; the system quickly acquires the properties of a fully developed cyclone and begins to drift towards the west. In a theoretical section, Dr. H. Jeffreys, regards a combination of the two principal theories so far advanced to explain the origin of cyclones—the 'millpond eddy' and the

[1] The storms of the Bay of Bengal and Arabian Sea appear to behave normally in this respect, but the great land mass to the north does not allow them to survive long enough to follow more than the first third or half of the typical path

[2] So far as I am aware, this point has not been emphasised hitherto. Its truth rests upon the accuracy of the charts of prevailing wind published in "Bartholomew's Physical Atlas," vol. 3, plate 14, which are due mainly to Koppen.

[3] "Hurricanes and Tropical Revolving Storms" By Mrs. E. V. Newnham. Meteorological Office Memoir, No. 19, 1922.

'convectional' theories—as necessary for a complete explanation.

Since 1920 several further contributions have been made to the literature of tropical cyclones. One deals with the region around the West Indies.[4] Redrawing the tracks of all known cyclones in this area since 1886, Mitchell found that no storm originated over the eastern two-thirds of the Caribbean Sea; many storms originated, however, south of the Cape Verde Islands, and some over the western third of the Caribbean Sea. The deciding factor in this case, as for the Indian cyclones, appears to be the presence or absence of a discontinuity between conflicting winds; such a discontinuity is absent over the eastern two-thirds of the Caribbean Sea. Another interesting fact pointed out by Mitchell is that the cyclone of this area 'recurves' (*i.e.* turns directly polewards) as soon as a trough of low pressure arrives to the north, irrespective of the longitude and time of year.

Another recent valuable publication deals statistically with the tropical cyclones of Australia, without, however, contributing much that is new to the theory of the storms.[5] The last paper to which I shall refer is concerned with the dynamics of the formation of cyclones.[6] Capt. Brunt follows Shaw in regarding simple thermal convection of moist air as the initial stage, the energy for the subsequent violent winds being supplied by the latent heat of condensation of the water vapour that is precipitated in the rising column of air before those winds arise. He lays stress on the importance of explaining how the removal of air from the centre of a developing storm is brought about, and presumes that it is effected by the discharge of the column of rising air into strong upper winds.

The verification or refutation of this and of the various alternative theories of the origin of cyclones that have been brought forward, which space does not permit me to describe, awaits a more complete knowledge of the temperature, humidity, and wind at all levels in the regions of formation of cyclones, which are unfortunately in most cases just where observations of any kind are most difficult to obtain.

The Reported Conversion of Hydrogen into Helium.

THE current (September) issue of the *Berichte* of the German Chemical Society contains a paper by Profs. F. Paneth and K. Peters on "The Transformation of Hydrogen into Helium," in which they describe in outline how they have succeeded in detecting the presence of very minute amounts of helium, of the order of one hundred millionth of a cubic centimetre, derived from hydrogen which had been absorbed by finely divided palladium at the ordinary temperature.

Theory indicating that this conversion would involve the liberation of much energy ($6{\cdot}4 \times 10^{11}$ cal. from 4 gram-atoms of hydrogen), the author's primary task was to find out if the change would take place without introducing energy from outside, *e.g.* in the presence of a catalyst; and in order to be able to detect very small quantities of helium they elaborated the spectroscopic method in such a way that the limiting amount detectable was 10^{-8}-10^{-9} c.c., or 10^{-12}-10^{-13} gm. Easily liquefiable gas was removed with liquid air and charcoal; oxygen was added and the hydrogen burnt on the surface of the catalyst; water-vapour and excess oxygen were removed with charcoal, and the residual gas was passed into a glass capillary-tube of 0·1 mm. section, which was surrounded with electrode-wires and placed before the slit of the spectroscope. Every precaution was taken to exclude atmospheric helium; the portion of the apparatus that was heated was surrounded with a vacuum-mantle and immersed in water. The presence of neon lines afforded a most valuable criterion of the presence of atmospheric gases; neon was never completely excluded, but the amount present was so small that it did not invalidate the author's main conclusion.

The method is so delicate that the liberation of helium from a mixture of thorium B and thorium C was easily detected, while it is sufficiently sensitive to determine the presence of helium in a few cubic centimetres of natural gas. By its means a natural gas containing 0·19 per cent. by volume of helium was discovered in Germany, and steps have been taken to exploit it commercially. The Canadian natural gas from which helium is extracted contains 0·33 per cent. by volume.

Attempts were made to effect the transformation by submitting hydrogen to the action of a silent electric discharge in an ozone apparatus, and by passing a prolonged and powerful discharge through it in a Geissler-tube fitted with aluminium electrodes; but no success was achieved. Nor was the attempt to produce helium by bombarding certain salts with cathode rays, as suggested by Lord Rayleigh, any more fertile, so that recourse was had to passing fairly large amounts of hydrogen—up to one litre—through heated palladium, in the hope that at the moment of exit a fraction of the protons and electrons would combine to form the helium nucleus. In this case the indications were favourable, but the result was inconclusive owing to the presence of atmospheric neon, and the absence of any proportionality between the strength of the helium lines and the amount of hydrogen that was used.

Finely-divided palladium, either as sponge, 'black,' or palladinised asbestos, was then used to absorb hydrogen at room temperature, and after different intervals of time the hydrogen was combined with oxygen, as previously described. The residual gas obtained after a 12-hours' contact between palladium and hydrogen exhibited four or five lines of the helium spectrum and only a single neon-line; there was also a distinct proportionality between the amount of helium observed and the duration of the time of contact. The activity of the different palladium preparations employed varied considerably; it invariably diminished with repeated use, but both the power of absorbing hydrogen and of effecting the transformation were restored by heating in hydrogen or oxygen, in a mixture

of these gases, or in a vacuum. No helium production was observed with palladium preparations that did not absorb hydrogen, although preparations were occasionally obtained that absorbed hydrogen well but gave little or no helium, especially if the hydrogen had been absorbed at a high temperature.

The above results indicated that palladium preparations that have long remained unused at room temperature should contain a little helium (not of atmospheric origin). Examination of a number of such specimens showed that helium was present in all of them, and in particular a specimen of palladinised asbestos, which had been purchased from Kahlbaum two years previously, was found to be relatively very rich, 1 gm. of it containing 10^{-6} c.c. of practically pure helium. After this specimen had been heated to expel the helium, and treated with oxygen for twelve hours, no fresh helium was detected, but at the end of five hours in contact with hydrogen a considerable amount of helium was found. This experiment was performed three times with the same result. The palladium, however, gradually lost its activity; at the beginning it produced helium at the rate of 10^{-8}-10^{-7} c.c. per day; after twenty treatments it became inactive. Its activity was restored, although not to the original degree, in the manner described above. Finely divided platinum is less active than palladium, and the action of pyrophoric nickel is weaker still.

The authors discuss fully the possible sources of error in their experiments, such as the ingress of atmospheric helium, the adsorptive capacity of glass for helium, the conceivable preferential adsorption of helium by palladium, or by asbestos, and the possibility of helium being formed as a radio-active disintegration product of palladium; all of which they consider to be excluded. The hydrogen and oxygen used by them contained less than 0·001 per cent. of air. They were not able to detect any trace of the energy liberated during the transformation, and they point out that the amount set free from the conversion of such small quantities of hydrogen—about 0·28 calorie—would be extremely difficult to detect, and particularly so if thermal changes due to absorption or formation of compounds also take place. They incline to the view that the liberated energy is more likely to appear as radiation, *e.g.* as γ or Millikan-rays, than as heat.

News and Views.

ONE of the subjects discussed at the recent World Power Conference at Basle was the exchange of electrical energy between countries. An interesting example of this interchange of energy occurs between Denmark and Sweden. Submarine cables crossing the Sund Straits transmit power at 25,000 volts and 50,000 volts respectively. When the water supply in Sweden is abundant they carry the excess hydroelectric power to Denmark, and when Sweden suffers from water shortage they convey thermally generated power in the reverse direction. It was pointed out that some countries, Switzerland for example, have great water power resources but yet are very unwilling to export electric power, and set up high tariffs. One of the reasons for their action would appear to be that, in the opinion of some Swiss engineers, Switzerland is destined to become one of the important centres for carrying out electrometallurgical and electrochemical processes on a large scale. In their opinion, the sale of electrical energy abroad helps the establishment of those industries outside their own frontiers and so is not in the national interest. Another objection is that the export of electricity in bulk to foreign countries will gradually subordinate Switzerland to these countries; the foreign capital introduced being conceivably a source of danger. Mr. Niesz of Baden held that these objections have no real foundation. The majority of the engineers present agreed that it is desirable that the authorities in different countries should place no obstacle in the way of a free interchange of electrical energy provided that economic conditions are favourable.

MR. ALAN COBHAM alighted on the Thames opposite the Houses of Parliament on October 1, thus completing his latest flying achievement. In recognition of his services to aviation the King has conferred upon Mr. Cobham the honour of knighthood (K.B.E.). His three long-distance flights are a notable advertisement for commercial aviation. The De Havilland-50 aeroplane, with Armstrong-Siddely "Puma" engine and interchangeable floats and wheels, was designed for flying in countries with undeveloped transport services, where lake, river, or sea offer natural alighting places. An aeroplane of this type was flown to Rangoon and back. The same aeroplane fitted with the more powerful "Jaguar" engine was flown to the Cape and back. Finally, the same aeroplane and engine, after overhaul and fitting of forged "Y-metal" aluminium pistons, was flown to Melbourne and back, floats being fitted as far as Port Darwin, wheels for trans-Australian flying. The structural alterations required for the heavier engine, if any, are not known, but the following are some of the main characteristics:

D.H.-50.	Puma Engine.	Jaguar (Radial) Engine.
Span, 13 m.	6 cyl. (water cooled)	14 cyl. (air cooled).
Surface, 41 m².	180 kw.	290 kw.
Total wgt., 1770 kgm.	1400 r.p.m.	1700 r.p.m.
Speed, 180 km./hr.	300 kgm. wgt.	360 kgm. wgt.

The last of the three flights was equivalent to flying 800 km. every other day from June 30 to October 1, a high feat of personal skill and endurance, and an equally remarkable record of aeroplane and engine performance.

THE specificity of quinine in curing or relieving the symptoms of malaria has long been known. At the present time, the chief drawback to its use is its cost, due in part to the few areas in which the bark yielding the highest proportion of this alkaloid can be cultivated and in part to the restriction of output. Other drugs have therefore been tried in the treatment of this disease; the other crystalline alkaloids present in the more common variety of bark, quinidine, cinchonine, and possibly cinchonidine, have been

shown by Fletcher to be nearly as efficacious as quinine itself (see *Brit. Med. Journ.*, 1926, vol. i. p. 154), and their use therefore should result in a considerable reduction in the cost of treatment. On the other hand, no synthetically prepared compound has so far been found to be of value, but this statement may soon be no longer true if the report from Germany which appeared in the *Times* of September 25 is confirmed. The new drug is called 'Plasmochin,' and has been tested both experimentally in birds and animals and also clinically of endemic malaria and in cases of general paralysis of the insane who have been submitted to the malarial treatment. This treatment consists in infecting the patient with one form of the malarial parasite, and after a week or two curing him with quinine; great improvement of the original symptoms has resulted in many cases. The drug appears to be non-toxic, but caution is expressed as to whether it will replace quinine completely in the treatment of malaria. It has, however, been found to destroy the crescent forms of the 'malignant' tertian parasite within five to seven days. It is possible that it may form a useful adjunct to treatment with quinine or the other cinchona alkaloids.

MR. G. N. HUMPHREYS, of the Uganda Survey Department, has recently led two expeditions to Ruwenzori; he has climbed most of the chief peaks, and made an extensive examination of the range. His first expedition in February of this year was hampered by bad weather, but he climbed Mount Speke and the peak Vittorio Emanuele, and an unnamed peak; and the expedition achieved the first crossing of the range from east to west, it used a pass near Mount Gessi, and discovered three new lakes, of which the largest is two miles long. The second expedition in July had better weather, and the party climbed both the peaks Margherita and Alexandra on Mount Stanley, some of the higher peaks on Mount Baker, and Mount Luigi di Savoia. The expeditions made some natural history collections A preliminary account of the journeys was given by Mr. Humphreys in a lecture to the Uganda Literary and Scientific Society on August 27 last.

THE British Aquarists' Association has just held its first exhibition in the British Sea Anglers' rooms in Fetter Lane, London, E.C. 4. Judging by the exhibits alone, one would gather that the primary object of the Association is the study of the elegant and comfortable management of freshwater vertebrates, and the provision of expert advice to its members on the construction and maintenance of aquaria. A glance through the *Amateur Aquarist and Reptilian Review*, the official organ of the Association, however, shows that it has much wider biological interests in the structure, habits and life-histories of aquatic organisms generally. In a first exhibition, it was natural that the goldfish family and the quainter and more ornamental water vertebrates should predominate, and we were surprised to find four healthy specimens of such a rarity as Proteus in one aquarium. The exhibition gave special attention to the problem of the respiratory balance. The mechanical method was represented by a recurrent siphon fountain of simple make, an aerating cylinder in which a pump is used to develop air-pressure sufficient for twelve hours' aeration, and a fish aquarium with a sluice under the perforated floor which flushes away the accumulated débris without disturbing the water above. Biologists who prefer the plant-animal balance would be interested to find that such a large variety of aquatic plants from all over the world can now be purchased from dealers in London. The experience of the Association should prove of value to biologists intending to do experimental work with living aquatic animals.

THE work of the Building Research Station of the Industrial Research Department is described in a ten-page pamphlet issued by H.M. Stationery Office. Originally housed in temporary buildings at Acton, this station has now been transferred to permanent quarters at Garston, near Watford, which change admits of considerably increased activities. The highly technical problems involved in modern building are often insufficiently appreciated These problems refer not only to the purely engineering, constructional, and accessories features contained in most large buildings but also embrace developments in the use of, and a scientific knowledge of, the materials which are popularly associated with ordinary building. To elucidate these matters, the co-operation of the chemist, physicist, architect, and engineer is necessary. As is pointed out, quite apart from the general claims of this industry to a share in the efforts of the scientific worker, the country is involved in huge sums spent upon housing, and it is in the national interest that every effort should be made to utilise science in the interests of real economy in construction. By arrangement with other institutions, the station carries out special researches in addition to the work within its own walls, and is prepared to deal with problems for private individuals at arranged fees. Included in the scope of its work is the collection and co-ordination of current results of investigation from other sources.

DURING the week-end September 24-27, the third conference of the Association of Special Libraries and Information Bureaux was held at Balliol College, Oxford. The immediate object of the Association is the preparation of a directory which, with suitable classification, will direct attention to the sources where special collections of books or other materials have been brought together, whether these be in public libraries or in private collections. This task is a large one, and it is being assisted by a grant of 2000*l.* from the Carnegie United Kingdom Trust. Information bureaux are now being rapidly founded in connexion with many industrial and commercial enterprises, and several of the papers and discussions at the conference dealt with these developments. Papers dealing with the collection of technical information and its utilisation by research associations for the benefit of manufacturers in different branches of industry were also read. The Association is keeping in close touch with foreign sources of information,

and is securing liaison with similar developments abroad. At the conference, Dr. de Vos Van Steenjiwk gave an account of the work of the new International Institute of Intellectual Co-operation at Paris. The Association, in preparing the directory and acting as a clearing-house for sources of information, is rapidly placing itself in a unique position to offer valuable service, which will doubtless attract a large membership from professional and business circles. Further information on the Association's work can be obtained from its office at 38 Bloomsbury Square, W.C.1.

DR. D. G. HOGARTH in "The Twilight of History," a lecture delivered as the eighth Earl Grey Memorial Lecture at Armstrong College, Newcastle, in February last, and now published by the Oxford University Press, suggests a new orientation in approach to the problems of the obscure period between the downfall of the second Late Minoan kingdom in Crete and the rise of Hellenism. He does not regard the decadence in art which is to be observed in this period as necessarily implying a set-back in civilisation. While he would agree with the late Sir William Ridgeway in the view that Minos was not 'Minoan' at all, and did not participate in the civilisation named after him, he would not concur in calling him the 'destroyer.' Neither the Achæan nor the Dorian invasion, on his view, was catastrophic. He argues that pre-eminence in artistic products is an accompaniment of an aristocratic regime based upon a subject population of inferior culture, whereas the decadence in artistic motives which follows Late Minoan II, being accompanied by improved technique, for example in pottery, points to the substitution of the artisan for the artist, and a wider diffusion of culture among the people at large. The wider distribution of Minoan products indicates a period of expansion rather than dispersal and the development of an export trade which brought the Greek world into contact with the fertilising influence of the Oriental. Dr. Hogarth concurs in the view that the break up of the Mycenæn Empire was due to the Dorians, but so far from regarding this as the beginning of a 'Dark Age,' he looks upon the isolated communities under hereditary nobles which they founded as the precedent condition of the evolution of the Greek city state. A brief summary does less than justice to Dr. Hogarth's sanity of outlook and his sense of proportion. A careful study of his stimulating lecture might perhaps serve to curb some of the wilder flights of enthusiasm which, apparently, fail to surmount a wall erected somewhere about 776 B.C.

IN connexion with the opening of the reorganised public exhibition galleries of the Imperial Institute, Mr. Arthur M. Samuel, Parliamentary Secretary of the Department of Overseas Trade, addressed a well-attended meeting of head teachers of schools in the London area, held in the great hall of the University of London on the evening of September 28. The Hon. W. G. A. Ormsby-Gore, Under-Secretary for the Colonies, and the Duchess of Atholl, Parliamentary Secretary to the Board of Education, also addressed the teachers. The galleries were opened to the public on the following day. The present system of arrangement, which has been introduced by the new director of the Institute, Lieut.-General Sir William Furse, has as its main object the development of the educational value of the collections, which are planned to illustrate as completely as possible the economic and physical geography of the overseas countries of the Empire. The plan of arrangement which has been adopted for the courts is in keeping with modern ideas in regard to the teaching of geography. Maps and models in relief illustrate the topography and configuration of the country, the distribution of rainfall and other important features. Wherever possible or appropriate, space is devoted to exhibits illustrating the ethnology of the country, and the visitor then passes to a series of show cases in which are displayed selected natural products and manufactures of the country, particular attention being given to new products and developing industries. Complete series of samples for inspection by commercial men and others are to be arranged in special sample rooms. Exhibits illustrating the opportunities for sport are also a feature in certain courts. Full use has been made of the experience gained at the British Empire Exhibition in developing effective means of display, a notable example being the installation of a striking series of finely executed dioramas which portray scenery and natural features, industries, and sport. The scheme has not yet reached its full development in all the courts, but it is clear that the reorganised galleries should prove of great value for teaching purposes and at the same time offer a most attractive display to the general public

THE *Empire Cotton Growing Review*, vol. 3, No. 3, July 1926, continues to publish interesting accounts of the possibilities of cotton-growing in various tropical dependencies overseas Mr. G. F. Keatinge, revisiting South Africa in 1925, finds that the production of 1000 bales in 1919, is now 10,000, but would have been more but that many farmers have been discouraged as the result of drought in 1924, excessive rain in 1925, and insect pests at all times. Where, however, cotton is grown continuously on the same land for a series of years, a slow accumulation of pests is to be expected. Cotton prospects in Papua and in New Guinea are discussed by Mr. G. Evans. This number of the journal contains the second part of an article of more general interest to agriculturists, in which Messrs. F. L. Engledow and G. Udny Yule discuss the principles and practice of yield trials. This discussion, which deals with the many difficulties of such yield trials in a critical and yet practical spirit, will be of very general value; the authors state that the form of their paper is the result of their experience in training six generations of 'cotton men' at the School of Agriculture, Cambridge. The Empire Cotton Growing Corporation has also published separately a very full report by Col. C. N. French upon cotton-growing in Nigeria, which is a very interesting discussion of the problems of cultivation, transport, and marketing which arise in a territory where cotton is grown by native farmers.

The report is a striking tribute to the work of the Director of Agriculture, Mr. Faulkner, and his staff.

WE have received a copy of No. 2 of *Continental Metallurgical and Chemical Engineering*, a publication in English, issued by the Dr. Joachim Stern Verlag in Berlin. This periodical is devoted to metallurgical and chemical subjects, and the number received, which is that for September, contains the first part of an article on the cutting and turning of metals, describing important experiments now in progress in the Technische Hochschule of Berlin with the object of determining the forces in action at the cutting edge of the tool and the mechanism of the cutting process. Another subject which is treated in detail is the extraction of radium, vanadium, and uranium from carnotite, whilst the manufacture of ruby glass and the production of synthetic camphor are also topics which receive notice. The review of current literature is, in this number, confined to chemical and metallurgical papers from French and German periodicals On the commercial aspect, the most interesting article is one describing the movement for the formation of a continental iron and steel syndicate, containing an account of the steps which have been taken in this direction in various European countries, mainly with the object of countering the efforts of the great American steel-marketing organisations. The new periodical is associated with the *Metallborse*.

THE issue of the *Physikalische Zeitschrift* for July 15 contains a portrait of the late Prof. Otto Lummer and an account of his life and work from the pen of Prof. E. Riecke. Otto Lummer was born in Gera on July 17, 1860, studied mathematics and physics at the Universities of Tübingen and Berlin, obtained the degree of doctor at the latter in 1884 and acted as assistant to Helmholtz at the University until 1887, when he followed his chief to the newly established Reichsanstalt at Charlottenburg. He lectured at Berlin from 1901 until 1904, when he became professor of physics at the University of Breslau He died suddenly on July 5, 1925 Throughout his life he was a skilled experimenter and an attractive lecturer. The work for which he is best known was done while at the Reichsanstalt—the invention of the Lummer-Brodhun photometer in 1889 and the Lummer plate in 1902, the accurate measurement of the ratio of the specific heats of gases with Pringsheim in 1887–1898, and the measurement of the emission spectrum of a black body also with Pringsheim in 1899–1900, which furnished Planck with the starting-point for the quantum theory. His work while at Breslau was concerned mainly with photometry and its industrial applications.

THE annual report of the Field Museum of Natural History, Chicago, for 1925 contains, as usual, much to make museum workers in Great Britain think. Take, for example, the expeditions during the year: there were three making archæological collections—in Mesopotamia, Egypt, and Peru; two making ethnological collections—in the neighbouring states and in Madagascar; three dealt with various branches of botany—in Peru, Chile, and British Guiana; one sought for fossil vertebrates in Argentina; the Roosevelts led a general zoological expedition through the high lands of central Asia; and four other zoological expeditions worked in Central Africa, Southern Georgia, Saskatchewan and Alberta, and British Columbia. Out of the 21 collectors thus engaged eight were members of the ordinary scientific staff, very nearly one-third of the whole. What one ponders over is how the staff manages to deal with the mass of material that is pouring in. That it does deal with some of it in a highly successful manner is clear from the photogravure plates of various exhibits, such as the man-eating lions of Tsavo and the reproduction of a flowering cactus from British Guiana. These plates, it should be mentioned, are all produced in the museum, and are but one example of its unusual activities. Many solutions of our problem suggest themselves, but one seems certain: the museum must employ many highly-skilled technical assistants. We should like to see a complete establishment list, with the rates of pay.

THE Royal Meteorological Society has lately issued the first three numbers of a new series of publications, entitled *Memoirs*, in which it is intended to include the more technical papers printed by the Society. Such papers have hitherto appeared in the *Quarterly Journal* of the Society, which is circulated to all the fellows, but with the recent growth in the mathematical and technical developments of meteorology, this course has been judged less suitable than the new plan now adopted. The *Quarterly Journal* is intended to make a wide general appeal to those interested in meteorology, and will continue to include a large number of the papers submitted to the Society, together with other meteorological notes and articles: but the more technical and difficult papers, which, for reasons of economy, will be sent only to those fellows who indicate their special interest in these papers and express a desire to receive them, will be noticed in the *Quarterly Journal* only by title or in abstract. The Society, like most other publishing scientific societies, finds the financial difficulties due to increased cost of printing enhanced by the growth in the number of papers presented to it, and this new departure is rendered possible only by the aid of a share of the recently increased Government grant for scientific publications, administered by the Royal Society.

ORDERS of the Committee of Privy Council have been issued by which Dr. Charles J. Martin, Director of the Lister Institute and professor of experimental pathology in the University of London, and Sir Frederick G. Hopkins, professor of bio-chemistry in the University of Cambridge, are appointed members of the Medical Research Council into the vacancies caused respectively by the death of Lieutenant-General Sir William B. Leishman and by the retirement of Prof. T. R. Elliott.

MR. W. R. THOMSON, formerly a member of the staff of the Royal Agricultural College, Cirencester, has been appointed by Messrs. Fertilisers Sales, Ltd., Adelaide House, King William Street, London, E.C.4, to be director of propaganda for calcium cyanamide in Ceylon.

THE Chemical Society is publishing a series of photographs of eminent chemists, reproduced by a photo-lithographic process. So far eight are available: Bunsen, Emil Fischer, Hofmann, Mendeléeff, Pasteur, Sir William Perkin, Ramsay, and Roscoe. The portraits should be admirable and inspiring decorations for chemical and other laboratories.

FROM the fifty-sixth annual report of the Newport (Mon.) Public Libraries, Museum, and Art Gallery, for 1925–26, we learn that a new building for the Museum and Art Gallery is as urgently needed and as far off as ever. Meanwhile valuable objects of art and science, which should find a home in Newport, are directed elsewhere, and the educational activities of the Museum are hampered for want of a lecture room

APPLICATIONS are invited for the following appointments, on or before the dates mentioned :—A medical practitioner as bacteriologist for the City of Salford—The Medical Officer of Health, 143 Regent Road, Salford (October 11). An assistant lecturer in the principles of teaching (logic, psychology and ethics) at the Glasgow Training Centre of the National Committee for the Training of Teachers—Director of Studies, Training Centre, Jordanhill, Glasgow (October 16). An assistant pathologist at the Royal Free Hospital and London School of Medicine for Women—The Secretary, R.F.H., Gray's Inn Road, W.C.1, or The Warden and Secretary, London School of Medicine for Women, Hunter Street, W.C.1 (October 18). A professor of mathematics, a reader in physics and a reader in chemistry at Raffles College, Singapore—The Board of Education or the Scottish Education Dept., Whitehall, S.W.1 (October 22). A lecturer and demonstrator in chemistry and a lecturer in pharmacy in the University of Sydney, New South Wales—The Agent-General for New South Wales, Australia House, Strand, W.C.2 (October 30). An Editor for "Science Abstracts" having a knowledge of physics, electrical engineering and foreign languages—The Secretary, Institution of Electrical Engineers, Savoy Place, Victoria Embankment, W.C.2 (November 8). An assistant curator in zoology in the Bristol Museum and Art Gallery—The Director (November 15). A State mining engineer to the Western Australian Government—The Agent-General for Western Australia, 115 Strand, W.C.2 (November 30). The "J. C. White" lectureship in bacteriology in the Queen's University, Belfast—The Secretary (December 1). A teacher of biology at Gordon College, Khartoum—The Sudan Government Offices, Wellington House, Buckingham Gate, S.W.1 (marked "Teacher of Biology"). A warden of the Ellis Llwyd Jones Hall of Residence for Women Students, Victoria University of Manchester—The Registrar of the University. A lecturer in mathematics at the Chelsea Polytechnic—The Secretary, Chelsea Polytechnic, Manresa Road, S.W 3.

Our Astronomical Column.

THE METEORIC PHENOMENA OF SEPTEMBER 6.—Mr. W. F. Denning writes that, with reference to the meteoric phenomena observed on Monday, Sept. 6, though there were probably two different meteors seen at about $20^{h}\ 45^{m}$ G.M.T., the various observations are not sufficiently definite to determine the real paths with certainty except in one case. This refers to the great fireball which was directed from the north-east and passed over Yorkshire from the North Sea to disappear finally over Matlock, Derbyshire. Its height was from 60 to 28 miles, path about 133 miles, and velocity 15 miles per second. The radiant point was near ϵ Persei over the north-east horizon at the time of the fireball's appearance.

Statements have appeared in the newspapers that a London photographer released a number of gas balloons earlier in the same evening. Those were so arranged as to acquire altitudes of about 5000 feet and to explode finally with great noise and light. The originator of the scheme alleges that he sent the balloons up as an 'amusement' and 'experiment,' and claims that the supposed meteors and curious flashes observed on the same evening were the products of his experiment. This claim cannot apply to the Yorkshire fireball at least, which gave a dazzling illumination, occasioned loud detonations, and caused buildings to vibrate as during an earthquake. A small gas bag could scarcely induce results of this character.

DESIGN OF A 25-FOOT REFLECTOR.—There is no finality in telescope design, and Mr. F. G. Pease, of Mt. Wilson Observatory, pronounces that the making of a 25-foot mirror is quite within the bounds of possibility, and gives a design for such an instrument and its dome in *Publ. Astr. Soc. Pacific* for August. He makes the focal length only 3·3 times the aperture, so that the dome has only twice the span of that of the Hooker telescope. The estimated cost is 12 million dollars. Various materials are suggested for the mirror: glass, pyrex, obsidian, stainless steel, Mr. Pease is not without hope that an alloy may be found with a low coefficient of expansion like invar, but superior in reflective power.

The proposed instrument would carry a 70-foot interferometer. Mr. Pease considers that the climate of Mt. Wilson would permit of the effective use of such an instrument on nearly as many nights as the 100-inch Hooker telescope

CATANIA OBSERVATORY.—This observatory undertook the photography of the zone $+46°$ to $55°$ of the Astrographic Catalogue The printing of its results is much in arrears, owing to shortage of funds since the War and frequent changes of directors (A. Ricco died in 1919 and B. Viaro in 1922), but the appearance of Vol. 2, Part 2 will be welcomed. This extends from declination to $-49°$, and from R.A. 3^{h} to 6^{h}. There are 48 pages of catalogue, with an average of about 120 stars on each, going down to mag 12·2 (photographic). The information given is fuller than in most astrographic catalogues, R.A. and decl being given for all stars (to $0{\cdot}01^{sec}$ and $0{\cdot}1''$), also meridian positions and spectral types for all stars for which they are available. There is difference of opinion as to the advisability of thus increasing the size and cost of the work, but there can be no question that it makes the catalogue much more convenient for reference.

The *Annuario* of the Observatory for 1926 contains drawings of sunspots and prominences by G. Favaro, and of Mars (opposition of 1924) by M. Maggini. The latter show an unusual number of small round markings, both bright and dark; some of the former may be clouds. A bright bridge crosses Syrtis Major, a feature that others have noticed at times.

Research Items.

ANALYSIS OF PREHISTORIC BRONZE.—Mr. A. Leslie Armstrong publishes, in *Man* for September, a number of analyses of bronze implements and founder's metal made by Prof. Desch in connexion with the work of the Bronze Age Implements Committee of the British Association. A palstave found at Windsor in 1864, formerly in the Hull Museum and now in the Ashmoleum Museum, Oxford, was one of the most interesting of the objects examined. Its metal had an abnormal appearance, and on analysis it proved to contain so much oxygen and sulphur that the metal was "hopelessly brittle" and could only be regarded as a founder's failure. The figures were copper 78·79, tin 16·49, nickel 0·49, lead 0·09, sulphur 0·68, total 96·54. Three implements from a hoard found at Westcroft, Shelf, near Halifax, were also brittle owing to excess of sulphur, the analysis of one revealing 1·50 of sulphur, copper 86·32, tin 12·14. The Everthorpe Hoard of thirteen socketed celts, a gouge, and three lumps of metal, now in the Hull Museum, was also examined, and revealed the surprising fact that the metal was practically pure copper, a condition unusual in English objects. The celts are unfinished foundry specimens and the analyses of three samples were practically identical, showing 98 to 99 per cent. of copper. A socketed celt, however, from the same hoard showed the remarkable result of copper 66·88, tin 10·54, and lead 22·36. Such an amount of lead is probably unique.

THE 'A' CEMETERY AT KISH, MESOPOTAMIA.—The Field Museum, Chicago, has undertaken the publication of the technical description of the pottery, metal, and stone implements, and other details of the more material side of the archæological discoveries of the Field Museum-Oxford University Expedition to Kish The first part, Vol. 1, now issued is by Mr. E. Mackay, the excavator, and deals with the finds in the 'A' cemetery, close to, and south of, the Ingharra series of mounds. This site was partially excavated between January and March 1924, when thirty-eight graves were opened. The finds presented many points of particular interest. On the site, which awaits further excavation, was a large building of plano-convex bricks, which had afterwards been enlarged, and after a considerable lapse of time the addition was repaired. The burials are dated at about 3000 B.C., when the buildings had fallen into a state of decay. The skeletal remains show that though the legs were bent, the bodies were not interred in the 'crouched' position and there is no indication of a rule of orientation. The pottery includes new and important types, the most striking being the handled form which is unique in Mesopotamia or elsewhere found in nearly every grave. It is made in three pieces skilfully joined, the chief peculiarity being the handle, which is hollow, and has the face and breasts of a female in clay applied to it. It is clearly in origin a spout, as in some cases the cavity of the handle communicates with the interior of the jar, and in no case is the handle actually secured to the rim. Nearly every grave was supplied with a pottery brazier made in two pieces. Nothing quite like them has been found excepting the Hittite 'champagne cups' of Bronze Age date, and a vessel from the prehistoric burials of southern India conjecturally dated 2500 B.C. Copper implements were numerous, especially knives and daggers. They were beaten out of thin sheet metal and as they seem too light in weight for actual use, were probably made for funerary purposes. Curious implements of sickle shape of which the use is difficult to determine may, it is suggested, have been used as strigils. The designs on the seals, as usual, throw light on the general culture of the period. The fauna represented suggests a semi-arid climate such as that of South Africa, and it is interesting to note that an antelope apparently was domesticable.

FOREST ECOLOGY IN SWEDEN.—The Swedish Institute of Experimental Forestry in 1923 acquired two forest areas in Västerbotten, northern Sweden, for scientific studies. Kulbäcksliden is about four square miles in area, and Svartberget is slightly smaller. In "Excursion Handbook" No. 11 of the Institute, the geology and vegetation of these forest areas are described by Messrs. O. Tamm and C. Malmström, with maps of the soil and vegetation formations. Over the greater part of the areas the plant communities have suffered no interference by human agency. The predominant tree is the Scots pine, but there is a considerable proportion of spruce. From an investigation of fossil pollen in peat bogs M. Malmström believes that pine and birch used to prevail, while spruce was absent or rare, and did not become an important forest tree until perhaps four thousand years ago. Spruce pollen increases rapidly in amount in later peat deposits, suggesting a rapid invasion of this tree. At the same time elm and lime disappeared. Spruce seedlings have an advantage over pine and birch in needing very little light. Thus as competition and crowding increases, the spruce is best able to hold its own. On the other hand, spruce has less resisting power than pine against forest fires, so that after a fire the pine again has a chance until eventually crowded out once more by spruce.

KAPOK.—The *Bulletin of the Imperial Institute*, vol. 24, No. 1, 1926, has an article, with bibliography, upon the prospects of the production of this fibre within the British Empire. The tree producing kapok, *Eriodendron anfractuosum*, belongs to the natural family Bombacaceæ and occurs in many tropical parts of the British Empire, but practically the entire commercial supply of the fibre is obtained from Java. On a relatively small scale it has been cultivated with success in Ceylon The hairs in kapok are attached to the inner wall of the capsule and not to the seed itself, so that the separation from the seed is much more easy than in the case of cotton. The hair cells are full of air and very light, and as they are unpermeable to moisture they are used throughout the world for the manufacture of life belts and similar appliances, but the chief use of kapok at present is for stuffing cushions, mattresses, etc. Hitherto great difficulty has been experienced in spinning kapok, owing to the smooth, slippery surface of the fibre, when this difficulty is overcome the yarn may not be strong enough for some purposes, but in the production of good non-conducting fabrics and in other directions kapok may find an extensive field of employment. The seed is rich in oil, and in the Dutch East Indies forms an important source of revenue. Cultivation of the kapok tree seems to offer few difficulties in a suitable climate, and propagation, either from seed or cuttings, is a simple matter.

FUNGI.—The Ministry of Agriculture and Fisheries has published 25 coloured plates, of a few (sixteen) of the edible British fungi and also of nine of the more dangerous poisonous species (London: H.M.S.O.). This handbook replaces a former edition, now out of

print; names and description have been brought up-to-date, and seven new plates inserted, four of more common species in place of rare species now omitted, three as more representative illustrations of the same species than the figures in the former handbook. The illustrations are clear and the description as non-technical as possible, but it is doubtful whether it is advisable for any but the competent mycologist to range so widely in his diet of fungi. The handbook is very cheap at 3*s.* in S/Cloth Boards or 2*s.* 6*d.* Quarter Boards. In the *Annals of the Royal Botanic Gardens, Peradeniya*, vol. 10, part 1, T. Petch continues his "Additions to the Ceylon Fungi," whilst the *Kew Bulletin*, No. 7, 1926, contains an account of the Fusaria of Jamaica, by C. G. Hansford. Dr. Paul A. Murphy and Robert M'Kay have a paper upon the downy mildew of onions (*Peronospora Schleideni*, Unger) in the *Scientific Proceedings of the Royal Dublin Society*, vol. 18 (N.S.) No. 22, 1926. Perennating mycelium in the bulbs seems to be the main method by which this disease hibernates in Ireland. In the *Transactions of the Royal Scottish Arboricultural Society* Dr. Malcolm Wilson, with collaborators, publishes brief notes upon *Rhizosphæra Kalkhoffii* Bubák, as a cause of defoliation in conifers, and upon *Rhabdocline Pseudotsugæ* Syd., a new disease of the Douglas fir in Scotland.

BLOCK LAVA AND ROPY LAVA.—It is well known that there are two contrasted types of lava flows known as *aa* or block lava and *pahoehoe* or ropy lava. The rough surfaces of the former are moderately crystalline, whereas the latter is covered with a smoother layer of glass which varies in vesicularity from a continuous solid to a froth. A flow frequently starts as *pahoehoe*, especially where the rate of flow is not too high to permit skins of chilled glass to form over the surface, while further on *aa* is formed. This may occur where there is an increase of slope giving turbulent conditions, or when the underlying lava stream has begun to crystallise so that it can no longer advance in a completely liquid state. At Mauna Loa most of the *pahoehoe* is formed during the declining phases of activity; crusts then form over the lava, which flows slowly in tunnels and advances by pushing out bright toes along the front of the stream. These in turn rapidly crust over, and the conditions are very different from the raging torrents with which the flank eruptions often begin. Experiments carried out by O. H. Emerson, and recorded in the *Am. Journ. Sci* for August, together with many pertinent field observations, converge in showing that *aa* lava is essentially due to crystallisation of the mass while it is flowing. It is concluded that the controlling factors in determining the final appearance of a lava flow are mainly mechanical, such as the thickness and viscosity of the flow, its degree of crystallisation at any given time, and its velocity. It has been thought that *aa* is formed by containing and releasing more gas than *pahoehoe*, for the bursting of vesicles often contributes to the roughness of a lava surface. Dr. Jaggar, however, is quoted to prove that there is no evidence as to which of the two forms, if either, gives off the greater quantity of gases.

ARCHÆAN ROCKS OF SOUTHERN INDIA.—In his presidential address to the Geological Section of the Indian Science Congress of 1924, now published in the *Records of the Mysore Geol. Dept*, 23, 37, 1926, Dr. W. F. Smeeth discusses the sequence and origin of the gneisses and associated rocks of Mysore. He adheres to his view that the chloritic and hornblendic rocks of the Dharwar group are the oldest of the complex, and that the gneisses, charnockites and granites are successive intrusions of later dates. Nevertheless, no sign has been detected of any old land surface or basement rock on which the oldest Dharwars could have been laid down or erupted. This failure has led to the hypotheses that the original underlying floor, together with the base of the Dharwars themselves, have been re-fused, or that they have foundered into the depths after having been stoped away by a magma rising from deeper sources. The upper or chloritic division of the Dharwars shows as a whole more folding and shearing than the lower or hornblendic division, and the contact relations indicate that the latter are, for the most part, intrusive towards the former. Confirmatory evidence is found in the structural relations of the banded quartz-ironstones that are developed among the chloritic schists. Acid intrusions which have been thought to be offshoots from the later Champion Gneiss are stated to be more abundant in the upper division than in the lower, and this discrepancy is met by the suggestion that some of them are associated with a period of granite intrusion still earlier than that of the Champion Gneiss, and also earlier than the intrusion of the hornblendic series.

BRAZILIAN METEOROLOGY.—The observations taken at the Central Observatory at Rio de Janeiro in 1921 are tabulated in full in the *Boletin Meteorologico* published by the Ministry of Agriculture. They are followed by a summary of the observations taken at some 80 other stations, and rainfall data at 25 other stations. In an appendix there are added the data obtained from various private observatories, owned mainly by railway and mining companies. The volume contains detailed rainfall maps, so far as statistics permit, for every month in the year. The lack of data in the far interior is noticeable in these maps, which show only five stations in the basin of the Amazon and its main tributaries. On the coast, however, the stations are numerous.

RECURRING MAGNETIC DISTURBANCES.—Largely through the work of Maunder and Chree, the '27-day recurrence tendency' is one of the most firmly established facts of terrestrial magnetism: the phrase denotes the tendency for a day following or preceding, at an interval which is an integral multiple of 27 days, a day of marked magnetic disturbance or calm, to share the same characteristic in diminished measure. The tendency is attributed to the association of magnetic disturbance with corpuscular emissions from particular disturbed regions of the solar surface: if on a given day such a region is suitably disposed towards the earth, so that its emissions impinge on the earth, then 27 days later, in consequence of the solar rotation, it will recur to approximately the same aspect relative to the earth, and if still active there will be recurrence of terrestrial magnetic activity at this interval; it is known that particular solar regions often remain disturbed for the duration of more than one solar rotation-period. The same hypothesis applies, *mutatis mutandis*, to days of magnetic calm, which are naturally associated with notably calm regions on the sun's surface. In *Terrestrial Magnetism*, June 1926, W. J. Peters and C. C. Ennis use the Ebro observations of 1910–1924 to prove that earth currents exhibit the same recurrence-tendency. This was to be anticipated, since it is almost certain that these currents are induced in the earth by the variations in the earth's magnetic field (themselves originating in electric currents

situated in the atmosphere); it is satisfactory, however, to have this anticipation confirmed.

THE ACOUSTICS OF BUILDINGS.—As the result of experiments which have been carried out at the National Physical Laboratory, Teddington, during the last two or three years, architects can now be told what will be the acoustical properties of any hall designed by them, before it is erected. The apparatus used in the predetermination of these properties is described by Dr. A. H. Davis and Mr. N. Fleming in the September issue of the *Journal of Scientific Instruments*. For the effects of floor, ceiling, side walls, and galleries, a small model in hard wood is made, the end walls being omitted. A spark from an electric machine is made to pass between two electrodes placed in the model at the point at which in the hall the sounds are produced, and, after a short interval, a second spark is made at a point in the model which corresponds to a point behind the source of sound in the hall. The position of the sound wave due to the first spark is shown by the shadow it casts on a photographic plate placed in the model at a point corresponding to one behind the back wall of the hall. By changing the interval between the two sparks, the sound waves before and after reflection are followed.

THE CATALYTIC DISSOCIATION OF CARBON MONOXIDE.—The reversibility of the reaction $CO_2 + C = 2CO$ was demonstrated by Deville in 1863, and although numerous experiments on the thermal decomposition of carbon monoxide, alone or in the presence of catalysts, have been carried out since that time, the existence of this equilibrium at comparatively low temperatures has but recently been observed. The minimum temperatures at which various catalysts cause the decomposition of pure carbon monoxide were determined by J. Cleminson and H. V. A. Briscoe in a series of experiments described in the August issue of the *Journal of the Chemical Society*. The pure gas was heated in a durosil vessel, connected with a mercury manometer, in the presence of the catalysts, the diminution in volume serving to measure the extent of decomposition. The temperatures at which the decomposition began were 300°, 290°, and 250° for carbon, magnesia, and alumina respectively.

FUMIGATION WITH HYDROCYANIC ACID.—Fumigation with hydrocyanic acid gas is the subject of *Science Bulletin*, No. 46, published by the Department of Agriculture of the Union of South Africa, which details the work of B. J. Smit and T. J. Naude on the distribution of the gas in a tented enclosure. In order to find the conditions for the most efficient fumigation, samples of the gas from different parts of a treated brick-chamber were drawn through potash solution and the hydrocyanic acid concentrations estimated. When the pot method is used, it is found that, under the influence of the heat of reaction between the hot sulphuric acid and the sodium cyanide, the gas rises to the top of the chamber and descends along the walls to the floor, the dose being in excess of the theoretical for the first few minutes. In fumigations with liquid hydrocyanic acid, the distribution of the gas depends on the nature and area of the surface on which the liquid is poured, but when the evaporation is aided by heat the results resemble those obtained by the pot method.

EKA-CÆSIUM.—Various attempts have recently been made to isolate eka-cæsium, the hitherto missing element 87. Assuming that $MsTh_2$, an actinium isotope, might undergo dual disintegration, and emit a small number of α-particles in addition to its normal β-ray disintegration, O. Hahn recently attempted to detect the missing element. He concluded that eka-cæsium, provided it has a half-value period of not less than a few hours, does not result from the disintegration of $MsTh_2$. Using the scintillation method, G. Hevesy has also investigated the problem of the missing element by counting the α-particles emitted by RdTh during its growth from $MsTh_2$. His results indicate that the fraction of $MsTh_2$ atoms which disintegrate under emission of α-particles is certainly less than 1/200,000. In a recent paper (*Phys. Zeit.* 27, p. 531, August 15, 1926), O. Hahn and O. Erbacher have carried the investigation a stage further. They used strong $MsTh_2$ preparations, of strength equivalent to 24-32 mgm. radium, which they freed completely from isotopes of radium, lead, and bismuth in the presence of iron, after which cæsium nitrate was added, and the $MsTh_2$ quantitatively separated from it. The cæsium was then precipitated, carefully washed and dried, and transferred to an electroscope. The measurement of its activity was commenced about thirty minutes after separation of the $MsTh_2$. The residual activities were probably due to traces of $MsTh_2$, and were so small that the authors conclude that if eka-cæsium is produced from $MsTh_2$ and has a half-period within the limits of a few minutes and ten years, the branching ratio is not greater than one in ten millions. By the observations of the β- and γ-activities of their purified $MsTh_2$ preparations during a period of 50 hours, four accurate decay curves of $MsTh_2$ were obtained, and these yield a mean value of 6·13 hours for the half-period of $MsTh_2$ ($\lambda = 0{\cdot}113$ hour^{-1}). This result agrees fairly well with the earlier determinations, but indicates that the value $T = 5{\cdot}95$ hours obtained by W. P. Widdowson and A. S. Russell is distinctly low.

AN ARABIC TREATISE ON ALCHEMY.—Additional information on the "somewhat shadowy figure" of Abu 'l- Qāsim al- 'Irāqī, an Arabic alchemist of the 13th century, whose work "Al- Muktasab" (Arabic text and English translation, Paris 1923) was published by Mr E. J. Holmyard, and was reviewed in NATURE (Aug 30, 1924, p 307), is now available in the July number of *Isis*. Mr Holmyard here gives translations of parts of other works of Abu 'l- Qāsim, in which (as in the first treatise) the influence of Alexandrian writers is very clear. In a list of secret names ("Decknamen") of materials, many are those "used by the Greeks". Among the names of mercury is "liquid gold" (which Mr. Holmyard does not comment upon). The Greek name is "liquid silver" (χυτὸς ἄργυρος in Aristotle, the earliest mention), but Ktesias mentions an Indian "liquid gold" (ὑγρὸς χρυσός). The elixir is called *al-tiryāq* (θηριακή, a nostrum invented by Andromachus of Crete, physician to Nero, which Sprengel says "was later applied without distinction to all the kinds of diseases"). Supposedly Greek names, which are obviously greatly disfigured, are left by Mr. Holmyard without comment. Among these are *halimus* for hæmatite (? *al īmus*, αἱματίτης); *isqūnās*, purified sulphur (? from φεῦγον, the sulphur being sublimed); *mughlīs*, salt of urine (probably made up from ὄμιχμα and ἅλς); *faluzabalis*, white lead (perhaps containing λιθάργυρος; the name 'Αφροσέληνον suggested by Mr. Holmyard seems improbable); *harfatis*, copper scales (Ruhland, *Lex.* 29, says *alfatida* is "cuprum ustum"); *badis*, trona (Ruhland, 100, *barach panis* is "nitrum salis"), *raus*, sulphur, etc.

Jubilee of the Mineralogical Society.

The opening of the Jubilee Celebration of the Mineralogical Society on Tuesday, September 21, was preceded by a very successful week's excursion to Cornwall under the leadership of Mr. Arthur Russell, which was attended by about eighteen members and guests.

On Tuesday, September 21, an informal gathering in the Mineral Gallery of the British Museum (Natural History), South Kensington, was followed by a visit to the Imperial College of Science, where was shown a series of exhibits in the Geological Department, and Prof. H. C. H. Carpenter exhibited and gave an account of the large crystals of aluminium and other metals that he has succeeded in making.

The afternoon began with a most interesting visit to the Royal Institution, where Sir William Bragg and his assistants showed models of crystals and the results obtained by the X-ray analysis of minerals. Sir William Bragg also took his guests over the Institution and showed the historic laboratories of Faraday, and the apparatus employed by him and by other famous investigators. Later in the afternoon, at the Jermyn Street Museum, Sir John Flett and the Museum curators exhibited the mineral and other collections, the library, and map-room, and entertained the visitors at tea.

The formal reception took place in the evening of Tuesday at a conversazione held by kind permission in the rooms of the Geological Society at Burlington House. Here Mr. Campbell Smith had arranged an interesting collection of apparatus and specimens. The latter included a beautiful set of gold nuggets, got together by one of the oldest members of the Mineralogical Society, Prof. Liversidge. The apparatus, consisting of goniometers, refractometers, etc., all of British workmanship, was mostly of recent design, but part was old and of historic interest from its association with earlier workers. After the formal reception the President delivered a short address dealing with the history of the Society, its relations with other kindred societies, and the main lines of work which it has accomplished and published.

The exhibits at the Geological Society's rooms were on view during the following day, September 22, and were visited and examined by many who had had too little opportunity on the previous evening. By kind permission of the Provost of University College, parties were also able to visit at 134 Gower Street the beautiful collection of Vesuvian rocks and minerals formed by the late Dr. H. J. Johnston-Lavis, and bequeathed by him to the University of London. In the afternoon the party was received at the Imperial Institute by Sir William Furse and Sir Richard Redmayne, who gave an account of the collections, and the intention of those in charge to make the Institute a new educational instrument with the definite aim of illustrating the products and characteristics of the various parts of the British Empire. The party then proceeded to the British Museum (Natural History), where they were received by the Trustees, the Assistant Secretary, and the Keepers of Mineralogy and Geology, and were shown some of the chief features of the Mineralogical Collections. Afterwards the party were photographed and entertained at tea provided by the Government.

The London part of the celebration closed with a dinner at the Connaught Rooms, at which about seventy were present, the chief speakers being Dr. Harry von Eckermann (Sweden), Prof. Paul Niggli (Switzerland), Prof. F. Wigglesworth Clarke (U.S.A.), Prof. J. L. H. Borgström (Finland), Prof. F. Rinne (Germany), and Dr. H. Ungemach (France), for the foreigners, and Sir Henry Miers, Sir Thomas Holland, Sir John Flett, and the President of the Mineralogical Society, for the hosts.

Letters were communicated, bearing messages of congratulation from many foreign societies which had been unable to send representatives to the gathering, among the most interesting being those from Prof. Victor Goldschmidt of Heidelberg, from Prof. Paul Groth, Prof. A. Lacroix, Prof. E. S. Dana, the veteran Gustav Tschermak, Dr. H. Michel, Prof. J. Morozewicz, Prof. F. J. Becke, Prof. F. Zambonini, and the Mineralogical Societies of Vienna, Russia, Hungary and America. Addresses were read and presented from the Geological Societies of Poland and Cornwall, and it was resolved to send telegrams of greeting to Prof. Tschermak, Prof. Dana, Prof. Goldschmidt, and Prof. Groth representing the oldest of the honorary members of the Society, and to Mr. B. Kitto, Prof. A. Liversidge, Dr. R. Pearce, and Mr. C. J. Woodward, veteran ordinary members of the Society, the last being one of the two survivors of the Crystallological Society.

On the following morning about a dozen left Euston for the north of England with Prof. A. Hutchinson of Cambridge, to study the Shap and Carrock Fell areas, the Alston district, and other famous mineral localities. The excursion closed at Cambridge on Friday, October 1, with visits to the Mineral Laboratories of the University and of Dr. A. E. H. Tutton.

The President of the Mineralogical Society, Prof. W. W. Watts, in his presidential address, extended a very warm welcome on behalf of the council and members of the Society to those who had come from far-distant parts of Europe and America to join in the celebration. He pointed out that the Society was not the first of its kind in Great Britain, but had been preceded in 1799 by a body who formed "The British Mineralogical Society," and continued active for seven years when they rejoined the Askesian Society, a selected number of which formed the nucleus from which the Geological Society grew. The minute book of that old Mineralogical Society is still preserved in the Science Library, and by the kind permission of Sir Henry Lyons was exhibited at the conversazione.

In the same year as the Mineralogical Society was founded, a more academic body, at first called the Crystallometric Association and afterwards the Crystallological Society, was formed, but it amalgamated with the Mineralogical Society in 1883, bringing with it such men as Maskelyne and Lewis, Fletcher and Miers, who afterwards served as presidents. As a result of this happy combination, the Mineralogical Society was free to publish crystallographic as well as its other purely mineralogical work.

The Society was fortunate in securing Henry Clifton Sorby as its first president and keeping the "Father of Petrology" in the chair for three years. His influence on the Society was very great, both in the optical and microscopic work which he founded, and in adding the advancement of the knowledge of petrology as one of the objects of the Society.

Sorby was followed by a line of presidents each of whom rendered conspicuous service to the science and to its Society; Heddle, with his long list of works on Scottish mineralogy; Bonney, with his series of papers on rocks and rock-forming minerals; Hudleston, of wide travel and critical instinct; Scott, with his broad chemical knowledge and his service to the finances of the Society; Fletcher, who not only wrote a series of masterly papers on meteorites but also revolutionised

crystal-optics by his conception of the optical indicatrix; Maskelyne and Lewis, professors of mineralogy at Oxford and Cambridge respectively, famous for their crystallographic work,—to mention only some of those who are no longer with us.

The work of these men reflects that of the Society. Always there have been pure mineralogical papers dealing with mineral types or mineral groups, topographic papers concerning areas at home and abroad famous for their unique or abundant minerals, and petrographic papers dealing with the naturally occurring associations of minerals. These have depended upon chemical analysis, measurement of crystals, and determinations of optical characters as revealed by the microscope and other optical instruments.

In addition to this there have been a number of papers devoted to the mathematical aspects of crystallography, to the expression of internal structure by outward form, to the physiology of mineral growth, repair, and destruction, to the minerals used as gems or for other economic purposes, their associations and genesis, and of later years to the atomic and molecular structure of crystals as revealed by X-ray analysis.

The organ of the Society, the *Mineralogical Magazine*, has appeared regularly throughout the life of the Society and, in addition to original communications read at the meetings, has contained abstracts and reviews, and lists of new mineral names. During the last few years (since 1920) the Society has published sections of mineralogical abstracts. These give concise accounts of mineralogical papers and works published elsewhere, and have been of the greatest service to all workers in mineralogy, crystallography, and petrology. Indeed, the Society has never been more active than at present, and there is every promise of a brilliant and useful future.

Classification of Amœbæ.[1]

THE purpose of the memoir before us is to set forth a description of 39 new species and 11 new genera of Amœbæ and to propose a classification of Amœbæ. That a revision of the systematics of Amœbæ is desirable is unquestioned. The author has endeavoured to obtain a secure basis for his revision by prolonged observation of the various species, several of which have been raised in cultures from a single example. Variations within the species such as have been frequently assumed and even asserted to occur by some writers were not found, and the author states that most free-living amœbæ can be recognised specifically at least as readily as ciliates or beetles. No special difficulty is met with in classifying about three-fourths of all the known species of Amœbæ, but the remainder are small species the morphology of which has not been studied with sufficient care for the purpose. The supposed shapelessness of Amœbæ has led to previous attempts to classify species wholly with respect to nuclear characters, but the author states that such a systematic basis is no more defensible here than it would be in other protozoa. The genus Protamœba has been defined as lacking nucleus and vacuoles; the author suggests that the enucleate daughters which occasionally arise during fission of an amœba have provided the basis for this genus, the validity of which he therefore doubts, and Gloidium has scarcely a better standing.

Prof. Schaeffer differentiates pseudopodia into determinate and indeterminate. The former grow to a more or less definitely limited size and are then withdrawn; they are generally conical and composed of clear protoplasm only, and they are usually extended only on an advancing part of an amœba. Indeterminate pseudopodia are not restricted as to size; they direct locomotion and may grow large enough to form the entire amœba. They are more or less cylindrical and filled with granular protoplasm.

In putting the question "How many good species of Amœbæ are now known?" the author states that it is not yet possible to give a definite answer. The large, free-living species hitherto described amount to about 85; the parasitic and culturable species are about 70, and with the new species described in the present paper the total number approaches 200. A natural system of classification of the amœbæ must be based on the larger species, and it is with these the author chiefly deals. The changes of form exhibited by an amœba are characteristic and provide the basis for a natural classification. He regards Trimastigamœba, a minute amœba which can take on a flagellate condition, as the most primitive genus.

Prof. Schaeffer describes the different conditions—natural and cultural—under which he has observed his material. He states that no species has yet been found to live and reproduce in both fresh and salt water, though one species can be transferred from sea water to fresh water without apparent injury, and will live about ten days, but reproduction was not observed. More species of amœbæ and more individuals are to be found in tidal pools rich in diatoms than under any other conditions.

The author discusses problems of nomenclature and considers that 'Amœba' must go and be replaced by 'Chaos,' and that the Amœba first called 'der kleine Proteus' (Roesel, 1755) is the same as *Proteus diffluens* Muller and the correct name is *Chaos diffluens*. On submitting this conclusion to about a score of representative American zoologists, the majority expressed their general agreement, but the author wisely remarks that it might be desirable to bring the case before the International Commission for consideration and decision.

The main part of the volume is devoted to careful descriptions of the species, and these are supported by excellent lithographed figures. The memoir forms a most important contribution to the systematic study of Amœbæ.

Ventilation in Factories.

THE importance of a proper system of heating and ventilation in factories for the comfort and health of the workers need not be emphasised. Considerable difference of opinion as to the correct system probably exists amongst engineers, so that a scientific examination of various common methods should prove of value in selecting that one which the workers find most satisfactory. Dr. H. M. Vernon and T. Bedford[1] have recently made a physiological study of the ventilation and heating in certain factories.

[1] Medical Research Council: Industrial Fatigue Research Board. Report No. 35: A Physiological Study of the Ventilation and Heating in certain Factories. By H. M. Vernon and T. Bedford, assisted by C. G. Warner. Pp. iv+82. (London: H.M. Stationery Office, 1926.) 3s. net.

Continuous records of air velocity and air temperature were taken by means of the hot-wire anemometer and the thermopile respectively. Vane anemometers to determine the directions of the air currents were also used, as well as the katathermometer for direct estimations of the cooling power of the air. The following may be considered the criteria by which a heating and ventilating system should be judged. The room should feel comfortably warm and fresh, yet be without draughts, the temperature at head level should be cooler than that at the level of the feet, and the incidence of sickness and ill-health should be a minimum.

The ideal temperature appears to be about 60° F.-63° F. The cooling power should be 7·0 in winter and about 6·0 in the hot weather, the difference being due to the acclimatisation of the body to the different seasons. These cooling powers can be attained with air velocities of 30 ft. per min. in winter and 50 ft.-100 ft. per min. in summer. The room feels 'too warm' when the temperature rises 4° F. and the cooling power falls one unit, and 'too cold' under the reverse conditions.

An important index of the actual temperature conditions is the temperature gradient from the floor level to the region of the head or higher. It is greatest when the heating system is placed above the heads of the workers: in fact, such a system is roundly condemned as leading to cold feet and hot heads and their accompanying discomforts, and should only be used in conjunction with a heating system at a lower level, when it is desired to avoid down draughts from skylights. The lowest gradient was found when the heating system was placed *under* the floor, and when at floor level it was nearly as satisfactory. The temperature used should not be too high, else the air currents induced become too rapid. It is important that these should be directed upwards, since expired air travels upwards, being lighter than room air, and hence with a down draught there is danger of the workers having to breathe each other's expired air, with the attendant risks of possible infection.

The system of ventilation which gave least draughts and yet most freshness to the air was one of natural ventilation by means of windows, with fan exhaustion in addition if necessary; the outlets for the latter should be situated 7 ft.-8 ft. above the floor. If a plenum system is installed, it should deliver the warm air near the floor from small inlets, and not from inlets situated above the heads of the workers; the latter leads to discomfort and is wasteful of energy. A plenum system delivering *cool* air above head level in conjunction with floor warming gives the most satisfactory type of heating when natural ventilation cannot be utilised.

The efficiency of any given system can be determined from the cooling power and its velocity and temperature components, together with a knowledge of the available window area and the extent to which it is utilised. The latter should be considered relative to the floor area and not to the cubic capacity of the room, since the ventilation is slightly better in a higher room than in a lower one with the same window and floor area.

Evidence is adduced in the report to show that the incidence of sickness is less in workrooms with a good ventilation and a satisfactory mean temperature. The report should, indeed, be studied by all who take part in the designing of modern factories.

International Agreements affecting Port Sanitary Work.

SIR GEORGE BUCHANAN gave a valuable address upon the above subject at the conference of Port Sanitary Authorities during the recent London congress of the Royal Sanitary Institute. He had recently attended on behalf of the British Government the fourth International Sanitary Conference at Paris, at which seventy nations were represented; and he considered that some good results had been achieved. The conference was held with the object of revising and bringing up-to-date the International Sanitary Convention, 1912, under which the various signatory governments agreed upon mutual action and common standards for dealing with the diseases liable to be carried on ships, including cholera, plague, typhus, smallpox, and yellow fever. The conference laid down some new lines of international action which are of great importance to British port sanitary authorities, on whom rests the daily burden of protecting their ports, as well as the rest of the country, from the risks from the importation of these diseases.

The deficiencies of the 1912 International Sanitary Conference have been obvious for many years. To take one example: a ship was only held to be 'infected' with plague when human cases of the disease had occurred during the voyage; but the most dangerous ship of all, with swarms of rats among which plague is prevalent, was not so classified and therefore came under no regulations.

In the new Convention an effort is made to increase the measures whereby countries may obtain all possible intelligence regarding the prevalence of certain infectious diseases. It gives further encouragement to the existing system of interchange of information regarding the incidence of infectious diseases by requiring the signatory governments to reply to any inquiries addressed to them, from the Office Internationale d'Hygiene Publique, for information on any subject affecting the risks of transmission of infectious disease from one country to another. Thus the Office Internationale will discharge the duty of acting as a kind of clearing house for information; and it is authorised to make agreements which will avoid duplication of effort.

In reference to plague, the establishment of new definitions by which a ship with plague-infected rats becomes an 'infected' ship, and a ship with an unusual mortality among rats, a 'suspected' ship, was readily agreed to, as was also the authorisation of measures to prevent rats reaching the shore directly or through merchandise. In ports designated as sufficiently equipped to undertake effective rat destruction, systematic measures will be required to be undertaken once in six months, and a certificate that this has been done, specifying methods and results, will carry the ship on to the next half-yearly period. The inspection officer is authorised to exempt from systematic measures when circumstances permit, and to issue an exemption certificate, which is also valid for six months.

In case of other diseases the measures required by the new Convention have been made to conform to our latest knowledge and experience; and all those applicable to the ship, passengers, and crew have been made strictly reasonable, the aim being to make them more efficacious and, where possible, less burdensome. Seeing how much of the world's immunity from pestilence is due to the measures outlined above, and to the spade work of the port sanitary authorities and their officials, the public has reason to be grateful to the representatives of the seventy nations for the valuable work they have accomplished.

The Measurement of Ocean Currents.[1]

THE application of Bjerknes' circulation theory to the movement of water masses in the oceans has provided a method of increasing utility for the study of ocean currents. If the temperature and salinity of the ocean are given for several known depths at several positions, the difference in velocity of the current at the surface and the various depths can be computed and mapped. It is frequently possible to make observations down to a depth where it may be assumed that no appreciable current exists.

In 1914 a survey in the neighbourhood of the River St. Lawrence was carried out for the Canadian Government by Dr. Johann Hjort and the data obtained were worked up by Prof. Sandström, whose explanation of the theory and its application in hydrography has hitherto been the only work of the kind in the English language. It is not without interest that this neighbourhood is stated to be the first to be charted by a vessel employed solely for that purpose, and that this survey was conducted by Captain Cook immediately previous to his expedition of discovery to the South Seas and the Pacific, which resulted in the addition of Australia to the British Empire.

The U.S. Coast Guard in *Bulletin* No. 14 has published a full account of Bjerknes' theory and the method of its application by Lieut.-Commander E. H. Smith, who is in charge of the scientific work carried out by the Atlantic Ice Patrol, a service inaugurated after the loss of the *Titanic* to warn vessels passing south of Newfoundland of the position of the larger icebergs, of which the Patrol follows the drift. The account is based on a series of lectures by Prof. Helland-Hansen at Bergen, and the examples by which the practical application of the theory is illustrated are taken from observations by the Ice Patrol. It is of particular interest that " the currents calculated from the observational data collected in 1922 off the Grand Banks agree very closely with the drifts of the icebergs of that same year and region " Here the method shows every prospect of being of definite and immediate economic value.

The *Bulletin* contains two handy tables from Hesselberg and Sverdrup's formulæ, to allow for the effect of pressure at different depths upon the specific volume at atmospheric pressure, a correction which becomes necessary where considerable depths are investigated, as in this area. Taking this into account, the method of calculation employed, involving the calculation of the dynamic depth, is in the opinion of the writer not so simple as that employed by Sandström—both methods yielding the same final result.

It is noteworthy that the big German scientific expedition arranged by the late Prof. Merz, which is at present engaged in a very complete investigation of the physical conditions of the South Atlantic, has planned its route in such a way as to make full use of the application of this theory in determining the currents and consequent exchange of the water masses.

It is not unreasonable to hope that this method may provide the means of investigating fluctuations in the north-going current of warm Atlantic water which bathes the western coast of Great Britain and affects our climate and sea fisheries. H. W. H.

[1] " A Practical Method for Determining Ocean Currents," by Edward H. Smith, Lieut.-Commander U.S. Coast Guard. *Coast Guard Bulletin*, No. 14. Washington, 1926.

University and Educational Intelligence.

CAMBRIDGE.—Prof. A. C. Seward, in his address on resigning the office of Vice-Chancellor, announced the offer of 150,000 dollars from the Trustees of the Laura Spelman Rockefeller Memorial for the establishment of a chair of political science. The new Vice-Chancellor is the master of Sidney Sussex College, the Rev. G. A. Weekes. The late Disney professor of archæology, Sir William Ridgeway, bequeathed to the University his collections of Stone, Bronze, and Iron Ages, including his series of barbaric currency coins, his collection of barbaric jewellery and of articles of ancient pottery.

J. D. Cockcroft, St. John's College, and J. A. Ratcliff, Sidney Sussex College, have been elected to the Clerk Maxwell Scholarship.

LEEDS.—Mr. E. L. E. Wheatcroft has been appointed to the newly created chair of electrical engineering. Mr. Wheatcroft read mathematics and engineering at Cambridge. His practical training was gained in the works of the British Thomson Houston Company and, later, with the General Electric Company in America. He has had an extensive experience in certain phases of heavy electrical engineering (particularly in regard to problems relating to the generation and transmission of power), and has carried out a considerable volume of research work.

In making this appointment the University has in mind the desirability of developing the Department of Electrical Engineering. Compared with some parts of the country, Yorkshire has followed a progressive policy in the distribution of electrical power, and it is felt that this policy should be reflected in the attention paid within the University to the study of the scientific principles of electrical engineering.

LIVERPOOL.—By the will of Mr. Samuel Turner, who died on July 18, the residue of his property is bequeathed to the University " to be applied as the University authorities in their discretion may think fit for the furtherance and advancement of medical research into the diseases of phthisis and cancer, and any kindred diseases " The bequest will apparently amount to approximately 30,000*l.* but will not be available until after the death of Mr. Turner's widow.

LONDON.—The following free public science lectures are announced :—" The Philosophic Significance of Spiritual Values," Prof. G. Dawes Hicks (at University College, October 1) ; " Is Mind governed by Laws ? " Prof. C. Spearman (at University College, October 12) ; " The Motivating of Conduct," P. Hopkins (at University College, November 4) ; " Extreme Cold," Prof. W. H. Keesom (at Imperial College of Science, October 13) ; " The Interaction of Pure Scientific Research and Electrical Engineering Practice," Prof. J. A. Fleming (at Institution of Electrical Engineers, eight, beginning October 20) , " Some Applications of Modern Science, Prof. E. V. Appleton and others (at King's College, seven, beginning October 7) ; " The Place of Mind in an Organic Theory of Nature," Prof. C. Lloyd Morgan (at King's College, three, beginning October 19) ; " Evil Spirits in Babylonian Religion," C. J. Gadd (at King's College, October 25) ; " Early Arabian Tribes," S. Smith (at King's College, December 10) ; Swiney Lectures on geology, Prof. W. T. Gordon (at King's College, twelve, beginning November 5) ; " The Present position of the Logic of Induction," Dr. C. D. Broad (at King's College, December 1).

Contemporary Birthdays.

October 10, 1871. Earl of Crawford and Balcarres, K.T., F.R.S.
October 10, 1838. Prof. W. Carmichael M'Intosh, F.R.S.
October 10, 1861. Dr. Fridthof Nansen, G.C.V.O.
October 11, 1875. Dr. Arthur William Hill, C.M.G., F.R.S.
October 11, 1864. Sir Henry George Lyons, F.R.S.
October 12, 1868. Prof. John T. Hewitt, F.R.S.

The Earl of Crawford and Balcarres was educated at Eton and Magdalen College, Oxford. Sometime president of the Board of Agriculture and Fisheries, he has been, since 1923, Chancellor of the University of Manchester. Lord Crawford is a trustee of the British Museum, the National Gallery, and National Portrait Gallery.

Prof. W. C. M'Intosh, emeritus professor of natural history in the University of St. Andrews, is about to celebrate his eighty-eighth birthday. We extend our most cordial congratulations. A fellow of the Linnean Society for sixty-three years, he will, next year, attain jubilee fellowship of the Royal Society. Born at St. Andrews, and educated at its University, his interests have ever centred and been in alliance with those of the ancient northern city. To record his long series of memoirs in zoology would absorb much letterpress. A pioneer of research in fishery problems, he was the first to found a marine biological station in Great Britain. Prof. M'Intosh was awarded a Royal medal of the Royal Society in 1899.

Dr. Fridthof Nansen, the distinguished Arctic explorer and naturalist, was born at Store Frœn, near Christiania (Oslo), at whose University he was educated, and where, since 1908, he has been professor of oceanography. In 1893 he left in the *Fram* to conduct his famous Arctic expedition. The narrative of this great polar adventure is recorded in "Farthest North" (1897). Dr. Nansen was Minister for Norway, at London, from 1906 until 1908.

Dr. Hill was educated at Marlborough and King's College, Cambridge. University lecturer in botany at Cambridge from 1905 until 1907, he was afterwards, until 1922, assistant-director of the Royal Botanic Gardens, Kew, succeeding then to the directorship on the retirement of Sir David Prain.

Sir H. G. Lyons, Colonel R.E. (retired), is a Londoner. Educated at Wellington College, he passed into the Royal Engineers. Director-General of the Geological Survey of Egypt and allied departments from 1896 until 1909, he has been, since 1920, Director and Secretary of the Science Museum, South Kensington. He is Hon. D.Sc., Oxford and Dublin. A past president of the Royal Meteorological Society, he was awarded its Symons gold medal in 1922 for services to meteorological science, in particular, investigations into the climatology of Egypt and the Sudan. His studies relative to the changes in the level of the Nile and Victoria Nyanza are well known. Sir Henry is chairman of the National Committee for Geodesy and Geophysics (International Research Council).

Prof. Hewitt, emeritus professor of chemistry in the University of London (East London College), was born at Windsor. His studies were conducted at the Royal College of Science, the University of Cambridge, and at Heidelberg.

Official Publications Received.

Transactions and Proceedings of the New Zealand Institute. Vol. 56 (New Series), July 12th. Pp. xxii+860+114 plates. (Wellington, N.Z.: W. A. G. Skinner.)

Wigan and District Mining and Technical College. Calendar, Seventieth Session 1926–1927. Pp. xvi+145. (Wigan.)

the International Catalogue has scarcely been used at all by chemists. Chemistry, however, is exceptional; some other sciences are far less well served, and unless the societies concerned, or private bodies, intend to undertake the work of abstracting or of compiling bibliographies in a comprehensive way, there appears to be scope for an international effort of this kind.

Related to this subject of abstracts is that of the use of scientific and technical libraries. We greatly appreciate the action of those learned societies which open their doors to students and to others who are not members. For example, in 1919, as a result of a conference of chemical and allied societies, the Chemical Society extended the chemical equipment of its library and admitted as readers the members of the Association of British Chemical Manufacturers, the Biochemical Society, the Faraday Society, the Institute of Chemistry, the Society of Chemical Industry, the Society of Dyers and Colourists, and the Society of Public Analysts. The effect of this wise policy is partly shown in the number of books borrowed during the year. This has risen from 2905 in 1918 to 4050 in 1925. During the year 1925, there were 6994 attendances of readers in the Library of the Chemical Society, of which 4746 were made by fellows and 2248 by members of contributing societies.

There is, of course, a difficulty in opening the doors of a library too widely: there may not be seating accommodation for all who would come in. As time goes on, many scientific libraries find their shelves fully occupied and are at a loss to know how to provide room for the new volumes.

Some libraries contain many volumes they do not really need which would be much more appropriately placed in some other institution. The Association of Special Libraries will be doing good work if it takes this matter in hand and induces each library to exchange or dispose of such works as it does not need and thus make room for books or periodicals more directly connected with its own special subject.

It is by no means desirable that all the older scientific books should be destroyed on the ground that they are out-of-date, for many of these books are valuable historical evidence of the state of scientific knowledge and theory at the time they were written. Indeed, some of them contain original observations which have since been overlooked. But provided that it was assured that a certain number of copies of these works would be preserved, the remainder might cheerfully be removed.

The Association of Special Libraries is not, however, concerned alone with the use of books: its object is "to facilitate the co-ordination and systematic use of sources of information in science, industry, commerce, public affairs, etc." It was appropriate, therefore, that in a paper entitled "A National Intelligence Service," Mr. J. G. Pearce should raise the question as to what is the most efficient method by which scientific and technical workers throughout the country may receive early information about new discoveries and new developments in the subjects with which they are concerned.

A central institution of the kind would have classified index-cards, each bearing the full reference to a book or paper, with a summary of its contents. When it is remembered that some 24,000 periodicals which may contain scientific articles are published throughout the world, and that to this number pamphlets and books must be added, it will be seen that the number of index-cards required to be prepared every year would be very large, probably at least a quarter of a million. The work of selection and indexing must be done by experts in each subject, and then the cards must be written, typewritten, or printed. When an inquiry was received, the staff of the institution would look up the index-cards bearing upon the subject, and would send copies of these, obtained either by typing or by photography.

The Association proposes to make use of the special libraries and information bureaux which already exist in Great Britain. There are several hundreds of these, including the libraries of learned societies, universities, colleges, public libraries, libraries of research associations and libraries of manufacturers and business firms. The first step is the preparation of a Directory of Special Libraries in Great Britain and Ireland. The general editor for this Directory is Mr. G. F. Barwick, late keeper of printed books at the British Museum, whose name is a guarantee that the work will be well done. It is hoped to publish the directory in the summer of 1927. Such a directory will indicate the library or libraries where information on a given subject is likely to be found. Apart from this directory, the Association proposes to answer inquiries from its members as to the literature on a particular subject by giving the names of those libraries that are likely to be able to give the information required.

There are divergent opinions concerning the desirability and practicability of special scientific libraries undertaking the work of information bureaux. Libraries undertaking this work would require greatly enlarged staffs. Information-hunting is a long and arduous pursuit, and we are informed by two experts in this business that the average time required to answer a single inquiry is about two days. On the other hand, the expense should not be prohibitive, for, as Dr. de Vos remarked, an information service should be made to pay for itself: firms and individuals could

afford to pay high fees if they were relieved from doing the work themselves. A second difficulty would be to find the personnel. Information work demands very special qualifications, both in regard to knowledge of books and other sources of information, of at least one science, and a natural *flair* for finding things out. Special training might solve this difficulty to some extent, and a real demand would probably create a supply. Large firms and institutions would, however, probably continue to employ their own information officers, so that the work of information bureaux set up in connexion with special libraries would consist mainly in serving the needs of individuals and small institutions. A further hindrance to the realisation of the scheme would be found in the inability of scientific libraries owned by learned societies to undertake work for outside firms and individuals; charters of incorporation would have to be carefully scanned before action was taken.

The language difficulty is a perennial one in the sphere of the dissemination of scientific knowledge, present methods being prodigiously wasteful in time, effort and money. Translators who possess the qualification of expert knowledge of science and language, including its idioms and technical terms, are exceedingly rare, and as a rule the work is badly remunerated. At the Oxford meeting, Mr. P. K. Turner, of the Research Department of Burndept Wireless, Ltd., spoke in no exaggerated terms of these difficulties, and his suggested solution the adoption of an international auxiliary language—though old, is one that cannot be overlooked.

Following closely on the lines of the International Auxiliary Language Committee of the British Association, Mr. Turner considered the rival claims of a dead language, a modern national language, and an invented language, and came to the conclusion that Latin is too difficult for the purpose, a modern language would inevitably raise international jealousies, and that an invented language, easy to learn, precise, and capable of providing new words for new concepts, would be best. Of the artificial languages now current, only Esperanto, its offshoot Ido, and Interlingua (Latin without inflexions) are of serious importance, and of these Esperanto has undoubtedly made the greatest headway. We have recently read a scientific treatise on the elementary principles of radio-communication written in Interlingua, the language sponsored by Prof. G. Peano, of the University of Turin, and were much impressed by its ready intelligibility and its brevity; but probably any of the three languages named would serve, with or without modifications, for international abstracts and bibliographies.

The fact remains, however, that none of these invented languages has made any progress in the scientific world. Whenever they are suggested they seem to raise a perfect *furore* among partisans of the dead and national languages. We hold no brief for any one of these linguistic devices which, like shorthand, mathematical, chemical and musical notations, have been invented to serve a special purpose, but in view of the very great advantages that would follow the adoption of a suitable medium for international communications in science, we think that the subject should not be allowed to drop. If the world were ruled by reason (which it is not, and probably never will be) an international auxiliary language would have been adopted many years ago; it remains to be seen how far civilisation will succeed in promoting the dictates of reason against the opposition of instinctive tendencies and age-long prejudices.

Propaganda and Philosophy.

(1) *The Gist of Evolution.* By Prof. Horatio Hackett Newman. Pp. x + 154. (New York: The Macmillan Co., 1926.) 6*s*. net.

(2) *Selected Articles on Evolution.* Compiled by Edith M. Phelps. (The Handbook Series.) Pp. liii + 283. (New York: The H. W. Wilson Co.; London: Sir Isaac Pitman and Sons, Ltd., 1926.) 2.40 dollars.

(3) *Science as Revelation.* By John M. Watson. Pp. 303 + 7 plates. (New York: The Macmillan Co., 1925.) 10*s*. net.

(4) *God and Evolution.* By the Rev. W. R. Matthews. (Liverpool Diocesan Board of Divinity Publications.) Pp. ix + 58. (London: Longmans, Green and Co., Ltd., 1926.) 3*s*. net.

So far as one can see from current apologetic literature, England and America present rather a strong contrast. The religious problem across the Atlantic seems merely to be the limited one of evolution *versus* the book of Genesis, an issue which engaged the attention of Englishmen half a century ago, when Americans were getting over their disastrous civil war. The three volumes from America before us all deal more or less directly with the Fundamentalist controversy, the seriousness of which is not understood in England, where we are inclined to laugh at it. It is, however, no laughing matter. It is already being converted into a political issue; the "Bible Schools" where non-graduates are trained for the ministry are engaged in an industrious propaganda, and in some places no political candidate would stand a chance of election who did not profess 'Biblical' views, and no teacher in a public institution could retain his position if he favoured evolution.

(1) In his volume, Prof. H. H Newman, who

participated in the Scopes trial, contributes a brief and clear statement of modern biological doctrines, written for popular use and avoiding technical language so far as possible. The late Lord Acton somewhere tells a story of a great medical specialist unable to pronounce definitely upon a case brought to him. As a clear plain verdict was insisted on by the patient's friends, the great man replied: "I cannot tell you myself, but I can recommend you to fifty doctors who would." The fact is that ignorance can always be dogmatic, and this is where the conscientious man of science is at a disadvantage. "The chemist, the astronomer, the geologist, equally with the biologist and the physicist, feel the inadequacy of their present knowledge of their subjects," writes Prof. Newman. The Fundamentalist has no such searchings of heart, and his omniscience is a controversial asset. Still, we may hope that Prof. Newman's "Gist of Evolution" will be read and pondered by intelligent people in America. It is admirably lucid, its topics are well chosen, and it is neither heavy nor verbose.

(2) Miss E. M. Phelps's book is a compilation of carefully selected articles on evolution, expressions of opinion on both sides of the controversy being included. We cannot imagine anything more useful for one anxious to get a clear grasp of the issue. Although a number of these articles might be selected for attention, that of Prof. John Dewey strikes us as peculiarly valuable as a diagnosis of the situation. It appeared in the *New Republic* of April 2, 1924. He points out that whereas in times past there were two parties to a dispute of this kind, *i.e.* the theological and the scientific specialists, nowadays there is a third, the general public. The real issue now "concerns the growing influence of the general public in matters of thought and belief, and the comparative failure of schooling up to the present time to instil even the rudiments of the scientific attitude in vast numbers of persons, so as to enable them to distinguish between matters of mere opinion and argument and those of fact and ascertainment of fact. . . .

"The realities of the situation centre about what can be done to ally the forces which have democratised society with the mental and moral attitudes of science. The worst of the predicament is a tendency towards a vicious circle. The forces that compel some degree of general schooling also make for a loose, scrappy, and talkative education, and this education in turn re-enforces the bad features of the underlying forces."

(3) These remarks seem applicable to the third volume under review. Mr. J. M. Watson's "Science as Revelation" is a book of rather ambitious scope, attempting to put in clear, brief, and popular form the results of research in all the sciences from physics to psychology. There follow two chapters on ethics and philosophy, and then two more on the new religion, and the new revelation, of science. We are inclined to think that so far as religion and ethics are concerned, our author unduly simplifies the problems. The real issues, namely, as to whether biological science does supply us with an enlightened ethic, and whether the cosmic process is for us or against us (as Huxley taught), he does not seem to face. He sometimes covers up the difficulties with rhetoric, as when he tells us that "Truth is the ONE GREAT GUIDE, and he who closely adheres to it cannot possibly go wrong." Surely this is prolix nonsense: for what the truth is about these matters is just what we would like to discover. Mr. Watson evades the real religious problem, which is not: Does God exist? but, What sort of a God exists? The book seems to us to preach a sort of inverted Fundamentalism; it strikes us as well-intentioned but shallow.

In England, as was observed above, the Genesis *versus* science issue has retired into the background. This may be because there exists a higher level of general education and intelligence in this country; or it may be that amongst ourselves the general public takes little interest in religious problems, so that they are left to the experts who naturally treat them with more intelligence. Between these alternative explanations, we hesitate to pronounce. At any rate, in reading Dr. Matthews' book (4), we breathe a different air; the atmosphere of embittered polemics is absent.

This does not mean that Dr. Matthews sees no important difference between the views he himself holds and those held by some evolutionary philosophers and men of science. He devotes a certain amount of attention to Mr. H. G. Wells and Mr. Bernard Shaw; but, as he says, "there is no arguing with prophets," and we are relieved when he turns "to the less inspiring but more coherent writings of systematic thinkers." His treatment of Prof. Alexander interests us most. There has always seemed to us a difficulty, or even an inconsistency, in the views of this highly original thinker. He asserts that there exists in the universe a tendency, or 'nisus,' to produce a series of qualities of existence; a series like a hierarchy of values which increase as the process continues. We have matter, life, mind, and, in due course (we may hope), deity. But there is no 'purpose' or plan behind this. The elements of the series just 'emerge'; and we must accept their 'emergence' with 'natural piety,' *i.e.* with a devout agnosticism. But what *is* this 'nisus'? Is it just a word to signify that the world is so constructed that, as a matter of fact, it does produce what 'emerges' (in which case the word really has no meaning)? Or does it signify that there is an 'urge'

in the universe which makes it creative? If so, we have got something indistinguishable from 'purpose.' Prof. Alexander is too clear a thinker to talk about 'unconscious purpose,' which is a contradiction in terms, and he prefers not to use the word at all. But 'nisus,' if it means anything, must end by meaning this.

Dr. Matthews seems to us at his best when engaged in philosophical criticism. We doubt if many biologists would follow him in attaching much importance to the views of Driesch, and although all the world recognises the debt which physiology owes to Dr. J. S. Haldane, few take his vitalistic theories seriously. The tendency now is clearly and strongly in favour of mechanistic interpretations. One strong point in Prof. Alexander's work is that he recognises this. We doubt if Dr. Matthews strengthens his case by patronising obsolete scientific theories. The most damaging criticisms of naturalism come from insistence on "the difficulties which inhere in any philosophy which excludes all idea of a supra-temporal reality" (p. 37). As a philosophical system, evolutionary naturalism is beset with difficulties: as a religion, it "is founded on as great an act of faith as any which the Christian doctrine of God requires of us." How true this is—but how unpopular!

We may hope that many students of science, as well as students of theology, will peruse these lectures. They are of a very high quality. We should like to wish them a good circulation in America as well as in Great Britain, when the contagion of Fundamentalist frenzy has passed.

J. C. H.

The Races of Mankind.

(1) *Les races et les peuples de la terre.* Par Dr. J. Deniker. Deuxième édition revue et considérablement augmentée. Pp. 750. (Paris: Masson et Cie, 1926.) 75 francs.

(2) *Race and History: an Ethnological Introduction to History.* By Prof. Eugène Pittard. (The History of Civilisation Series.) Translated by V. C. C. Collum. Pp. xxiii + 505. (London: Kegan Paul and Co., Ltd.; New York: Alfred A. Knopf, 1926.) 21*s.* net.

THE reluctance of anthropologists whole-heartedly to apply to the human family the strict principles of classification and phylogenetic arrangement adopted in the wider field of biology is a very curious phenomenon. Yet it is a fact that students of man, even biologists, commonly disregard the significance usually associated in biology with such terms as race and species; and even when this element of confusion is eliminated there still remains some uncertainty as to what constitute the criteria of race. Many years ago Huxley humorously claimed exemption from the disturbing influence of race consciousness that so obviously distorts the outlook of many, if not most, writers on anthropology, on the ground that he enjoyed the serene impartiality of a mongrel.

This factor of personal or racial bias has been a potent factor in causing confusion in the study of race. When, early in the nineteenth century, efforts were made to emancipate the Greeks from Turkish rule, ethnology was used as a political instrument. Ever since then scarcely any national or social conflict anywhere in the world has been free from anthropological irrelevances, which have had the disastrous effect of hampering the calm and dispassionate study of a subject that teems with intrinsic difficulties. One has only to recall the distorting effects of such national prejudice in the claims for Teutonic ascendency and the northern origin of civilisation, the conflicts associated with the phrases 'Yellow Peril' and 'Nordic Race,' and the ever-present antagonism between black and white in the United States, to realise how scientific impartiality has been warped.

Even when such influences are exorcised, two other disturbing factors remain. There is first the selection of the qualities to be used in the determination of race and the estimation of their relative value. Secondly, the factor of racial admixture must be given due consideration by making allowance for its effects. The chief element of confusion in the definition of human races has been due to the former factor, and especially the lack of a due sense of proportion. Examples of this are the exclusion of Bushmen from the Negro race because their skin is not black, suggesting a close affinity between aboriginal Australians and Europeans because there are similarities in the hair, or between Negroes and Mongols because they both have flat noses. But perhaps the most potent element of confusion is the persistence of the term Caucasian, which involves the failure to accord adequate recognition to the fact that there are at least three definite and distinct races, commonly called Mediterranean, Nordic, and Alpine, in the population of Europe and western Asia. Even when the six easily differentiated races—Australian, Negro, Mongol, Mediterranean, Alpine, and Nordic are recognised, there still remains the problem of assigning to each its degrees of affinity to the rest. This can only be done by devising a tentative phylogenetic tree to indicate which races are primitive and which are specialised or advanced.

No work has yet been published that deals with the question of race in such a way as to give adequate recognition to these principles, but the books by Dr. Deniker and Prof. Pittard make a serious attempt to introduce some sort of order and a right perspective

into these questions and to deal with the problems of race in a strictly biological way. They also emphasise the need for caution—never more necessary than at the present time—of not confusing race with culture, language, political aptitude, or distinctive moral qualities.

(1) Of the works dealing with the whole world, perhaps the sanest and the best-balanced is that written in 1900 by the late Dr. Deniker, the learned librarian of the Natural History Museum in Paris. By dealing with both race and culture in intimate association one with the other, he was immune from the sort of errors which writers are liable to commit when they deal with only one aspect of anthropology and neglect the other. Another factor that enhanced the value of Dr. Deniker's book was the information derived from Russian and other Slavonic literature, which is a sealed book to most western anthropologists. At the time of his death in 1918 he was engaged in the task of preparing a revised and considerably enlarged edition of his excellent book. With the help of a number of his colleagues in Paris the author's family has just brought out this new edition after a lapse of eight years. During this time anthropology has made great strides. Hence this book can scarcely be regarded as quite up-to-date. Nevertheless, the improved edition of a book which for more than a quarter of a century has been the standard text-book on the subject is most welcome.

(2) In his foreword to Prof. Pittard's book, M. Henry Berr tells us that in 1912 Dr. Deniker promised to write a volume on race and history for the series of monographs he is editing under the title " L'Évolution de l'humanité " (which is now being issued in English under the general title " The History of Civilisation "). On the death of Dr. Deniker he entrusted the task to Prof. Eugène Pittard, of the University of Geneva, who is well known as an industrious and careful worker in physical anthropology, especially of Switzerland and the Balkan area.

The book is not a treatise on race, nor does it deal in the strict sense of the term with history. It is rather a series of essays on some of the more contentious problems in which factors of race came into some relationship with history. The method of treatment is cautious, if not elusive. In fact much of the book is written in the form of questions to which the author gives no decisive answer. Here is a typical example of Prof. Pittard's method of exposition :

" The abuse of the influence of physical environment as the principal determinant of variations in man reveals to us another attempt at facile explanation in the application of the law of minimum effort. What has not been solemnly put down to it ? With what assurance has it been sought to convince us that environment is everything, that men are eminently plastic beings, submitting without protest to every sort of influence ! No single character could resist the moulding hand of environment, that all-powerful sculptor who, just as education renders our intellect and moral character rigid, petrifies as with a glaze our different morphologies. Has not the influence of environment been invoked to explain the anatomical variety seen in Jews, thenceforward acquired by very reason of such influence ? Does not the morphological Americanisation of various European immigrants in America call, on certain points, for all reserve on our part ? What mechanism other than hybridisation could environment employ to mould the cranial character of the new Americans ? No one is able to tell us." (P. 14.)

This quotation is typical of the style and method of the book as a whole. Two-thirds of the volume are devoted to Europe. The remaining third deals with Turks, Phœnicians, Jews, Arabs, Iranians, and Tatars, with brief essays on the peoples of India, China, Japan, Egypt, Mexico, the Malay Archipelago, and Oceania.

The book as a whole is a welcome corrective to much that is misleading and confusing in modern anthropological literature. Prof. Pittard does occasionally relent from his attitude of cautious avoidance of direct expression of his views. On most of these occasions he reveals a very conservative adherence to the opinions generally held by French anthropologists, and in particular by Prof. Boule. Thus he accepts without question the opinion that the figurines of the so-called Upper Palæolithic, so misleadingly described as steatopygous, afford evidence of the former presence of people of Hottentot affinities in Europe, a fallacy that Prof. Verneau justly exposed in his Huxley Lecture to the Royal Anthropological Institute in 1924. But Prof. Pittard also adopts Prof. Boule's theory that Verneau's Grimaldi race is really negroid and affords corroboration of the Hottentot speculation ! Having recently examined the two skeletons from the Grottes des Enfants at Monaco, I am convinced that there are no just reasons for calling the 'Grimaldi race' negroid.

Prof. Pittard pours gentle scorn on the recent campaign in favour of the supremacy of the Nordic race. Nevertheless he ironically says that the

" despised brachycephals, these representatives of the inferior race *Homo alpinus*, would seem to have invented and propagated two things of capital importance to the progress of civilisation. It is to them that we probably owe the culture of cereals and animal domestication, and that is by no means a small contribution. It might even be said to outweigh a certain number of raids and massacres. Did not these inventions, indeed, have a larger part in determining social progress, and for a longer time, and was not their influence of wider extent than all the warlike disturbances of the Northerners put together ? "

There are, however, no valid reasons for assuming that the Alpine people did invent these fundamental contributions to civilisation. At the meeting of the Australasian Association for the Advancement of Science in 1921, Prof. Thomas Cherry set forth evidence establishing the fact that it was members of the Mediterranean race who made these inventions (see also NATURE, June 10, 1920, p. 474).

The problems of determining the ancestry and the original home of the human family, and whether men everywhere spontaneously invented the Chellean *coup de poing*—which Prof. Pittard calls the hypothesis of prehistorians—are brushed aside in two pages of provocative queries, none of which are answered. Instead of this Prof. Pittard says "an attitude of doubt is the wisest." "If an answer must be given to the question put, we shall have to be honest and say that we do not know."

The book affords an amazing revelation of the extent of the misconceptions concerning the Piltdown skull still entertained on the continent. The Piltdown cranium reveals a closer approximation to the condition found in the young chimpanzee than any other human skull does. Yet Prof. Pittard tells his readers (p. 56) that it "would seem to indicate a more highly evolved race" than Heidelberg man. But he goes further than this when he suggests

"the possibility of the Heidelberg race having given birth to the Piltdown race, and the Piltdown race of the type with progressive characters which we meet with in Aurignacian times."

In spite of these defects the book is valuable and interesting. If it adds a few more misunderstandings to the literature of anthropology, it more than atones for this by helping to remove a host of others.

In her translation Miss Collum has wisely kept as near as possible to a strictly literal version of the French. If at times the idiom is uncouth, it enables the reader to realise exactly what the author wrote in a highly controversial subject. The word 'humanité' would be more correctly rendered into English by 'mankind' and not by 'humanity.' The word 'peninsula' is wrongly spelt throughout the book. In fact both in Deniker's and Pittard's book there is an unusually large series of typographical errors.

G. ELLIOT SMITH.

The Influence of Science.

Science and Civilization. Essays Arranged and Edited by F. S. Marvin. (The Unity Series, 6.) Pp. 350. (London: Oxford University Press, 1926.) 6s. net.

RATHER more than nine centuries ago, Avicenna bestowed the title of "The Remedy" upon his great treatise on natural philosophy. It is not difficult to appreciate the meaning which lay behind the choice of this unexpected name: natural philosophy, or simply science as we prefer to call it now, was in Avicenna's opinion the cure for the manifold ills of mankind and a tonic to brace humanity for the future. The natural supplement to this opinion is Comte's statement *Savoir afin de prévoir*, which is the motto of the present book. It is now three years since "Science and Civilization" was first published, and because, amid the flood of ephemeral literature which issues from the innumerable presses of the world, those books which are of lasting value run a grave risk of being swept away, we are grateful to Oxford for this new and cheaper edition. The essays which Mr. F. S. Marvin has here edited are, indeed, so valuable and so inspiring that we could have wished for an even less expensive edition: six shillings, though a modest price for a book in these days, is still too much to allow of that wide diffusion which all of us would like to see in the present instance.

No one can feel satisfied with the results which the widespread teaching of science in Great Britain has so far produced. The majority of men appear not to have retained the merest fragment of the scientific facts they presumably learnt at school, and they certainly show no sign of having assimilated scientific principles and method. Even among men of science themselves it is not rare to find science regarded as a craft rather than as a philosophy, and a successful chemist or physicist is often on no higher an intellectual level than a skilled motor mechanic. In these circumstances, science will still advance so long as destiny throws up from time to time the man of insight and genius—the Dalton, the Clerk-Maxwell, the J. J. Thomson—but is that progress likely to be as thorough or as rapid as would be desirable? Is it in the least degree probable that the intellectual advance of the nation at large will keep pace with even a comparatively slow advance of science if present conditions continue? It seems that the answer to both these questions must be a regretful "No"; whereupon the further question arises: What will be the effect upon civilisation if the general intellectual level lags seriously behind the progress of science? In the last year or two this question has been discussed by several talented and imaginative novelists, philosophers and men of science, but we may draw a lesson from the past—the mobilisation of scientific resources for purposes of wholesale destruction during the War showed us only too well what fate may lie in store for the world if the powers and forces of science are misapplied.

It is a common plea that men of science, collectively, are not responsible for the evil uses to which mankind may put scientific knowledge, but is not the argument

fallacious? A man who invents a new weed-killer and leaves it lying about, so that his child poisons himself with it, cannot be absolved from blame on the score that his invention was wrongly applied. If a chemist produces a tremendously effective explosive, fully realising that in all probability the first use men will make of it will be to destroy one another, it is very difficult to acquit him altogether. Read this extract from an account of the Spanish operations in Morocco: "Like the fiery rain of Dante, the bombs crashed from the skies, smashing villages, burning crops, slaying the wounded and murdering women and children. . . . For these bravos of the air there were not even the usual sporting risks of war—no fearless hostile airmen to grapple with; no anti-aircraft guns to face. A good breakfast, a pleasant ride, a few brave men killed, a few children rendered homeless and orphans—then back to a good dinner." Has science, which made things like this possible, no responsibility? Am I my brother's keeper?

In a certain sense, of course, science is non-moral, and in the illustration given above it is clear that the wrongful action lay not in the invention of the weed-killer but in the carelessness which left it unguarded. Science *qua* science is not responsible for its misuse, and we are perfectly justified in insisting upon this when the opponent of progress points to the ruined village, the slave of cocaine or the blinded victim of the vitriol-thrower. It is, however, impossible to divorce science from the scientist, and the latter is human and shares human responsibilities. To adopt a sentence of Dean Inge's in a sense different from that in which he used it, "we must not regard the world of science as an objectively existing fact, wholly independent of us who observe it." The scientist, in fact, has a double duty: he must not only further the course of science but must also do his utmost to ensure the right use of the control of Nature he places in men's hands.

Such books as "Science and Civilization" are eminently serviceable for the latter purpose, since they make the unreflective man of science reflect and at the same time manifest to the general public, in a way which more technical books could not, what Sir Richard Gregory has happily called the "Spirit and Service of Science."

Of all the good things which Mr. Marvin has collected for us it is difficult to single out any particular essay for special mention, but the attention of all who are engaged in teaching science—whether in universities, colleges, or schools may be earnestly directed to the essay on "Science and Education." For the root of the whole problem appears to us to lie in the way in which science is taught, and more especially in the way in which it is taught in our schools. Mr. Heath's thoughtful study should be read by every schoolmaster, whether a science master or not, and although his warm approval of the methods of Sanderson of Oundle may leave some of us cold, all of us will realise better than we did before the magnitude of our responsibility and of our opportunity.

The essays which deal with the history of science in its social aspects are still, as when first published, the best of their kind; they show that a true internationalism, which the League of Nations is laboriously striving to effect in the world of politics, has already and for centuries past been effected in the world of science. Scientific internationalism, superior to but not destructive of local patriotism, affords the best safeguard for the future of civilisation, and Mr. Marvin and his collaborators have the solid satisfaction of knowing that they have made a not insignificant contribution to this end.

E. J. HOLMYARD.

Modern Industrial Chemistry.

(1) *An Introduction to Industrial Chemistry.* By Dr. S. I. Levy. Pp. xiii + 288 + 16 plates. (London: G. Bell and Sons, Ltd., 1926.) 15*s.* net.

(2) *Industrial Chemistry: a Manual for the Student and Manufacturer.* Edited by Allen Rogers. Fourth edition. In 2 vols. Vol. 1: Inorganic. Pp. xx + 511 + xxiii. Vol. 2: Organic. Pp. iv + 512-1267. (London, Bombay and Sydney: Constable and Co., Ltd., 1925.) 52*s.* 6*d* net.

(1) IN his introduction to industrial chemistry, Dr. Levy presents an aspect of a branch of technology which is not usually portrayed in treatises dealing with the application of chemical principles to factory operations. The new departure consists in directing special attention to the utilisation of all factors involved in efficient large scale production, these essential factors being grouped under the heading of "Costing."

As a typical example the author selects the manufacture of aniline from such commercially available materials as benzene, sodium nitrate, sulphuric acid, and iron filings. The factory method of keeping stock accounts of raw materials, intermediates, and final product is illustrated. Plant record sheets and overall consumption figures are also computed and furnish data for the tabulation of a flow sheet showing the efficiency of the process at each stage. The cost price of the final product is determined by drawing up a cost sheet, taking into account not only the price of materials but also overhead charges and the cost of various services. The exact incidence of the separate items on the cost of production is readily revealed by expressing these data in simple graphical form.

Following on this concrete example of the importance of process costing, the author deals with such typical large scale operations as heating and cooling, pulverising, mixing, filtration, extraction, distillation, sublimation, and desiccation. A short section is devoted to the works equipment required in the storage, transportation, and manipulation of gases, liquids, and solids.

A general survey of chemical industry condensed into 40 pages is so sketchy that it is of doubtful utility and detracts from the merit of a treatise which otherwise sets up a new standard of excellence among technological text-books. A similar criticism applies to the short chapter on the fuel industries.

To the topic of sulphuric acid, however, an authoritative chapter is devoted which contains valuable details and includes the author's war experiences as shown by the data then collected in regard to the relative costs of production of sulphuric acid by the chamber process and by the various contact processes. The concluding sections deal with the alkali industry and with the manufacture of intermediates and explosives. The economic factor is again emphasised and flow sheets are appended giving the costs of production of the principal service explosives.

As indicated by Sir William Pope in his introduction to this volume, the treatise is modelled on unconventional lines and may accordingly be read with advantage by every one interested in the industrial applications of chemistry.

(2) These two volumes are the fourth edition of a comprehensive manual written by a group of American chemists and covering a wide range of industrial topics.

Vol. 1, which deals mainly with inorganic subjects, commences with a chapter on general processes as carried out in the factory; but sometimes, as in the case of autoclaves, the information given is only slight. Water for industrial use, a matter of general interest, receives attention in a separate chapter having its own bibliography. A very readable essay on sulphuric acid contains interesting details, especially in regard to American practice, but English readers will be surprised to find no mention of Messel and his associates in the survey of the historical development of the contact process.

A chapter on elements and compounds, arranged alphabetically, contains references to these materials which are sometimes misleading and generally too fragmentary to be of any practical value. Cobalt is dismissed in a few lines as colour producing element, but its increasingly important alloys are not mentioned. Under the heading of hydrogen peroxide there is no reference to the concentrated forms of this oxidising agent. The statement that sodium nitrite is prepared by heating sodium nitrate and metallic lead refers to an unhealthy process which happily has become obsolete. Altogether this section on elements and compounds is a hopeless attempt to compete with the larger chemical encyclopædias.

Ozone is discussed in the foregoing section and again in the section on electro-chemical industries, so that in future editions the editor might well consider the desirability of having a separate chapter on the atmospheric gases, including in this section oxygen and ozone.

The second and larger volume of this treatise contains instructive essays on various industries based on organic chemistry. The products of the distillation of coal are discussed from different viewpoints in several chapters, and the destructive distillation of wood is the subject of a separate section. In view of the increasing production of synthetic methyl alcohol, a chapter might appropriately have been added on this alcohol and its derivatives, including formaldehyde and its industrially important condensation products. The section on explosives is too short to be of value for reference purposes, and the following statement is misleading (p. 1183): "Titra-nitroaniline (*sic*) made by nitrating aniline." The patented nitration starts from *meta*-nitroaniline prepared from dinitrobenzene.

There are, however, many excellent monographs in this organic section, and among them may be mentioned the informative articles on essential oils, perfumes, and flavouring materials, on resins, gums, and turpentine, and on leather.

What is Mind?

Mental Life: an Introduction to Psychology. By Dr. B. Edgell. Pp. xvi+275. (London: Methuen and Co., Ltd., 1926.) 7*s*. 6*d*. net.

PSYCHOLOGISTS are faced with the difficult task of clearly distinguishing their field of study, on one side, from philosophy and, on the other, from biology. The domains of other sciences were originally defined in naive, common-sense terms that raised no initial difficulty. On the basis of common experience every one knew what was meant by 'heat,' but with its scientific study, unexpected difficulties arose. The 'caloric' proved weightless, and 'heat' was then described as a mode of motion. The facts of radiation raised fresh difficulty, and theory gave, first, 'insensible heat' and then motion of an immaterial ether. This entailed the difficulty of a kinetic energy from which the term mass had vanished: to be dealt with in turn by recasting the meaning of energy in the light of electro-magnetic theory and the theory of relativity.

Still, however, the definition of 'heat' presents difficulties which are but evaded in the modern tendency to fall back on some reference to crude introspective evidence and common-sense belief such as: 'The agent which produces in us certain sensations.'

Put 'mind' in place of 'heat' and just because 'mind' is of greater interest we find that, before the days of experimental science, it had been so studied that the problem of its ultimate nature had already reached the almost hopeless position in which 'matter' and 'electricity' now find themselves. Modern psychologists are tempted to benefit by the experience of experimental science and leave to philosophy their ultimate problem. Not—What is mind? but—What are its activities? seems problem enough Psychology becomes the "science of mental life" (p. xi).

'Life' however is as elusive as 'mind.' Biology disowns the problem of 'life' and is content to be the 'science of living things.' Possibly, shorn of all that is best left to metaphysics, nothing remains of a 'science of mental life' that is not well within the purview of the 'science of living things'! Accept this conclusion and psychology becomes the 'science of behaviour.' But the crude facts of mental activity are known to every one, and even medicine has found in *mental* sickness, as opposed to *organic* lesion, the easiest explanation of certain forms of bodily incapacity. Explanatory theory in terms of 'unconscious mental activity' follows and leads the way into highly speculative regions of 'new psychology,' in which an attempt is made to supply the need felt of an abiding something that, through all changes, continues. Psychology becomes the 'science of the unconscious.' Physics in similar straits formulated the theory of the ether.

As a result of this difficult position, many an 'introduction' to psychology, after a few words on the foolishness of 'the old psychology,' reveals itself as concerned only with some particular modern development or school of thought It is therefore refreshing to meet a work that is entitled to its claim: an introduction to *psychology*. With clear knowledge of the 'old,' Dr. Edgell has reviewed much of the 'new' and given it its place in that evergrowing body of knowledge in the formulation of which Aristotle played no unimportant part.

The general line of treatment follows James and Ward and brings their work up-to-date with new facts and theories that have taken sufficiently definite shape to be presentable in form suitable for the general reader and beginner.

Controversial matter has of necessity been included, and psychologists will welcome the author's statement of position on 'Freudian theory' and 'behaviourism.' Considering the theories of Freud, Adler, and Jung, she writes: "All attempts to reduce primitive values to one inclusive category seem futile, for, even when combined, these three types of appeal may be far from exhausting primitive possibilities" (p. 157). Then, dealing with Freudian theory in more detail, "It may well be that, notwithstanding the success attendant on psycho-analysis, the unconscious as conceived by Professor Freud, is a 'false cause' . . . the Freudian theory appears to conflict with any intelligible view of mental life" (p. 160).

In opposition to the narrow Freudian view of 'the unconscious' the author uses the term for the "organisation of meanings and values (knowledge and character) . . . the abiding structure of mind" (p. 158). This leads to interesting corollaries including apparently a disavowal of the fundamental Freudian belief in unconscious mental activities (p. 173).

Behaviourism is reviewed in an appendix. The inadequacy of the experimental basis to support the deductions drawn therefrom is stressed. Really to secure the behaviourist position "conditioned reflexes should be established in circumstances where there is reasonable evidence of the complete absence of what the psychologist calls consciousness" (p. 265). Behaviourism "breaks down as a system of psychology and is no more successful in shelving the problem of mind and body than was its precursor, epiphenomenalism" (p. 268).

The definition 'science of mental life' also attempts to shelve the difficulties surrounding the idea of mind as an abiding entity (p. xi), but leads to a position almost identical with that of James when he wrote: "The thoughts themselves are the thinker." "We must be on our guard," writes the author, "against treating . . . the subject or individual experient [as if he] were something over and above his experience" (p. 19). We find difficulty in attempting to harmonise this with the 'unconscious' as "an organisation . . . the abiding structure of mind" Then we realise that much of the book is concerned with this 'structure' rather than with 'experience,' and reading, "This structure is being built up by the events of mental life; in its turn it determines the function of mental events, their meaning and their value" (p. 126), we again grow hopeful that it will yet be possible for psychologists to follow Prof. McDougall back to the definition 'science of mind' as the best to cover both "facts of mental activity and facts of mental structure" ("Outline of Psychology," p. 41). In such a definition any particular theory of the ultimate nature of mind is no more posited or necessary than were theories of the ultimate nature of electricity and matter in the original definitions of the fields of study of the physicist and chemist.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Spectrographic Junction between the X-ray Region and the Extreme Ultra-Violet.

IN previous papers (*Comptes rendus*, **182**, 1083, and **183**, 193, May and July 1926) a method was given, suitable for spectrographic work in the unknown region between 20 and 150 Ångström units. In the meantime, some $K\alpha$ lines belonging to light elements (oxygen, carbon, boron), and a few N barium lines, have been measured. It was interesting to apply the new method to the detection of lowest frequency N and O series of a heavy element. Thanks to the kind help of Dr. Holst, Director of the Philips Laboratory, I obtained a sample of thorium wire, prepared by Dr de Boer, and I used it as a hot cathode in the X-ray tube of my vacuum spectrograph. With an exposure of 4 hours, with a current of 20 milliamperes under 2·8 kilowatts peak value, I obtained good thorium spectra The middle part of each plate is covered by a filter consisting of goldbeater's foil, $7 \cdot 10^{-6}$ cm. thick, used to estimate penetrating power and order of spectra. All the lines detected are new N and O thorium lines of very low frequency. A very strong 45·3 Å.U. line coincides with the $K\alpha$ line of carbon, but is a different one. This is proved by three facts that tantalum, molybdenum or zirconium hot-wire cathodes, used in the same conditions, do not show the carbon line; that the thorium deposit on the target was very important and visible to the naked eye; that measurements of critical potentials, made with another apparatus, by the ionisation method, do not show at all the carbon K critical potential (287 volts) but the two well-defined N_3 (355 volts) and N_{12} (312 volts) thorium critical voltages, corresponding to the respective emission of 45·3 and 51·5 Å.U. lines.

The strong 45·3 Å.U. line appears in three successive orders and covers, by its broadness, a new line, 48·2 Å.U., which appears only in the second order. This one cannot be the first order line, as it is shown by application of the combination principle, and is, in fact, the highest frequency line in the O series. All the recorded lines fit very closely into the theoretical requirements Only one line, O_5P_3, is missing, probably owing to faintness, its probable intensity being supposed to be only half of that of the 71 Å.U. line.

These lines are tabulated below and designated by the usual terminology:

λ Å.U.	ν/R	Line.	Intensity.	Combination.	Corresponding Energy Levels ν/R.
45·3	21·0	$N\beta$	very strong	N_3 O_{12}	N_3 = 26·2 (directly measured) O_{12} = 5·2
48·2	18·9	$O\delta$	medium	O_6 P_{12}	O_6 = 20·4 P_{12} = 1·5
51·5	17·7	$N\alpha$	strong	N_{12} O_{12}	N_{12} = 23·0 (direct m.), O_{12} = 5·3
71·1	12·8	$O\gamma$	faint	O_4 P_3	O_4 = 14·8 P_3 = 2
121	7·5	$O\beta$	faint	O_3 P_{12}	O_3 = 8·5, P_{12} = 1

The only low-frequency line escaping detection ($O\alpha$) would have a wave-length of about 230 Å.U. It is the last pure Röntgen line waiting to be found. In the short wave-length side of the spectrum, higher frequency N lines are faint and fogged by the strong optical reflection upon the grating of very soft X-rays. Nevertheless two faint lines, 26 and 27·2 Å.U., have once been found.

Remarkable is the simplicity of these spectra in which there is neither spark- nor semi-optical lines, thanks to the small exciting potential. This series of measurements completes in this way our knowledge of Röntgen series and atomic levels and, at the same time, leads to the long-desired spectrographic junction between ordinary X-rays and Millikan optical spectra in the extreme ultra-violet (136 Å.U.: short wave-length limit of aluminium).

September 16.

Prof. Labbé's Production of "Allomorphs."

PROF. LABBÉ in a recent paper (*Arch. Zool. Exp.*, t. 62, p 498, 1924), in speaking of some copepods and other animals, has made the following statement:—

"The eggs of species *A* laid in a medium of *p*H 8·2 would give the form *A*, but at *p*H 8·4 would give the form *A′*, and at *p*H 8·6 the form *A″*. . . .

"It is exact for Artemia, but for the other forms the fact is more important, for it brings about the transition [il conduit à l'émiettement] of one species to another; this is what I shall call the *allomorph* or the allomorphs of the species"

The paper then goes on to state that various allomorphs have been obtained experimentally by a gradual increase in *p*H It also claims that *Cyclops helgolandicus* Rehberg is an allomorph of this type, *Cyclops bicuspidatus* Claus being the real species.

Mr Robert Gurney (NATURE, vol. 118, p. 336, 1926) has severely criticised Prof Labbé's statements and leads one to think that the necessary attention to detail has not been given and that the allomorphs were not really the offspring of the species described. Mr. Gurney suggests that the mistake might have arisen through the accidental introduction of the minute larvæ of other species

I wish to bring forward evidence of an entirely different nature which leads to the same conclusion as that of Mr Gurney.

For the last three years I have been making a detailed study of the genus Cyclops, an important group of copepods, and in every case the *p*H value of the water in which the animals were actually living was taken In this way in Great Britain alone I have recorded 31 species, 5 of which are new to the country and 3 new to science. I do not propose to give here either a full list of the species or of their ranges of *p*H since the work is by no means finished, but I will give simply the ranges observed for a few of the better known ones:

Species.	Range of *p*H.
Cyclops vulgaris	4·6–9·8
„ *strenuus*	4·6–8·6
„ *lucidulus*	4·4–7·4
„ [illegible]	4·6–8·2
„ *pulchellus* (syn. *bicuspidatus*)	5·8–8·6
„ *signatus* (syn. *fuscus*)	5·0–8·0
„ *annulicornis* (syn. *albidus*)	4·4–9·8
„ *serrulatus* (syn. *Leptocyclops agilis*)	4·6–9·8
„ *prasinus*	4·6–9·8
„ *fimbriatus*	5·0–8·1
„ *nanus*	4·4–7·2
„ *venustus*	5·1–7·4

It is more than likely that as time goes on these ranges will be increased, but I have carried out observations in the following districts: The Isle of

Skye, Perthshire, Folkestone and Hythe, Dartmoor, Cambridge, Oxford, and of course Wilts.

When it is found that a number of well-known species such as those given above can be found with such large ranges of *p*H, it seems impossible to accept Prof. Labbé's statement that a small increase of *p*H is responsible for the transition of one species into another.

In this connexion further observations may be cited. I have found *Cyclops fimbriatus* living in three inches of foul muddy water and dredged it up on the same day in 100 feet of clear water from a Scottish loch. Prof Sars records the dredging of exactly the same species from 300 feet of water. This is by no means an isolated case. In addition, many of the species of Cyclops are absolutely cosmopolitan, the same species being recorded from the Arctic Circle to the equator wherever there is fresh water.

As a third kind of direct observation I should add that in a series of experiments on the spine formulae of *Cyclops lacunae*, I bred several generations of the well-known species *C. signatus* and *C. albidus*. The description of these experiments is now in the press and full details are given; suffice it to say here that the animals were bred in jars in an incubator, as controls, and that during the experiments the *p*H gradually went up from 7·2 to 8·6 The spine formulæ were observed as carefully as possible and both species bred absolutely true to type, and I do not know of any more exacting test.

My experiments and observations therefore do not agree with those of Prof. Labbé, and it is surely now almost an established fact that the alterations of *p*H within reasonable limits have little or no direct effect on freshwater entomostraca or insect larvæ, but a profound effect on most of the protozoa It is well known of course that certain animals bred in captivity and under abnormal conditions may give rise gradually to a series of monstrosities, *e.g.* the Chinese gold-fish described by Tornier, but there is nothing in these experiments comparable to the transition of one species into another in Nature

Finally, there is abundant literature, including that given by Prof. Labbé himself, dealing with the continual change of *p*H that takes place normally in any exposed piece of water, and since the entomostracan fauna often remains practically unchanged for weeks and in some cases for months, it is surely obvious that most of the species are not affected by small changes of *p*H, and in some cases they are not affected even by considerable changes

A. G. LOWNDES.

Marlborough.

'Pwdre Ser' (The Rot of the Stars).

PERHAPS I may be allowed to reopen a subject which gave rise to a very interesting correspondence in NATURE in 1910. I refer to the mysterious jelly-like substance found lying about in open spaces, and popularly connected with 'shooting-stars,' about which Prof. T. McKenny Hughes contributed an interesting article to these columns on June 23, 1910. Many suggestions as to the origin of this substance were made both by Prof. Hughes and by later correspondents, but no definite conclusion seems to have been reached. Of course it cannot be taken for granted that the 'jelly' is always of the same nature. It may well be that the 'jellies' recorded by some observers were the plasmodia of Myxomycetes, or masses of Nostoc or some other organism. But it seems to have been suggested so early as 1667 by Merrett that the jelly consisted of the viscera of frogs. He says (I quote from Prof. Hughes) ". . . Regiae Societati palam ostendi solummodo oriri ex intestinis ranarum a corvis in unum locum congestis, quod aliis etiam ejusdem societatis viri praestantissimi postea confirmarunt."

The German observer Melsheimer, again, as was pointed out in these columns by Dr. G. H. Pethybridge, considered the jelly to be the remains of the oviducts of frogs. Melsheimer (*Jahresber. Westfälischen Provinzial-Vereins für Wiss. u. Kunst*, Münster, Sitzung February 28, 1908, p. 53) believed that these were left on the ground, or thrown up undigested, by some animal which devoured frogs, such as the heron, polecat, or water-vole. He also carried out experiments which showed that the oviducts of frogs, if dissected out and exposed to moisture, formed just such masses of jelly, and in some cases eventually became covered with colonies of algæ of the type of Nostoc.

I am in a position to state that the explanation offered by these writers is, at least in some instances, the correct one. My father, the Rev. F. Baylis, who has for some years visited Dartmoor during the summer and autumn, has both last year and this found such jelly-like masses lying on the moor. This year he has forwarded his 'finds' to me for examination, and I have been able to satisfy myself that they consist of parts of the viscera of either frogs or toads. In one specimen the 'jelly' was accompanied by portions of both oviducts in a fair state of preservation, with part of the ovaries, containing the characteristic black eggs, resembling shot, and with the greater part of the animal's alimentary canal, to which the urinary bladder was attached.

What appears to happen is that the gelatinous secretion of the glands lining the oviducts, when exposed to moisture, swells up to such an extent that the oviducts split open longitudinally, and their contents soon assume the appearance of an amorphous jelly. With advancing decomposition, the jelly persists for some time, but the tissue from which it originated may become unrecognisable. I have carefully examined stained microscopic preparations of the tissue, which was on this occasion comparatively fresh, and compared them with similar preparations of the wall of the oviduct of a known frog, supplied by my colleague, Mr H. W. Parker. By this means both Mr. Parker and myself were able to satisfy ourselves completely that the tissues were of the same kind From the fact that the stomach, which evidently belonged to the same animal, contained recognisable remains of a fairly large earthworm, I am inclined to believe that the animal was a toad rather than a frog.

The question now arises: How do the viscera of toads or frogs come to be lying on the ground in such situations? One specimen came from near the top of a 'tor.' If the animal had been swallowed by a heron or other bird, and its remains disgorged, it seems probable that these soft parts would have been digested more rapidly than the muscular and bony portions, of which there is no trace. I am inclined, therefore, to believe that some carnivorous creature (such as the weasel, stoat, badger, crow, or buzzard) is in the habit of disembowelling toads or frogs, and leaving some of the viscera on the site of the 'kill.' It would be interesting to know whether any direct observations have been made which bear upon this question.

Science and Psychical Research.

IN Dr. Tillyard's rejoinder to my letter on this subject, published in NATURE for August 28, he cites Richet as one of the great scientific men who have studied psychical phenomena and have become convinced of their genuineness. He couples Richet with Crookes, Lodge, and others in this respect, but without even suggesting any difference between the individual beliefs of these eminent men. Since I read this my attention has been directed to a statement published by Richet only a little more than two years ago, which appears to me to be of the highest importance

As we know, Crookes believed that the phenomena which he observed were due to spirits—that is to say, to the discarnate manes of deceased human beings—and Lodge too appears clearly to be of the same opinion. From every human point of view this, of course, is a momentous belief, as indicating the survival after death of human personality. But what does Richet believe?—Richet, who is put by Dr. Tillyard in exactly the same category as Crookes and Lodge.

In the *Proceedings of the Society for Psychical Research* for May 1924, in an article on "The Difficulty of Survival from the Scientific Point of View," Richet, after some evident hesitation, makes the uncompromising statement: "I am forced to regard the spiritistic hypothesis, not only as undemonstrated, but, still more, as being in formal opposition to a great number of facts."

Some may perhaps criticise the word 'spiritistic' which Richet uses. It does not appear to be a dictionary word; but it seems clear from the rest of Richet's article that he uses it as meaning 'pertaining to spirits,' and that what he wishes to convey is that he is quite unconvinced that psychical phenomena are in any way due to spirits, or that such phenomena afford any evidence that spirits exist.

It seems to me, therefore, entirely wrong to class Richet as a spiritualist like Crookes and Lodge, as to do so is most misleading.

A. A. CAMPBELL SWINTON.

Amsterdam,
September 28.

As Mr. Campbell Swinton has directed attention to the National Laboratory of Psychical Research in his letter published in NATURE of September 25, I may perhaps be allowed to modify his observations, which I strongly suspect were intended to be disparaging.

The National Laboratory is no more and no less a "purely private concern" than any other society founded for the purpose of scientific investigation and research. The institution is presided over by Lord Sands, and its vice-presidents and correspondents include Viscountess Grey of Fallodon and many eminent psychists and university professors in all parts of the world. The National Laboratory is governed by a council consisting of well-known London medical men and others whose concern is solely to elucidate the deep mysteries of psychic phenomena and, if possible, to discover the laws governing them. A perusal of our list of members would reveal to Mr. Swinton many names famous in various branches of science.

If we have erred in the naming of our organisation, fellow-sinners to the extent of seven columns in the "Telephone Directory" have committed the same 'crime.' Only lack of intelligence or gross carelessness could possibly account for any confusion between the name of our institution and that of the National Physical Laboratory. Both organisations are engaged in an endeavour to increase the sum total of the world's knowledge by scientific means, the only difference being that the National Physical Laboratory is supported by the taxpayers and we are not. I admit that the substitution of the word 'International' for 'National' would more properly describe our activities. Mr. Swinton's remark that the name of our laboratory seems to be *suggestio falsi* is as untrue as it is unjust.

It is curious that 'emotional disturbances' have never before been recorded by means of a thermograph; it is still more curious that at séances with eminent mediums the changes in the sitters' thermal conditions should exactly synchronise with the production of phenomena, witnessed under excellent lighting conditions and simultaneously recorded by means of a dictaphone. The fact is, of course, that when no medium is present the graph shows a steadily rising curve with no lowering of the temperature. But if we have proved that 'emotional disturbances' on the part of the sitters three feet away from the thermograph will lower the temperature several degrees, the founding of the National Laboratory of Psychical Research will not have been in vain!

HARRY PRICE.
(Honorary Director.)

16 Queensberry Place, London, S.W.7,
September 29.

I WOULD not follow Mr. Campbell Swinton further—I have already done so in the correspondence columns of four newspapers—if he did not make a specific attack upon my accuracy. I must vindicate this by explaining the incident mentioned, while admitting that his misreading of it is not unnatural.

I had seen a representative of the *Morning Post* and had suggested that the picture be published. He told me that he feared it would not reproduce. After one interview I thought that I would at least send it up, and I did so, quoting what their representative had said. Therefore I am quite accurate when I say that when I *first* approached the *Morning Post* I made no suggestion that the photograph would not reproduce. How could I, who profess no knowledge of such matters, instruct a newspaper as to whether they could reproduce or not?

Distribution of Intensity in the Spectrum of γ-Rays.

NEW information concerning the spectrum of γ-rays may be obtained if we consider the energy of Compton's recoil electrons. As has been shown already (NATURE, 116, p. 206, 1925), these electrons can be observed in a Wilson's cloud expansion chamber. In the case of very fast electrons, their velocity is determined from the curvature of the tracks photographed in a homogeneous magnetic field. The energy of recoil E and the frequency ν of the primary rays are connected by the following relation of Debye and Compton:

$$\frac{E}{h\nu} = \frac{2\alpha}{1 + 2\alpha + (1 + \alpha)^2 \mathrm{tg}^2\theta}, \quad . \quad . \quad (D.\text{-}C.)$$

where $\alpha = h\nu/mc^2$, m is the mass of the electron, and θ is

the angle between the direction of the recoil and that of the primary rays.

Using photographs of the tracks, it is not possible to attain the same accuracy as with the usual methods. But, though only approximate values of the frequency ν can be obtained, this method, nevertheless, provides quite satisfactory results as regards the distribution of energy in the spectrum. Wilson's cloud expansion chamber allows a direct counting of the separate quanta of the scattered radiation, as in this case every observed recoil electron represents one single quantum.

I obtained about two hundred stereoscopical photographs of tracks of secondary electrons, produced in a gas under the action of γ-rays hardened by 3 mm. of lead. Out of all observed tracks, those were chosen where the angle θ lay approximately within the limits of 0°-20°. The value $H\rho$ (H = strength of the magnetic field, ρ = radius of curvature) was determined for 170 tracks, which satisfied the above condition.

The results are shown in the accompanying diagram (Fig 1).

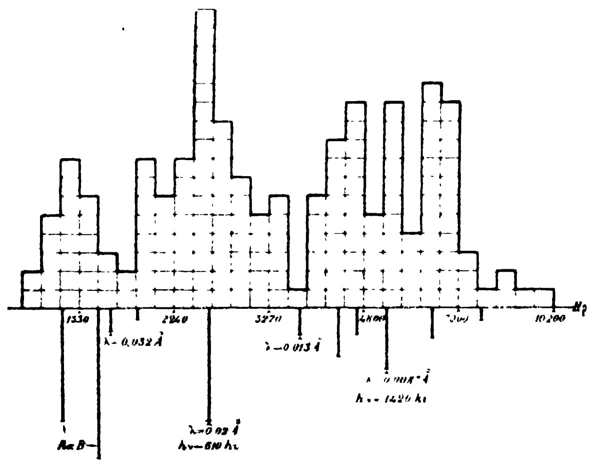

FIG. 1.

The values of $H\rho$ are plotted on a logarithmic scale, one division of which corresponds to about 8 per cent. of the value $H\rho$

The number of squares corresponding to one division is equal to the number of observed electrons for which the value $H\rho$ was found to lie in the limits of the given division. Definite values of $H\rho$ are also given for each separate line of the spectrum of γ-rays, found by Ellis (*Proc Cam Phil Soc.*, **22**, 369, 1924); these values of $H\rho$ correspond to those for the energy E, which follow from relation (*D.-C.*) in the case of ν being put equal to the frequency of the given line and the angle θ to 10°. On the diagram the separate lines of Ellis's spectrum are represented by straight lines, the lengths of which are proportional to the intensity of the corresponding line, as given by Ellis

The distribution thus obtained corresponds, in its outlines, to Ellis's spectrum, as could be predicted from the quantum relation (*D.-C.*)

It is probable that, in the interval $0{\cdot}03 > \lambda > 0{\cdot}014$ A.U., there exists either a continuous γ-radiation or some more lines beside those registered by Ellis (This assumption is in accord with Thibaud's research (*Ann. de Phys.*, vol 5, 73, 1926).)

In order to determine the intensities in the primary beam, we have still to account for the probability of recoil in the given conditions (θ 20°). Compton's theory gives a definite value for this probability. The distribution of intensities which can be deduced directly from my experimental data did not agree with the distribution obtained by Ahmad, who has used the ionisation method and also based himself on Compton's theory (*Proc. Roy. Soc.*, **109**, 206, 1925).

Light-Organs in Littoral Cephalopoda.

THE large group of pelagic 'squids' known as the Egopsida, which includes the greatest number of families of living cephalopods, is characterised by the frequent occurrence of light-organs situated in a variety of places both on the outer surface and within the mantle-cavity. The Myopsida (which include the true squids (Loligo) and cuttlefish (Sepia)), on the other hand, are poor in luminous species. Dr. S. S. Berry in his recent survey of the occurrence of luminous organs in Cephalopoda (*Biological Bulletin*, **38**, 1920, pp. 141 and 171) lists 99 luminescent species of Egopsida (57 per cent), 27 of Myopsida (12 per cent) and 2 of Octopoda (1 per cent). We cannot believe that these organs are necessarily correlated with the habit of living permanently in, or periodically descending to, great depths. Many of the Octopoda are permanent inhabitants of the deeper layers of the sea and are yet devoid of luminous organs. There may be some special source of correlation between the occurrence of light-organs and abyssal habitat which may be responsible for the occurrence of the former among the Egopsida, but not among the Octopoda Of this we have no certain evidence at present

The view that the presence of light-organs is directly correlated with reduction of light, and hence with abyssal habitat, gains some support from the fact that, while many Egopsida have a considerable vertical range, in the Myopsida, which are regarded as mainly littoral in habit, light-organs occur in only 12 per cent. of the species The exact vertical range of individual genera of Myopsida is a little obscure, and it is obvious that in several of them it is considerable Due consideration must of course be given to the fact that unless a specimen is taken in a closing net the exact depth of its regular habitat cannot be satisfactorily assessed However, there is not much doubt that the Sepiolidae inhabit relatively shallow water (down to about 100 fathoms), while the Loliginidae and Sepiidae are definitely littoral, though it is at present uncertain how deep they range in the course of their reproductive cycle. Nevertheless, paired photogenic organs situated immediately over the ink-sac were recorded by W Meyer (*Zool. Anz.*, **30**, p. 388, 1906) in *Sepiola rondeletii* (surface - 100 fathoms) In the Loliginidae and Sepiidae, two very large families, no photogenic organs at all were recorded by Berry in his survey of the group (see above). Thanks, however, to the acuteness of M Armand Krempf, director of the oceanographical and fishery service of Indo-China, and to the courtesy of Dr. R. Ph. Dollfus, Secrétaire Général de l'Institut Scientifique Chérifien, I am able to record the occurrence of rectal light-organs, exactly similar to those of *Sepiola rondeletii*, in a new species of Loligo (shortly to be described) from Indo-China The species in question is obviously of littoral habit.

The general considerations outlined above and this new observation render it very desirable to collect exact data as to the distribution and habits of these animals. Without such data it must remain impossible to decide whether these luminous organs are adaptive

in the usual sense of that word and, if so, to what needs they correspond (*e.g.* the search for food or the attraction of mating-partners), or whether they are at the offset developed without reference to the welfare of the organism. G. C. ROBSON.

Electrostatic Moments of Molecules.

I HAVE made recently some observations on the electrostatic moments of molecules. A beam of molecules, all having sensibly parallel velocities, was passed through an electrostatic field, so arranged that the quantity d^2v/dx^2 (x measured perpendicular to the direction of the molecular motion) was of the order of 10^6 e.s.u./cm ^{2}. Experiments were made on the metal potassium and on the compounds sodium chloride, mercuric chloride, and arsenic trioxide. It was found that potassium had a moment too small to detect, and it has been impossible so far to induce any polarisation in the molecule in the largest field used—330 e.s.u./cm. There was no deflexion which might be put down to the molecules $(K)n$. If such are present their concentration must be very small—less than 1 per cent. of the total number, or they have no moment and the field cannot polarise an appreciable number of them.

Some experiments of a qualitative sort have been done on the binary and ternary compounds sodium chloride and mercuric chloride. The molecules of both these substances were deflected appreciably by the field, and the moment was estimated to be of the order of magnitude 10^{-18} e.s.u. cm. As these experiments were done with the aid of a knife edge, it is difficult to estimate the field through which the molecules passed.

With a much better apparatus in which a charged wire was placed in the path of the moving molecules, an experiment was done on arsenic trioxide. In this case several deflected lines were visible, and the moment deduced appears to be somewhat larger than in the case of the other two salts. It is difficult without a systematic series of experiments to offer a definite interpretation of these observations, as there is to be taken into consideration a number of possible effects, for example, the rotational energy of the molecules, the polarisation which the field may induce in them, and finally, effects due to different molecular states. R. J. CLARK.

The Cavendish Laboratory,
Cambridge.

Lengthened Chain Compounds of Sulphur.

IN a recent issue of NATURE (August 21, p. 283) attention is directed to some lengthened chain compounds of sulphur described by Sir P. C. Rây and K. C. Bose-Rây (*J. Indian Chem. Soc.*, 1926, 3, 75) as products of the interaction of dithioethylene glycol and ethylene dibromide. Of the three points which are emphasised by the authors, namely, (*a*) the isolation of a compound containing bromine, (*b*) the high molecular weight of this compound, and (*c*) its formulation as having a long chain structure, two cannot be regarded as new, whilst the evidence for the third is unconvincing. For the very similar reaction of ethylene dibromide with potassium sulphide was shown by Crafts so long ago as 1863 (*Annalen*, **128**, 220) to yield such substances of presumably high molecular weight containing 12-28 per cent. of bromine and with a ratio of C : H = 1 : 2. Moreover, the suggestion that these substances have a long open chain structure has recently been put forward on more than one occasion (*J. Chem. Soc.*, 1921, **119**, 1861 ; 1925, **127**, 2676).

It seems probable that such products are mixtures of substances of the general formula $A.(S.C_2H_4)_n.S.B$, where A and B may be alike or different and have any of the structures: $-CH_2.CH_2OH$, $-CH:CH_2$, or $-CH_2.CH_2X$ (where X is a halogen). If n be large, the composition of the whole will differ very slightly from that of a polymer of ethylene sulphide. But at the same time the easy isolation of a single pure chemical individual from such a mixture of closely related substances is not to be expected.

The experiments recorded by Sir P. C. Rây do not in fact provide any convincing evidence that such a separation of pure substances was effected, although it is claimed that this was so after one or two crystallisations. There are also several indications in the paper that the "compounds" were still mixtures. For example, it is improbable that members of what would constitute a single homologous series of compounds of the general formula $Br.C_2H_4(S.C_2H_4)_n.Br$ would have the following melting points when pure:

Value of n .	10	12	16	24	26	32	40	48
Melting point .	120°	100°	162°	117°	145-155°	157-159°	170°	163°

In no case was the molecular weight of one of these substances satisfactorily confirmed. The ebullioscopic determination made on one of them led to a value about half of that expected (1486 in place of 3068). The authors attribute this to a surprising disruption of the molecule by the ethylene dibromide used as a solvent, but it is much more likely to be due to the presence from the first of a mixture of substances some of which do not contain bromine. In any case it cannot reasonably be claimed that any substance was shown to have the high molecular weight stated. G. M. BENNETT.

The University,
Sheffield.

Prof. Paul Kammerer.

I REGRET to have to announce the death of Prof. Dr. Paul Kammerer, who shot himself on the Hochschneeberg, near Vienna, on September 23. In a letter (received after his death) he accuses himself of failures in his personal affairs, but emphasises that he has never committed the scientific tricks hinted at by some of his critics. He deemed the rest of his life too short to be able to take up again the same experiments, and declared himself too weary for this task. Although other than these seem to have been the main causes for his weariness of life, yet this sad end to a precious life may be a warning to those who have impugned the honour of a fellow-worker on unproven grounds. It is in fulfilment of a wish expressed by Kammerer that I beg the editor of NATURE to publish his last word on the much-debated but not solved question of a particular one of his specimens. Having convinced himself of the state it is in now, Kammerer alleges that someone must have manipulated it ; he does not allude to a suspicion whom this might have been.

Need I add that Kammerer's work on the modifiability of animals, especially on poecilogony and adaptation to colour of background in Salamandra and the reappearance of functional eyes in Proteus kept in appropriate light, will secure him a lasting place in the memory of biologists, even if some other of his papers were open to criticism.

HANS PRZIBRAM.

Vienna II. Prater, "Vivarium."

English Provincial Universities: Demand and Supply.

THE elevation of University College, Reading, to full university status has naturally led to a certain amount of speculation as to the prospects of other colleges which aim at achieving a like development. A careful survey of the demand for and supply of university education in Great Britain was included in last year's Report of the University Grants Committee, which pointed out that in spite of serious financial distress among the classes from which university students are mainly drawn, in spite of a rise in fees and in personal expenses, there were 56·9 per cent. more full-time students of both sexes at British universities and colleges than before the War. There can, the committee thought, be little doubt that the demand for university education cannot long remain stationary even at this higher level, and that it will continue to grow both in volume and intensity. The growth is, in fact, clearly traceable to causes which are likely to operate in the future with increasing force.

One may distinguish between the demand for professional or vocational education at a university—the bread-and-butter studies—and the demand for the other advantages which a university education offers, advantages associated with the ideal of a 'liberal education.' Both have been and are being stimulated by the rapid increase in the secondary school population, which has multiplied the number of young people fitted for and capable of appreciating the value of university training while creating a demand for more teachers which the universities alone can properly supply. The ever-extending applications of science to industrial purposes, the instalment by industrial concerns of private laboratories and research departments, and the development of industrial research associations, provide an ever-widening field for men and women trained in the scientific departments of universities. There is, moreover, in the world of commerce and industry a growing appreciation of the value of the university-trained mind, and the opinion gains ground "that for the direction of operations which tend every day to become more and more dependent for their success upon the understanding of a complicated network of world conditions, disciplined imagination, breadth of outlook, and mastery of general principles are the qualities needed—qualities which it is the object of a good university education to develop." Meanwhile the demand of the learned professions and the public services grows no less, and the local government authorities have begun to compete with the central government for the services of university graduates.

Partly as a result of the widening of the university area of influence, there has come about a broadening of the basis of university studies in all faculties, and this has tended to increase the number of those who would pursue at a university the ideal of a 'liberal education.'

A potent cause of growth in the *effective* demand for university education in Britain has been the generous provision by local authorities of scholarships tenable in universities. It has been estimated that this amounts to something like 300,000*l*. per annum.

So much for the demand. In discussing the question whether the supply would be able to meet it, the committee directed attention to its statistics of students in attendance at each of the universities, and pointed out that there are few at which there is not ample scope for expansion without any danger of introducing the methods of mass production—expansion which would meet all the needs likely to arise for a good many years to come, at much less cost than would be incurred in creating new universities or raising to the university level institutions which are now below it: "We consider that a relatively small number of universities, staffed and equipped on a worthy scale, will be of more value to the nation than a larger number of universities of inferior strength."

Turning now from these general considerations to particular examples, the present position and prospects of the three university colleges at Nottingham, Southampton, and Exeter may be briefly described as follows:

UNIVERSITY COLLEGE, NOTTINGHAM

This College was founded by the municipality of Nottingham and opened in 1881 by the Duke of Albany; it took up the Cambridge extension courses, of which Nottingham was one of the earliest centres, and the evening classes which for many years had been held at the Mechanics' Institution. From these beginnings it has developed its present work.

The College building, which houses also the Free Public Library, is situated in the centre of the city, but new buildings are in process of erection on a very fine site, three miles distant, presented by Sir Jesse Boot as part of a gift of 350,000*l*. made in 1920 to the city of Nottingham. From the gift, 110,000*l*. was allocated to the new buildings, for which Sir Jesse Boot made supplementary gifts amounting to 40,000*l*. An anonymous donor gave 100,000*l*. in 1922 as a contribution towards the establishment of an "East Midlands University," and this sum was added to the building fund, making 250,000*l*. in all. Sir Jesse Boot has since added to his benefactions; among other gifts he has provided 12,000*l*. more for the buildings and 9000*l*. for the sports ground. The present buildings in Shakespeare Street will continue to house the technical day courses and the evening classes.

At the ceremony of laying the foundation-stone of the new building on June 14, 1922, Lord Haldane suggested that a university for the East Midlands might be organised on something like the pattern which is now in operation in Wales, the university looking to the constituent colleges to develop the teaching of their own students and preserve all the records and to conduct examinations for degrees under the university's supervision. He thought it would be possible to start a university on these lines with four faculties: arts, science, engineering, and commerce. The other constituent colleges of the projected university were not named, but Leicester, Loughborough, and Derby are all within easy reach, and the colleges at those places would presumably come into the scheme.

The instruction at University College, Nottingham, is organised in faculties of arts (including education and music), economics (including commerce and law), pure science (including pharmacy), and applied science (engineering and technology, textiles and mining). A department of adult education is conducted by a whole-time professor, assisted by four staff tutors, two organising lecturers, and about thirty-five part-time tutors and lecturers. The College has shown

great enterprise in developing this department to a high degree of efficiency since the War. It makes special provision for the instruction of foreign students throughout the academic year.

Much advanced work is carried on, there having been in 1924–25 twenty-four research students in addition to students doing post-graduation work in education or in secondary training. The total number of full-time students in 1924–25 was 472, including 175 women. The distribution by faculties was: arts and economics, 204 (women 130); pure science, 204 (women 45); medicine, 6; technology, 58. Ninety-seven students were accommodated in residential halls. Part-time students numbered 734 (women 97), and there were in addition 1545 students taking courses not of a university standard, and 1867 university tutorial class three-year students.

On the score of amount of instruction provided and research work undertaken, Nottingham ranks higher than Reading. It is in provision of residential halls for its students and in finance that it falls short. A scheme for providing additional halls of residence both for men and for women has, however, been begun and has already received contributions and promises of support. The total income of the College in 1924–1925 was 59,609*l*. as against Reading's 84,150*l*., and its income from endowments 1600*l*. as against 12,148*l*. Its grants from local authorities amounted to 14,532*l*. plus 2500*l* set apart for scholarships, hostels, etc.; its parliamentary grants to 25,548*l*., its tuition and examination fees to 12,878*l*., and other income to 5051*l*.

The book value of its lands and buildings and permanent equipment is 405,888*l*., and its endowment investments 2381*l*. A few more bequests such as that of Mr. W. H. Revis (37,000*l*.) would enable the College, either alone or in association with others, to make out a very strong case for a university charter.

UNIVERSITY COLLEGE, SOUTHAMPTON

The College at Southampton originated in the Hartley Institute for Technical Training, founded in 1850 and formally opened by Lord Palmerston in 1862. For thirty years its function was that of a technical college only, but in 1899 it was recognised by the Board of Education as a training college for teachers. Three years later (after investigation and report by the Treasury) the College was promoted to a place in the list of university colleges in receipt of Treasury grant. New buildings on the outskirts of the town were opened on June 20, 1914, by Lord Haldane. On the outbreak, six weeks later, of the War, the College authorities handed over the buildings to be used as a hospital, and it was not until October 1919 that the College actually took possession of its new home. The buildings are not yet completed, and a good deal of the work now being done is carried on with huts as lecture rooms and laboratories.

The College prepares students for degree examinations of the University of London, the examinations of various professional bodies such as the Pharmaceutical Society, Institute of Chemistry, Institutions of Mechanical, Civil and Electrical Engineers, Royal Institute of British Architects, Surveyors' Institution, Law Society, etc., and for its own diplomas in engineering, commerce and economics, geography, law, music, and English (for foreign students). Its department of education for the training of teachers has a high standard of admission (London matriculation) and prepares students not only for the Board of Education's Certificate examination (conducted internally, at the College) but also for the teachers' diploma and higher diploma in pedagogy of the University of London and other advanced examinations in professional subjects. An increasing number of these students take also university degree examinations. The original work of the College as a technical institution still flourishes in the shape of evening classes in arts, pure and applied science, engineering, etc. There is an old students' association with nearly two thousand members.

In 1925–26 the number of full-time students was 316, including 157 women. The number resident in college hostels was 192 (women 94). Two-thirds of the full-time students (82 men and 131 women) were working in the Faculty of Arts; 86 were students of pure science; 17 were engineering students. Part-time students numbered 294, including 28 women. In addition, there were 253 students taking courses not of a university standard and 112 students attending university tutorial (three-year) classes. The book value of lands and buildings as at July 31, 1925, was 64,591*l*., and endowment investments amounted to 12,347*l*. The total income of the year 1924–25 was 31,962*l*., derived from: parliamentary grants (15,139*l*., increased in 1925–26 by 4000*l*.), local authorities' grants (9236*l*.), tuition and examination fees (6094*l*.), endowments (644*l*.), and other sources (849*l*.). Student expenses have been kept low, and it is claimed that a university education may be acquired at Southampton at an inclusive cost of 105*l* a year.

Although the College is able at present to pay its way, further expansion and improvement are dependent on the success of efforts now being made to raise additional funds. In May 1925 an appeal was launched for 500,000*l*. for the endowment of chairs and the provision of additional buildings, with the view of eventually obtaining a charter for a projected "University of Wessex." Geographically, Southampton would seem to be the most appropriate centre for university education for East Dorset, South Hants, the Isle of Wight and Channel Islands, and West Sussex. The towns of Poole, Bournemouth, Salisbury, Portsmouth, Winchester, and Chichester are all within easy distance. In 1925–26, 119 out of the total number (316) of full-time students lived at home, and 72 others came from homes within a radius of thirty miles, whilst 125 came from beyond that radius.

The case for a University of Wessex rests partly on the regional demand, present and prospective, for regional facilities for university education, and partly on the incidental and indirect benefits likely to accrue to the inhabitants of the region in consequence of having a university in their midst. It may be anticipated, therefore, that Southampton will, like Nottingham, largely develop its university extension activities and its commercial and technological departments. Southampton being within such easy reach of French ports, a university with a strong faculty of commerce would attract many students from France. The engineering department of the College is at present a small one, but its efficiency is proved by the fact that the students when they leave college readily obtain employment, and some of them have already risen to very considerable distinction. Were money forthcoming, this department would be capable of important developments, especially in the study of marine and aeronautical engineering, for which Southampton offers excellent opportunities.

UNIVERSITY COLLEGE, EXETER.

The University College of the south-west of England, Exeter, formerly known as the Royal Albert Memorial College, originated in 1865, when memorial buildings consisting of a museum, a library, and adjuncts for the study of art, science, and literature were erected. With the co-operation of the Local Lectures Syndicate of the University of Cambridge, the work of the

institution was re-modelled and co-ordinated in 1893, when the first principal was appointed, but it was not until 1901 that the educational work was organised for development on the lines of a university college with the provision of a curriculum for the external examinations of the University of London.

The College was placed upon the list of university institutions in receipt of grant from H.M. Treasury as from August 1, 1922, when it was incorporated under its present name as a company limited by guarantee, and the college buildings and halls of residence were transferred to it by the Exeter City Council. From that time its progress has been rapid, the number of degree students in the four years ending 1924–25 having been 96, 139, 187, and 211 respectively. The total number of full-time students in 1924–25 was 332, of whom 221 were in the teachers' training department. Residential halls provide accommodation for 134 women and 110 men students. Part-time students numbered 38 and occasional students 40. There are departments of biology, chemistry, classics, education, English, geography, history and economics, law, pure and applied mathematics, modern languages, music, philosophy, physics, and extra-mural studies. The total income was 29,067*l.*, including parliamentary grants 12,317*l.*, grants from local education authorities 10,384*l.*, tuition and examination fees 5040*l.*, income from endowment 674*l.*, and from other sources 1112*l.* The book value of its land, buildings, and permanent equipment is 81,433*l.*, and its endowment investments 11,603*l.*

These figures do not suggest that the College is likely to qualify soon for full university status, but it might conceivably join with the Technical Schools, Plymouth, the Seale-Hayne Agricultural College, Newton Abbot, and the Camborne School of Mines, to form a federal university. An important scheme for co-operation with the Technical Schools, Plymouth, has been worked out providing for degree and diploma courses in civil, electrical, marine, and mechanical engineering and in commerce at Plymouth, and the extension of the law teaching and extra-mural work already carried on there by the College. An appeal was launched in October 1925 for 100,000*l.* for the equipment and endowment.

University College, Hull.

The plans for the proposed University College for Hull, for which the Right Hon. T. R. Ferens gave 250,000*l.*, provide for an organisation somewhat similar in scope to that of University College, Southampton, with the addition of a department of agriculture and, eventually, departments of shipbuilding and applied chemistry of the oil, colour, gas, and spirit industries.

Lest the account already given of the policy of the University Grants Committee in regard to proposals for establishing new universities should be misunderstood, it must be added that the Committee is careful to point out that its "view of what is prudent at one particular stage of our history betokens no lack of sympathy with the general desire for a wider avenue to university education, or with the ambitions of certain large and populous cities to rival the more fortunate communities which already possess universities of their own." The Committee hopes that "as returning prosperity enables the schemes of local education authorities under the Education Act to be carried into effect, the local colleges will play an increasingly distinguished part in the higher education of the people, and will steadily raise the level of national knowledge and culture. It may well be that some of these will, in course of time, establish a claim to university rank and receive charters as independent universities."

Fluctuations in the Abundance of a Species considered Mathematically.

By Prof. Vito Volterra, For. Mem. R.S., President of the R. Accademia dei Lincei.

A consideration of biological associations, or of the mutual interactions between two or more species associated together, has led me to certain mathematical results which may be set forth as follows.

The first case I have considered is that of two associated species, of which one, finding sufficient food in its environment, would multiply indefinitely when left to itself, while the other would perish for lack of nourishment if left alone; but the second feeds upon the first, and so the two species can co-exist together.

The proportional rate of increase of the eaten species diminishes as the number of individuals of the eating species increases, while the augmentation of the eating species increases with the increase of the number of individuals of the eaten species. Having determined the laws of this increase and diminution, it is possible to establish two differential equations of the first order, non-linear, which can be integrated. The integrals reveal the fact that the numbers of individuals of the two species are periodic functions of the time, with equal periods but with different phases, so that each species goes through a cycle relative to the other during a period, a process which may be called the 'fluctuation of the two species.' Figs. 1 and 2 give representations of different possible cycles, corresponding to different initial values of the number of individuals of the two species: ordinates representing the eating, and abscissæ the eaten species.

The co-ordinates of a point on a cycle are the concurrent values of the numbers of individuals of the two species, those of the central point Ω being the mean values; and the following laws have been deduced from integration of the differential equations which represent the fluctuation:

I. The fluctuation of the two species is periodic, the period depending only on the coefficients of increase and of destruction of the two species, and on the initial numbers of the individuals of the two species.

II. The average numbers of the two species tend to constant values, whatever the initial numbers may have been, so long as the coefficients of increase or of destruction of the two species and also the coefficients of protection and attack remain constant. (Laws I. and II. are illustrated in Fig. 2.)

III. If we try to destroy individuals of both species uniformly and proportionately to their number, the average number of individuals of the *eaten* species grows and the average number of the eating species diminishes (see Fig. 1). But increased protection of

[1] V. Volterra.—Variazioni e fluttuazioni del numero di individui in specie animali conviventi.—*Memorie della R. Accademia dei Lincei* (Cl. di Sci. Fis. etc.), ser. 6, vol. ii. fasc. 3, 85 pp., 1926.

the eaten species increases the average numbers of both.

In the case of small fluctuations, we have the following approximate laws:

(1) Small fluctuations are isochronous, *i.e.* their period is not sensibly affected either by the initial

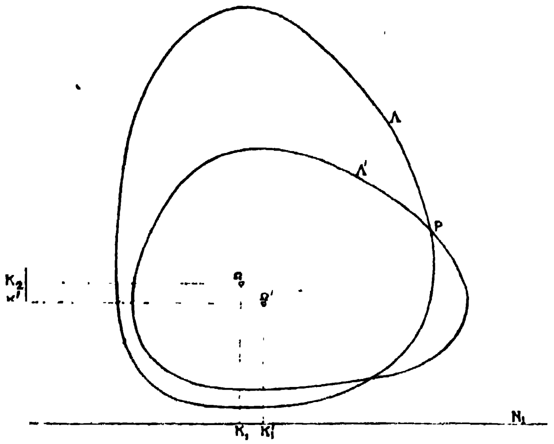

FIG. 1.

number of individuals, or by the conditions of protection and offence.

(2) The period of fluctuation is proportional to the product of the square roots of the time required for the first species to double itself, and for the second species to reduce itself to half. If the first species doubles itself in the time t_1 and the second species is reduced to half in the time t_2, the period is $T = \frac{2\pi}{\log_e 2}\sqrt{t_1 t_2} = 9{\cdot}06\sqrt{t_1 t_2}$.

(3) The steady destruction of individuals of the eating species accelerates the fluctuation, and the destruction of individuals of the eaten species retards it.

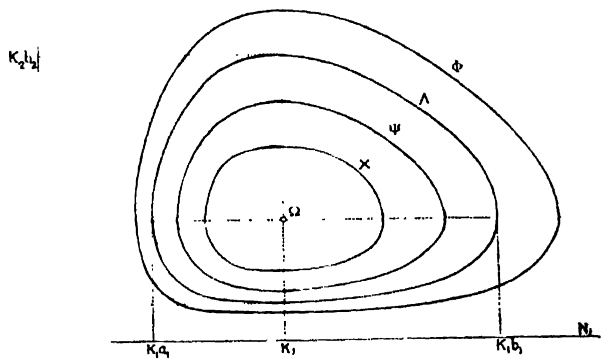
With the contemporaneous and uniform destruction of individuals of the two species, the ratio between the amplitude of the fluctuation of the eaten species and that of the eating species tends to increase.

In Fig. 1 are represented two cycles, the second of which corresponds to a perturbation produced in the first by a constant and proportionate destruction of the individuals of the two species. The centre Ω' of the perturbed curve is displaced, in respect to the centre Ω of the primitive curve, downwards and to the right; this reveals an augmentation of the average number of individuals of the first species, and a diminution of the average number of the second.

Law III. is undoubtedly the most interesting of all, because it affords the best actual verification so far found of the theory. For Dr. U. d'Ancona, comparing fishery statistics in the Adriatic Sea before the War, during the War (when fishing almost ceased), and after fishing was resumed at the end of the War, has ascertained that the voracious species (selachians), which feed on other fishes, had increased during the War as compared with the preceding and following periods, while the contrary had been the case for the number of individuals of the eaten species.[2] In other words, a complete closure of the fishery was a form of 'protection' under which the voracious fishes were much the better and prospered accordingly, but the ordinary food-fishes, on which these are accustomed to prey, were worse off than before. This is in agreement with Fig. 1, and with Law III. My theoretical researches, which I was induced to undertake by the statistical studies begun by Dr. d'Ancona, correspond accordingly with his results.

Charles Darwin had an intuition of these phenomena in relation to the struggle for existence when in Chap. iii. of his "Origin of Species" he wrote: "The amount of food for each species of course gives the extreme limit to which each can increase; but very frequently it is not the obtaining food, but the serving as prey to other animals, which determines the average number of a species. Thus there seems to be little doubt that the stock of partridges, grouse, and hares on any very large estate depends chiefly on the destruction of vermin. If not one head of game were shot during the next twenty years in England, and at the same time if no vermin were destroyed, there would in all probability be less game than at present, although hundreds of thousands of game animals are now annually shot."

Law III. is, however, true only up to a certain limit. It is evident that if the destruction of both species continue, their exhaustion will ensue. It is therefore necessary to ascertain up to just what point it is profitable to destroy both species in order to obtain the greatest augmentation in the average number of the eaten species. We arrive in this manner at a curious example of a mathematical *upper limit* without the existence of a *maximum*. There is in fact a limit of destruction beyond which both species are exhausted. If we remain below it, the average number of the eaten species grows as this limit is approached; but once the limit is reached, the eating species tends to exhaustion and the fluctuation ceases, while the number of individuals of the eaten species tends asymptotically



towards a value which is less than the average formerly reached.

Besides the case dealt with above, a study of variations in the number of individuals of two associated species can also be made in all cases in which the species interact either favourably or injuriously, in all possible degrees or combinations. All such cases can be classified in distinct types, and in each of these it is possible to

[2] U. d'Ancona.—Dell' influenza della stasi peschereccia del periodo 1914-1918 sul patrimonio ittico dell' Alto Adriatico.—*Memorie del R. Comitato Talassografico Italiano* (in course of publication).

follow the numerical variations of the two species by the help of formulæ, or of diagrams to correspond. It is easy to see from these diagrams *which species is winning in the struggle for existence, and which of them is in process of extinction.*

Again, it is certain that many facts of medical interest may be classed among phenomena resulting from concurrent and reciprocal action between different species—between the human species and pathogenic germs, between parasitic species and those on which they are parasites. The periodicity of epidemics may be connected with the same phenomena.

A second part of my investigation is devoted to a general study of biological association, where any number of species may be living together. I have studied two types of association, and have called them *conservative* and *dissipative associations.*

For the first or conservative association, equivalent values may be assigned to the different species so that the destruction of a certain number of individuals belonging to one species by another species, to its own benefit, corresponds to an increase in numbers of the latter species, in the precise ratio which the said equivalents express. Moreover, in a conservative association, the number of individuals of every species has no influence on its own augmentation. The case of two species, already dealt with: the case of n species, where individuals of the first eat those of the second, and the latter those of the third, and so on to the nth; the case of four species so connected that the first eats the second and the second is also eaten by the third, which in its turn is eaten by the fourth; all these cases are examples of biological conservative associations, if we neglect actions between individuals of the same species. The variation in numbers of the conservative associations depends on a system of differential quadratic equations associated with a skew-symmetric determinant.

Owing to the peculiar properties of these skew-symmetric determinants, and to the differences between those of odd and those of even order, we must treat in different ways the cases where odd and where even numbers of biological species are associated together. When the number is odd, then, if the coefficients allow a 'stationary state,' we shall always have fluctuations such as to maintain the number of individuals of each species between positive limits. These limits are dependent on initial conditions, which may be so assumed as to restrict these limits to any extent we please.

The average numerical values of the different species tend, in periods of time of infinite duration, towards the corresponding values for the stationary state, and are therefore independent of the initial values.

The case of an odd number of species does not correspond to a condition of stability for a strictly conservative system.

In the case of associations which I call *dissipative*, if a stationary state exists, the variations will be fluctuations which slowly extinguish themselves, or are asymptotical. From an analytical point of view, the dissipative association is characterised by a definite positive quadratic form.

The analogous form is null in the case of a conservative system. The dissipative actions work in a way analogous to friction in a mechanical system.

Therefore the terms conservative and dissipative may also be applied to the fluctuations, which in the first case continue to exist, and in the second are dissipated. It will be observed that to prove the existence of the fluctuations, we follow an analysis different from that used in elastic or electric vibrations, the equations here employed being not linear but quadratic.

Applying this theory to a particular case, suppose three different species living together in a limited area, such as an island. Of these three species the first eats the second, which in turn eats the third. We may take for example a carnivorous species, feeding upon a herbivorous animal, which in turn feeds on a certain plant species—assuming that for the last the same method may be used which we apply to animals. The same method may also be employed in the case of insects parasitic upon plants, and of parasites of such parasites.

If we suppose that system to be conservative, that is, if we neglect the actions between individuals of the same species, we may have two different cases which are distinguished by the values of the coefficients occurring in the equations:

(1) The food which reaches the carnivorous species through the herbivorous is not sufficient to maintain the carnivorous species; and so the latter is exhausted, while the herbivorous animal and the plant tend to a periodical fluctuation.

(2) The vegetable species grows indefinitely. This case is, however, incompatible with the limitation of the island, which does not allow the indefinite multiplication of the plant. It is therefore necessary in this case to suppose the system to be dissipative, admitting that the coefficient of increase of the vegetable species is dependent on the number of existing plants, and then we have three cases: Either (1) both animal species are exhausted; or (2) only the carnivorous species is exhausted, while the herbivorous and the plant tend to a fluctuation of gradually diminishing amplitude or to an asymptotic variation; or (3) all three species live together without exhausting themselves, but vary asymptotically in a common fluctuation of gradually diminishing amplitude, the characteristic elements of which can be determined.

Side by side with the general theory, we may make various special inquiries. Thus, for example, we may suppose the coefficient of increase of the species to have an annual period, a supposition tending to establish a law of forced fluctuations superposed on the free fluctuations of the biological association considered.

We may also study how exhaustion takes place of a species in a biological conservative association of an uneven number of species; or in general how exhaustion takes place of species in dissipative associations; or what perturbation is produced when a new species is introduced into an association in equilibrium.

Seeing that a great number of biological phenomena are characteristic of *associations* of species, it is to be hoped that this theory may receive further verification and may be of some use to biologists.

Obituary.

ARTHUR WALTON ROWE.

HARD as it is to see friends go who have played their part upon our shifting stage, it is still harder to lose those who are in the plenitude of their power, before they have fully delivered the message you know they have in them. Arthur Rowe was one of the most remarkable, complex and cryptic natures it has been my fortune to encounter. During the past five and twenty years, probably no one has been on closer terms of continued intimacy with him than I was. We came together in a curious way. At the close of 1900, I had a bad attack of influenza. Feeling very miserable and having little faith in local medical opinion, I said I should go to Margate and put myself into the hands of a physician there who, I knew, had done remarkable geological work: therefore, should be of exceptional intelligence. I did so and fortunately called in Rowe—only to discover that I had pneumonia upon me. Happily we soon disposed of this and then began to talk shop together. I had advisedly taken with me a bookful of my photographs displaying the geology of the Dorset coast. He had just published the first of his papers on "The Zones of the White Chalk of the English Coast—Kent and Sussex," unillustrated. He proposed that we should join forces. So it came that I illustrated for him Parts II. to V. (Dorset 1901, Devon 1903, Yorkshire 1904, the Isle of Wight 1908), which were published by the Geologists' Association.

Rowe was born September 27, 1858. He died September 17, 1926. He was the son of Dr. Thomas Smith Rowe of Margate. He led a very lonely childhood and started geology when quite a boy—in fact, he was a naturalist from birth. His parents were very strict with him, stinted his pocket money and allowed him no youthful companions. He was educated at King's School, Canterbury, at the University of Durham and St. Mary's Hospital.

Rowe began to practise with his father in 1884 and held the house surgeonship at the Royal Sea Bathing Hospital at about that time. He retired in 1910, after having long been the leading practitioner in Margate. He was adored by his patients. He worked very hard at his practice and was able to develop his bent as a scientific inquirer only on Sundays and holidays—a fortnight at Easter and a fortnight in the autumn.

Rowe was a very difficult character to understand. Naturally reticent, his reticence was accentuated by the overmastering tendency of medical etiquette to compel reticence and he became more and more asocial with time. He was given to hobbies and an unusual mixture of the naturalist-collector with the highest type of scientific inquirer—I use the term inquirer advisedly. Excepting Lapworth, no one has so impressed me in the field. He had an exceptional faculty of learning and mastering a subject, an exceptional sense of order and exactness, an exceptional care for truth. His devotion to work was extraordinary. The phrase used by W. P. D. S. in the *Times*—"Whatever he took up (and he took up many things) he did more thoroughly than any other man I have known"—is an exact description of him. Whatever subject he took up, for the time being he thought of nothing else and could talk of nothing else. Unfortunately, he had in him no element of personal ambition—years ago, when some of us wished to prefer his claim to the Royal Society, he would allow nothing of the kind. As the Society has no means of discovering modest men, he remained unencouraged—except by the Geological Society, which gave him the Wollaston award in 1901 and a Lyell medal in 1911. Quite exceptionally, two Lyell medals were awarded that year, the other recipient being Dr. Bather. There was a tie in the voting between amateur and professional.

We owe the earliest attempts at zoning the Upper Cretaceous to Price and Barrois. Little was done, especially with the Upper Chalk, until Rowe took it in hand. He had developed a beautiful method of uncovering and displaying the exterior characters and internal structure of fossils, especially the more delicate forms preserved in the Chalk (involving the use of the dental engine). This enabled him to reveal minute variations in shape and aspect previously unsuspected. Collecting the material personally, he noticed that these variations were in sensitive relation with the exact position of the organisms in the succession of the Chalk strata and it occurred to him that the fossil sea urchins in particular might be useful as indicators of the age of any particular portion of the Chalk sequence: in fact, his first scientific contribution was "An Analysis of the Genus Micraster" (1899) A trial in the Dover area convinced him that he had found the key to the succession and he used this in many localities and published many maps and correlating memoirs which have thrown clear light upon the lapse of time and upon geological evolution in the later Cretaceous period. His methods proved to be of use in the hands of other observers and practically the whole of the British Chalk has now been zoned and correlated, Rowe's services being not merely those of a pioneer but the generous helper and inspirer of his contemporaries and successors.

There also fell into Rowe's hands, possessed as he was of an accurate and delicate time scale, most important details with regard to the time succession of evolutionary changes in the chief types of organisms that he studied. He was able to put on record a long series of accurately observed facts bearing upon their evolution and thus made contributions to zoology as important as those which he made to geological science. It should be added, he was greatly aided by C. Davies Sherborn.

Rowe lived at the back of Margate, at Shottendane, in a most beautiful sylvan hollow. He acquired the site in 1903 and very soon developed a passion for gardening which for a time overcame all other interests. About three years ago, he suddenly dropped gardening to excavate an old Roman site, near at hand, work which he did almost entirely himself. He had a profound knowledge of Margate history and had accumulated an invaluable collection of prints and documents. He was also a student of words, having been influenced in early life by Trench's fascinating book. At one time, he was very active in local affairs and did much to raise public taste in music. He sang well in early days and his wife was an accomplished musician. Their son inherits the gift of music.

Year after year I have urged him to get back to his chalk work. We had even talked of producing a chalk atlas together. I am glad to say that his interest in geology was so far revived that only six weeks before he died, when I was about to visit him, he wrote to me that he was ill but had finished a paper on the serpulids and I hear also one on "The Great Chalk Sea," which he probably, of all men, was the most competent to picture. He had been in bad health but would not give in until the papers were written and told his medical adviser, his former partner, that he had waited to send for him until they were finished. The act was characteristic of the man—he never thought of sparing himself. It is sad that the world is ever selfish and has no way of caring for such men and providing that they use themselves with consideration and full effect: we respect genius but little until we can no longer use it. Some day, when work such as Rowe's is described in readable form, the walls of ignorance will be shattered and the wondrous beauty of the lowly organisms of which chalk is composed will be made manifest. Our present indifference to geology is little short of criminal, seeing that it is the story of our earth.

HENRY E. ARMSTRONG.

REV. F. D. MORICE.

THE Rev. Francis David Morice, well known as an authority on certain families of Hymenoptera, died at Woking in his seventy-eighth year, on September 23. Educated at Winchester, from which he passed in 1866 to New College, Oxford, he gained high distinction as a classical scholar, and in 1874 was appointed a master at Rugby under Dr. Jex-Blake. Here he remained for twenty years, retiring ultimately in 1894 to Woking, where he took a house next to his great friend Edward Saunders, and devoted himself to entomological research.

During the latter half of the years at Rugby, Mr. Morice had frequently consulted Saunders regarding his captures of local bees and wasps. The results were published from time to time (1888–92) in the *Report* of the School Natural History Society. From this time until recently Mr. Morice made numerous contributions to the literature of his subject, at first dealing mainly with the chrysids (cuckoo wasps), aculeates, and fossores, but latterly confining himself almost solely to the Tenthredinidæ (saw-flies). Here, probably, his most valuable work was done in his careful tabulation of British native species (1903–16). His conclusions were arrived at only after full discussions with continental students and an exchange of material, and it had long been his wish to gather his scattered papers in monographic form. But he had barely begun this revision when his death occurred.

Mr. Morice wielded a considerable influence, both among British and continental Hymenopterists. His knowledge of the palæarctic non-parasitic Hymenoptera, and of their distribution, was comprehensive and exact, and he had besides made several specialised studies, *e.g.* on the structure of the terebra in saw-flies. In nomenclatural discussion also his opinions were valuable, backed as they were by a sound scholarship, aware not merely of the rules but also of the elasticity in practice of classical usage. He will be remembered, however, chiefly as a consultant and helper of younger workers. A constant stream of collections, small and great, found its way to Woking for identification, and the work was never refused.

Mr. Morice joined the Entomological Society in 1889, and became its president in 1911. He was a regular attendant at entomological gatherings, and so recently as July of last year was present at the third International Entomological Congress held at Zurich; for, to the end, he greatly enjoyed the society of his fellow-workers. He also spent much time as a voluntary worker on the British Museum collections at South Kensington, to which institution he presented the important British collection formed by Edward Saunders. His own collection he bequeathed to Oxford.

J. W.

WE regret to announce the following deaths:

Mr. G. W. Lamplugh, F.R.S., lately assistant director of the Geological Survey of Great Britain, and president in 1918–20 of the Geological Society, on October 9, aged sixty seven years.

Major W. E. Marshall, Principal Medical Officer of Health to the Sudan Defence Force, formerly an assistant bacteriologist at the Lister Institute of Preventive Medicine, on September 24.

Mr. H. W. Page, consulting surgeon to St. Mary's Hospital, London, past president of the Neurological Society of London, and the author of numerous contributions to medical and surgical literature, on September 9, in his eighty-first year.

News and Views.

DURING the recent Church Congress at Southport, one day was largely engaged with discussion on the 'religion and science' issue. The most notable utterances were a sermon by Dr. Lang, the Archbishop of York, and a paper written by the late Vice-Chancellor of the University of Liverpool, the distinguished pathologist Dr. Adami, whose recent death was a grave loss to medical science. Dr. Lang directed attention to the change of outlook in contemporary science, which "is beginning to ask questions about fundamental presuppositions hitherto taken for granted, about the meaning of the universe as a whole." Science, in other words, seems to be becoming more philosophical. The Archbishop then made a strong plea that this new orientation in science should be met, on the part of the Church, by "an attitude of the fullest sympathy and trust." "The Church will not merely be detached. Its members will be ready to accept whatever truths in the region of natural science or historical criticism seem to be really established, and to welcome them as new revelations of the divine working." This must rank as a really significant utterance, and, if it speaks for the Church of England as a whole, is a most hopeful sign of the times.

DR. ADAMI's paper to the Church Congress outlined the attitude of the man of science towards faith and

the spiritual life. Three possible attitudes are indicated: (1) Negation of everything that is outside the boundaries of the senses and therefore incapable of being tested by physical means. (2) Acceptance of and belief in things of the spirit as of a world that is wholly apart from the material universe, and so from science. This was the attitude of Pasteur (under whom, it is interesting to note, Dr. Adami studied). (3) Belief that science and faith are governed by the same laws and that their methods are essentially identical. Rejecting the first two attitudes, Dr. Adami developed the third, showing how scientific knowledge advances by the use of hypotheses and the perpetual revision of theories in respect to new facts. Thus the Newtonian physics has been revised by Einstein, and Dalton's chemistry by J. J. Thomson and Sir Ernest Rutherford. The method of science is that of a search after truth by "progressive assumptions," and the search for religious truth is guided by a similar principle. It, too, is 'pragmatic,' and based on hypothesis and experiment.

DR. ADAMI'S paper was followed by one read by the Rev. J C. Hardwick, which dealt primarily with certain ethical difficulties presented by the facts of biological science, instancing the behaviour of the ichneumon wasp. He suggested that the difficulties arise from regarding Nature as a completed system rather than as an incomplete process, various stages of which co-exist and find themselves in disharmony. If Nature is to be judged, she should be judged by her latest products, *i.e.* in the light of man and his ideals, rather than by the wasp or the slug. It was refreshing to find authoritative spokesmen expressing views which cannot fail to create a new atmosphere. How far the audience realised the implications of all they heard may be doubtful. Dr Lang's allusion to the results of "historical criticism" is especially significant, for it is these, rather than the facts of natural science, which create problems for theologians to-day. Furthermore, Dr. Adami's policy of revised hypotheses would spell the end of all theological finality; though, to be sure, this might give religion a new lease of life

SIR OLIVER LODGE, on October 7, began at the Mansion House, London, a series of lectures endowed by Mr. Halley Stewart on the general theme of religion and science, with special reference to human progress. Sir Oliver said that he is impressed with the majesty and possibilities of the universe, as contrasted with the comparatively narrow outlook of the average of those engaged in the work of the world. With regard to religion and science, he does not feel oppressed by any conflict between them when both are reasonably understood. Both involve knowledge of certain aspects of the same universe, and controversies arising between them must spring from misunderstanding and limitation of outlook. As for scientific knowledge we little know whither its increase will lead us. The aspect of science which appeals to the majority of mankind is to be found in the applications and conveniences which can be derived from it. But the power to control the forces of Nature and to adapt them to our ends must depend for its value on what those ends are. The uses we now make of our increased powers may not be such as really conduce to the progress of humanity. In spite of the scientific and mechanical progress of the nineteenth century, no one can feel that we have arrived at a stable and satisfactory stage of civilisation. Though material development ought to conduce to human progress, there is no inevitable connexion between the two. Increased power over Nature involves increased power to destroy. Yet, on the other hand, if competition gave place to co-operation, and if each individual sought the welfare of the whole, the possibilities of life on this planet would be found to be such as have scarcely yet been imagined. Sir Oliver is inclined to believe that the possibilities of Christ's teaching of love and forgiveness are to-day being more clearly realised, and there will come a day when human intercourse will be saturated with it. The lecture was characteristic of the new outlook which sees that the chief problem raised by the rapid development of scientific technique is an ethical problem, and it is doubtful if this can be solved in isolation from religion.

MR. DANIEL GUGGENHEIM, the copper magnate, has given a sum of 500,000*l.* for the promotion of aeronautics. His son, Mr. Harry Guggenheim, is president, and Admiral H. I. Cone is vice-president, of the board of management of the fund. Admiral Cone was in command of the U S.A naval forces on foreign service in 1917-18, was wounded in the sinking of a British destroyer by submarine, is a Commander of the British Empire, and holds the Distinguished Service Order. Major R. H. Mayo, well known in British technical aeronautics, represents the board in Great Britain, and has assisted the president and vice-president, during a recent visit, in considering methods of applying the fund. They have come to the conclusion that the Royal Aeronautical Society is an appropriate body through which direct expenditure may be made in Great Britain towards co-ordinating international scientific and technical information, and a grant of 1000*l.* has been made for the year 1926-27. In the U.S.A. 60,000*l* has been allocated to each of two Californian institutions—the Leland Stanford University at Palo Alto and the California Institute of Technology at Pasadena—for the purpose of equipping and carrying on schools of areonautics. Prof. W. F. Durand holds the chair of engineering at Leland Stanford University, and Dr. R. A. Millikan is president of the California Institute of Technology; their names suggest a due balance between technical development and physical research

THE seventh year of the Tidal Institute of the University of Liverpool, according to the annual report for 1925 just issued, has been devoted mainly to the analysis of tidal observations and the preparation of tide tables The method devised in 1923 for the execution of such work on a large scale has been thoroughly tested, and has proved effective and in all respects satisfactory. New advances have been

made in regard to the prediction of tides in shallow waters; a request to analyse records from Avonmouth, where the shallow-water effects are extremely acute, led the secretary, Dr. Doodson, to devise harmonic corrections which are more general and more widely applicable than the non-harmonic corrections hitherto used in such cases. An entirely new problem of great importance to navigation in many regions was raised by a request of the Canadian Hydrographic Office for a method of predicting the times of turning of tidal currents, affected by large diurnal constituents, from records of such times alone; Dr. Doodson has devised such a method, which is being applied and tested. The Institute has undertaken tidal analyses or predictions for the Admiralty, the Port of London Authority, the Lower Liao River Conservancy for Newchang, the International Council for the Exploration of the North Sea, the New Zealand and Queensland Governments, and the other bodies already mentioned. A radio receiving set has been installed so that weather reports may be utilised to assist in a proposed new service of daily predictions of meteorological perturbations of sea-level at Liverpool.

THE papers read at the recent Conference of Public Lighting Engineers in Newcastle-upon-Tyne dealt with matters of professional rather than scientific interest, but there were several points mentioned that are not generally known. Mr. Colquhoon, in the course of his paper, stated that Scottish boroughs have a statutory obligation to provide proper public lighting, but there is apparently no similar obligation in England, the only legal requirement being that obstructions on roadways (such as those due to repairs) must be lighted by night. Similarly, in a paper entitled "Lighting Hours," Mr. Beveredge explained that there is no standard legal schedule of the hours for which public lamps must be lighted, each authority acts at its discretion, and there is considerable variation in the practice of different towns. It is only the drivers of vehicles who are required to exhibit lights during specified hours. There was some discussion on the practicability of a standard schedule for lighting hours, but it was suggested that at least two schedules, one for the south and one for the north of England, might be required. The possibility of compliance with a rigid scheme of lighting hours also depends largely on the facilities for lighting up and extinguishing, *i.e.* the extent to which automatic methods of control are available. The question of the lighting of important arterial roads designed for motor-traffic was also discussed. There is a general feeling that the lighting of such routes ought not to be left entirely to the discretion of the individual authorities in areas traversed, and that a portion of the Roads Fund might be applied to lighting by the Ministry of Transport, which is already interested in the maintenance of the surfaces of roads.

AUTUMN in Great Britain has this year continued generally exceptionally fine and mostly warm. In September the weather was fine and dry, the total rainfall being remarkably low in some southern districts; Southampton had a total of only a quarter of an inch. The weather was very warm in the third week of September, the thermometer in the shade registering 88° at Greenwich on September 19, and in many places the highest temperature of the year was experienced. In the south-east of England, the mean temperature for the month was about 4° above the normal. There were four days during the month at Greenwich with the solar radiation temperature above 140°. For the first three weeks there was not a single day with the mean temperature below the average. There was a considerable drop of temperature after September 25. Some October temperatures during the first ten days of the month touched 70°, mostly registering about 65°; in 1921, five years ago, October was remarkably fine and warm, the thermometer at Greenwich exceeding 80° on several days in the early part of the month. There was a break on Saturday, October 9, due to the arrival over Great Britain of a vigorous secondary disturbance from the Atlantic, and gales were experienced in places on the coasts, with heavy rain showers in places. Colder weather spread over the country in the rear of the disturbance and the conditions became more normal for the season of the year.

THE inaugural address at the opening of the eighty-fifth session of the School of Pharmacy of the Pharmaceutical Society was delivered on October 6 by Dr. J. F. Tocher, of the University of Aberdeen. In the course of his remarks, Dr. Tocher commented on the possible reasons which lead to the adoption of pharmacy as a career, and hoped for the time when students of all kinds might be classified according to their ascertained intelligence, so that their teachers would be able to impart knowledge to them more successfully. But such tests would scarcely distinguish between those who favoured pharmacy as a profession and others whose thoughts turned towards different careers. With increasing knowledge, the training of the pharmacist becomes more arduous: the rapidly expanding list of drugs used in medicine requires knowledge of their properties and uses, and of the tests necessary to ensure their purity. In the Pharmacological Laboratory which the Society has recently opened, the student will be able to gain first-hand experience in the testing of those drugs which require for their assay the use of animals. Thus although the minimum standard of knowledge has been raised with the advance in knowledge in the other sciences, the enthusiastic student will find ample opportunity not only to reach this standard but also to progress beyond it.

A REPORT by Prof. J. Borozdin, quoted by the Riga correspondent in the issue of the *Times* of October 8, gives a brief account of the results of excavations carried out by Prof. Farmakovsky in the neighbourhood of Nikolaieff, where he has been working for the last twenty years, on the site, hitherto not identified, of the Milesian colony of Olbia (which was described by Herodotus), at the mouth of the River Bug. The excavations now embrace an area of 287,000 sq. yd., not including a necropolis, and the objects brought to

light include dwellings, temples, and vaults. In the centre of the town stand the ruins of a temple of Apollo. Nine successive strata of remains have been discovered; these show a variety of influences from several sources, including Attica and the Roman Empire as well as Miletus. Of even greater interest are the excavations at the village of Usatoff, some five miles out of Odessa. Here a culture has been found which is said to exhibit the transition from neolithic to bronze and to be advanced of its type. It is that of a settled agricultural community with earthen dwellings closely resembling the culture of Tripolje. The pottery is of the characteristic painted type, having strong points of resemblance to the widely diffused painted pottery which, with wide divergences and of varying epochs, it is true, is found in China, central Asia at Anau, India, Elam, Mesopotamia, Cappadocia, and Syria, and in Europe in southern Russia, Rumania, Bulgaria, Thessaly, and southern Italy. An example is said to have been discovered in the Crimea. Further information will no doubt confirm the importance of the discovery, which should serve to throw additional light on the difficult question of the relationship and lines of diffusion of this remarkable type of prehistoric ware.

THE Trueman Wood Lecture of the Royal Society of Arts will be delivered on October 27 at 8 P.M. by Dr. R. J. Tillyard, chief of the Biological Department of the Cawthron Institute of Scientific Research, Nelson, New Zealand, who will take as his subject "The Progress of Economic Entomology."

THE James Forrest Lecture for 1926 of the Institution of Civil Engineers, which was to have been given in May, will be delivered at the Institution on Tuesday, October 26, at 6 o'clock, by Senator G. Marconi, who will take as his subject "Radio Communications." Before the lecture, the Kelvin Medal for 1926, which has been awarded by the Kelvin Medal Committee to the Hon. Sir Charles A. Parsons, will be presented to him by Sir William Ellis, president of the Institution.

PROF. HANS THIRRING, professor of physics in the University of Vienna, will deliver a lecture in English on October 19, on "The Position of Science towards Psychical Research," at the National Laboratory of Psychical Research, 16 Queensberry Place, South Kensington, London, S.W.7. This lecture is one of a series arranged for the season 1926–27, which includes one by Mr. Stanley de Brath on "Animism, Spiritism and Spiritualism" (February 15), and another by M. René Sudre (in English) on "Psychical Research and Psychology" (March 15).

THE three Cantor Lectures on thermometry which have been given by Mr. W. F. Higgins of the National Physical Laboratory to the Royal Society of Arts are reproduced in the issues of the *Journal* of the Society for September 3, 10, and 17. They furnish the best account available in English of the properties and behaviour of the mercury-in-glass thermometer, of the methods used in its standardisation, and of the precautions to take in order to obtain the most accurate results from it. Mr. Higgins looks forward to the time when the mercury-in-silica thermometer will be substituted for the mercury-in-glass thermometer for all accurate work.

THE seventy-ninth annual meeting of the Palæontographical Society was held at Burlington House on October 1, Dr. F. A. Bather, vice-president, in the chair. The annual report announced the completion of Miss Chandler's monograph of the Upper Eocene flora of Hordle, and the early issue of further instalments of the monographs of Gault Ammonites, Malacostracous Crustacea, and Palæozoic Asterozoa. The council appealed for the help of more personal subscribers, the larger number of the supporters of the Society being now public institutions. Prof. W. T. Gordon, and Messrs. G. Barrow, A. T. Hopwood, and J. Pringle were elected new members of council. Mr. E. T. Newton was re-elected president, and Mr. Robert S. Herries and Sir A. Smith Woodward were re-elected treasurer and secretary respectively.

THE council of the Institution of Civil Engineers has made the following awards for the session 1925–1926 in respect of selected engineering papers, published without discussion: A Telford Gold Medal and the Indian Premium to Mr. C. R. White (London); a Telford Gold Medal to Mr. E. L. Everatt (Bombay); and Telford Premiums to Dr. B. Hague (Glasgow); Prof. A. H. Gibson (Manchester) and Mr. S. Labrow (Bury) jointly; and Dr. W. J. Walker (Johannesburg). The following awards have been made in respect of papers read at students' meetings in London or by students before meetings of local associations during the same session: The James Forrest Medal and a Miller Prize to Mr. D. S. Matheson (London); and Miller Prizes to Mr. H. R. Lintern (Shepton Mallet), Mr. R. D. Carr (Cupar), Mr. C. Peel (Frodsham), Mr. R. S. Bamber (Leeds), Mr. N. R. Rice (Dar-es-Salaam), Mr. J. G. Kimber (Eastbourne), and Mr. J. B. Mayers (Birmingham).

THE Earl of Balfour presided at a congregation at Cambridge on Tuesday, October 5, when the University commemorated the three-hundredth anniversary of the death of Francis Bacon, Lord Verulam, by awarding honorary degrees to the Cavendish professor of physics, Sir Ernest Rutherford, and to Prof. W. S. Holdsworth, Vinerian professor of English law in the University of Oxford. The public orator spoke of Bacon, eminent in civil law and natural science, as a follower of the Stoics, who taught us to strive to adjust our laws to the laws of Nature; Dr. C. D. Broad, Trinity College, who lectured to the University on Bacon, described him as the father of inductive philosophy, one who discovered and explicitly stated the methods and principles of scientific research, which his successors have used with success. An afternoon reception was given by Trinity College and a dinner in the evening, at which the Earl of Balfour spoke to the toast of Bacon's memory.

A RECENT issue of the *Weekly News Bulletin* of the U.S.S.R. Society of Cultural Relations with Foreign Countries contains under the heading "Scientific

Life" an account of measures recently adopted for encouraging intellectual activity. The title "merited" has been established, to be conferred for distinguished service by scientific and technical workers. Money premiums are to be given for inventions and suggestions, even though they may not directly result in the saving of expenditure. Instances of pensions for prominent services in science are also mentioned. Under "International Cultural Relations" are reports of visits to Russia by Profs. Erlander of Stockholm, Wiegond and Rodenwald of Berlin, and Temer of Strasbourg, and visits to Egypt by the Rector of the Russian Hydrological Institute to take part in the International Navigation Congress at Cairo, and to the Balkan countries and Italy by N. P. Sycher of the Russian Academy of History of Material Culture.

WE have received from Messrs. Stafford, Allen and Sons, Ltd., Cowper Street, Finsbury, London, E.C. 2, a sample of 'Sira' immersion oil and of 'Sira' mountant. Originally produced as a result of researches conducted at the British Scientific Instrument Research Association, these products are now prepared by the manufacturers in accordance with the directions of the Association. The refractive index of the immersion oil (1·524 at 20°) is adjusted to suit modern high-power object glasses, condensers, and micro cover glasses. An important feature of the oil is its freedom from corrosive action on metals or on optical glass. 'Sira' mountant, being quite neutral, may be advantageously used in place of Canada balsam, the acidic properties of which are known to affect certain stains and other substances when mounted in it. These 'Sira' products, which may be obtained from all scientific instrument makers and dealers, should prove of considerable value to microscopists whose work demands critical observation, in assisting them to obtain the best possible results from their microscope and its accessories.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A pathologist for the City of Nottingham—The Town Clerk, Guildhall, Nottingham (October 18). A junior inspector of mines for North Wales (Lancashire and North Wales Division)—The Under-Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (October 25). A mycologist under the Ceylon Rubber Research Scheme—The Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1 (January 1). A lecturer in physics in the University of Otago, New Zealand—The High Commissioner for New Zealand, 415 Strand, W.C.2. A junior technical officer at an Admiralty Experimental Establishment, with good theoretical and practical manufacturing knowledge of the design of electrical apparatus—The Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1. A lecturer in mechanical engineering at the School of Science and Art, Newark-on-Trent—The Secretary, Old Magnus Buildings, Appleton Gate, Newark-on-Trent. A junior mathematical mistress—subsidiary subjects geography and botany—at the Southport High School for Girls—Application forms from the Director of Education, Education Office, Southport, but returnable to the Headmistress.

Our Astronomical Column.

MINOR PLANETS.—Vol. 9, No. 9 of the *Journal des Observateurs*, contains a study of the orbit of No. 117 Lomia by M. Henri Blondel. This covers the period from 1913 to 1925, and includes the perturbations by Jupiter and Saturn. A good agreement with observation is obtained. It is noted that observations over a period of some four months are required to obtain a good orbit from a single opposition. It is suggested that ephemerides should be extended over a longer range than is usually done.

This is a favourable time for observing the interesting planet 132 Aethra, which was recovered a few years ago after being lost for half a century. It is in high north declination and of magnitude 11. Ephemeris for 0^h by H. Hartog (*Astr. Nach.* 5464):

	R.A.	N. Decl.
Oct. 16	$3^h\ 33^m\ 16^s$	$41°\ 16'$
„ 28	3 23 36	40 30

ANOTHER DETONATING FIREBALL.—Mr. W. F. Denning writes that a very large meteor was visible on the evening of Saturday, October 2, at $19^h\ 25^m$ G.M.T. As observed at Bristol, its path was from $330° - 7°$ to $34° + 14°$. A considerable number of observations have been received, and a comparison of these shows that the object passed from over the English Channel (45 miles south of Brighton), northwards over the western suburbs of London, and on to the northern region of Hertfordshire, where it exploded at a height of about 11 miles. The radiant point was in Capricornus at $305° - 13°$. The velocity of the fireball was about 13 miles per second along a real course of about 125 miles. The nucleus was green, followed by red sparks. The weather being generally clear in the south of England, the phenomenon was pretty generally witnessed, though observers differ materially in their impressions concerning it. The radiant of the fireball agrees with that of a well-known shower in July and August.

C. SCHOCH'S RESEARCHES ON ANCIENT ECLIPSES.—Allusion has already been made in these columns to Schoch's conclusions on the eclipse of the Odyssey, which he identified as that of April 16, B.C. 1178. He has now discussed a still more ancient eclipse, that in the tenth year of the Hittite king Mursilis II. He identifies this as the annular eclipse of B.C. 1335, March 13, which was central in the region of the Azzi (about Erzeroum). The total eclipse of Jan. 8, 1340, is excluded, since military operations would not take place so early in the year in that elevated region. Schoch notes that the region is the same as that afterwards traversed in the retreat of the Ten Thousand. He has also identified various eclipses mentioned by Greek poets:

Poet.	Date B.C.
Mimnermos, same as eclipse of Thales	May 28, 585.
Stesichoros and Kydias. . . .	May 19, 557.
Agathokles eclipse, concluded position of Agathokles in Straits of Messina	Aug. 15, 310.

Research Items.

THE ORIGIN OF THE MASAI AND THE WILD TRIBES OF BORNEO.—In the *Journal of the East Africa and Uganda Natural History Society*, No. 26, August 1925, Mr. C. Cardale Luck puts forward a theory that the Masai and related tribes of East Africa are the ancient Israelites, while the wild tribes of Borneo, the Kenyah, Kayan, Punam, etc., are the ancient Edomites. Merker's theory of the Semitic origin of the Masai, it is pointed out, might have been extended to identify them with the ancient Israelites, had it not been conditioned by the view that if their route of migration was through the Nile valley, it must have taken place in the prehistoric period before the Egyptian settlement. The historical evidence, however, points to the possibility of a movement of Asiatic peoples in the required direction in Egyptian historic times in the influx of Semitic peoples after the Hyksos period, the transference of captives after the Egyptian conquests, the flight of such of the Israelites as were not carried off into Assyria before the victorious armies of that power, and the desertion into Ethiopia of mercenaries, presumed to be Asiatic, under Psamtek and Tanutamen of the Nubian dynasty. Looking at the evidence afforded by the Masai and kindred tribes, distribution of language clearly suggests a north to south movement. The religion of the Masai, a trinity of Engai, a feminine supreme deity, and two inferior deities, a black or good god and a red or evil god, points to an original mother goddess worship, ultimately of Asiatic origin The Canaanites in passing through Egypt confused her with Hathor, the minor gods of the Masai being Osiris and Set. Tribal names of the Masai also point to Canaan, Ma-a-sae, L'Aiser and Gidon being equated with Ma-na-say, Je-ezer, and Gideon. Similar equivalences are found in the Bornean religion, belief, and nomenclature and pointing to a Canaanitish origin

SICKNESS, DEATH AND BURIAL AMONG THE MAORI.—Notes from a native source in the original and in translation relating to the ritual of death and burial among the Maori of New Zealand are given by Mr Elsdon Best in the *Journal of the Polynesian Society*, Vol. 35. No 1, which contain certain data not hitherto recorded, and some interesting formulæ. In former times there was little ritual pertaining to burial, and indeed the ceremonies performed over a sick person were more elaborate, possibly owing to the fact that the custom of exhumation and final disposal of the remains was looked upon as the real burial. There were several ritualistic performances by which the shamanistic adepts diagnosed the cause of illness. This was usually either black magic or infringement of the laws of *tapu*. The ceremony here quoted, for a chief seized with severe illness, involved the use of formulæ absolving a person from the polluting effect of all immoral or wrongful acts committed from childhood up to that time. The dead were usually disposed of by inhumation, but sometimes they were merely placed in a cave The body was flexed before it was cold, the knees being drawn up to touch the trunk and bound with a cord. In a few cases it was exposed to a rude drying process. The exhumation took place some years, sometimes so many as eight, after the first burial, although, as a number of exhumations took place at one time, there must have been considerable variation. The function was one of remarkable *tapu*; it involved the employment of adepts and was carried out with an elaborate ritual; the final destination of the remains was a cave, fissure, or hollow tree. Great care and skill were exercised in removing the bones, especially in recovering the small bones. Articles placed with the dead such as weapons and ornaments, both at the primary and secondary burials, were sometimes recovered for the relatives by a priestly adept, with the performance of certain ceremonial observances.

ALIEN PLANTS IN THE ISLE OF WIGHT.—The bulk of vol. 1, part 5 of the *Proceedings of the Isle of Wight Natural History Society* for 1924 is occupied by a list of the alien plants of Hampshire and the Isle of Wight, by John F. Rayner. The list is a very long one and has obviously been in compilation for some years, the author being helped by a number of local botanists, as well as by veteran systematists, as Dr. Claridge Druce.

AN ANTARCTIC FLORA.—The Australasian Antarctic Expedition, 1911–14, has recently published as vol. 7, part 5, some beautiful photographs of the very characteristic flora of Macquarie Island, which were not available when the late Mr. F. T. Cheeseman prepared his report on the vascular flora of Macquarie Island, owing to the disturbance of personnel and records of the expedition brought about by the War. The photographs of *Pleurophyllum Hookeri*, of *Stilbocarpa polaris*, and of such cushion plants as *Azorella selago*, are of great ecological value, some photographs giving detail of individual plants beautifully, whilst others show in a striking manner their characteristic distribution on this wind-swept antarctic island. All the conspicuous members of the flora are represented photographically in these 19 plates, while Mr. Harold Hamilton supplies brief notes on the ecology.

PENTOSANS AND COLD RESISTANCE IN PLANTS.—Of recent years, American workers, especially J. T. Rosa and Victor R. Boswell, have tried to establish a connexion between the pentosan content of certain plants and their resistance to frost damage. The underlying assumption has been that the water-imbibing properties of the colloidal pentosans have enabled these plants to retain the water in this form and thus resist the tendency to ice-formation and consequent protoplasmic disorganisation. Arguing further that the retention of water by imbibition by the pentosans should be effective against force of dehydration, Rosa compared the transpiration rates and rates of drying of cold resistant and non-resistant plants. Both Rosa and Boswell agree that the hardened plants lose water more slowly under comparable conditions, and suggest in fact that this property provides a simple test, in horticultural practice, of the relative hardiness of a plant. This attractive theory comes out very badly from a thorough investigation by Prof. Doyle and Miss Phyllis Clinch, of the Department of Botany, University College, Dublin, who have tested its application to evergreens, and particularly conifers. In conifers they conclude (*Scientific Proceedings of Royal Dublin Society*, vol. 18 (N.S.) No. 21, 1926) that no relation, seasonal or otherwise, can be established between hardiness and pentosan content. Furthermore (same *Journal*, No. 24, 1926), they show that the rates of drying show no relation to pentosan content, and on physico-chemical grounds there seems little reason to expect any other result, whilst until Rosa and Boswell have repeated their drying experiments with chopped-up tissues, there is little or no reason to assume that pentosan content has any connexion with the differences in drying shown by hardy and non-hardy varieties.

MINERALS FROM THE RUBY MINE DISTRICT OF BURMA.—A notable contribution to the mineralogy of Burma is published by F. D. Adams and R. P. D. Graham in the *Trans. Roy. Soc. Canada*, Section 4, 1926, p. 113. Between the Irawadi and Mogok the exposures show alternating bands of gneiss and coarsely crystalline limestones which recall the sections through the Grenville series of the Canadian Shield. Half way along the road to Mogok a large intrusive body of granite occurs with an enormous pegmatite dyke near its eastern border. The dyke is made up mainly of kaolinised orthoclase and quartz, the latter being often in large transparent crystals Lepidolite crystals up to six inches across are described, and muscovite, topaz and cassiterite. An interesting nepheline-sodalite rock occurs at Mogok, the sodalite from which has a beautiful deep lilac colour. The colour fades on exposure to light, and disappears immediately when the mineral is slightly warmed, this being a characteristic of all pink sodalite. A nepheline-ægerine-augite rock (urtite) was found at Sinkwa, 13 miles from Mogok. Both nepheline rocks resemble very closely varieties occurring in the Bancroft district of Ontario, and afford additional examples of the common association with crystalline limestones. Other minerals described are chrysoberyl, sillimanite and forsterite from Mogok. A more detailed description of the geology of this part of Burma, together with an account of the methods adopted in working the deposits for rubies, was given by Prof. Adams in the *Bull Canadian Inst. Min. Met*, 29, Feb. 1926.

PLATINUM IN SOUTH AFRICA.—In *Economic Geology*, Nos. 2 and 3, 1926, Dr. P A. Wagner gives a very full account of the occurrence of platinum in the Transvaal and Southern Rhodesia. As the chief deposits have already been noticed in NATURE, attention is here directed to the genetic considerations with which Dr Wagner concludes his study. Concentrations of platinum are more widely distributed in South Africa than in any other part of the world, and the platinum-bearing rocks have been produced in practically all the periods of igneous activity from the earliest Archæan onwards From the Vaal River to the Zambezi the principal deposits are confined to a narrow meridional belt that cuts indiscriminately across all the other structural features Some deeply underlying region must therefore have contributed the ores, suggesting that the *sima* or peridotite zone beneath South Africa is, or has been, unusually richly endowed with platinum J. E Spurr has already advocated the idea of great *ore canals*, stable throughout geological time, from which igneous magmas have abstracted ores and, ascending in the crust, have concentrated the metals nearer the surface. Dr Wagner similarly conceives the presence below the platinum belt of a great platinum-rich canal which has provided the material transferred towards the surface by successive igneous intrusions. It is also pointed out that there is an equally remarkable gold province in south-east Africa which may well have drawn its gold from the same canal It is worthy of notice that if the hypothesis be true in the form in which it is advocated by Spurr and Wagner, it raises a most serious objection to the migration of continents over the substratum that has been envisaged by Wegener, and somewhat differently by Joly. On the other hand, the conception itself is in accord with the inference drawn by Holmes (from the atomic weight of lead) that lead ores must have had some source independent of any later concentration from the magmas of igneous rocks. Another point is that no ore deposits are found in oceanic islands, suggesting that the continental rocks are more probably the original home of most ores rather than the underlying *sima*. If this be so, then the ore canals may represent concentrations produced in and near the bases of the continents at the time of their origin. If, then, the continents moved laterally in later ages, the canals would be carried with them, and not left beneath and behind as they would otherwise be.

TIDES AND SEA SEICHES.—Tidal features of local coastal origin and sea seiches are discussed by Prof. J. Proudman in a recent *Geophysical Supplement* (vol. 1, No. 6, 1925) of the *Monthly Notices of the Royal Astronomical Society*. The paper is illustrated with many diagrams of cotidal lines relating either to actual regions or typical ideal cases (curved and rectangular capes and bays, circular and elliptic islands, and a passage between two seas). Deductions as to the deformation of the cotidal lines by such local features are made on a mathematical basis, and actual cases of the phenomena are instanced, on the British or Irish coasts. The effect of the neighbouring coast-line on sea-seiches in a narrow bay is also considered.

IRRIGATION IN INDIA.—A review of irrigation in British India during 1924–25 has been published by the Public Works Branch of the Department of Industries and Labour. During the year the monsoon, after beginning weak, was practically normal in total rainfall, and there was appreciable defect only in Orissa and Kashmir, with excess in the western United Provinces, the North-West Frontier, Rajputana, and Malabar. The total area irrigated by works of all kinds was 27·2 million acres, which was about a million acres less than in the record year 1922 23. It is of interest to note that 12·4 per cent. of the total cropped area was irrigated by Government works. The review gives full details of the financial side of irrigation and drainage works during the year.

PRESSURE AND WINDS OVER THE CHINA SEA.—A large-scale atlas of twelve maps showing the mean atmospheric pressure and wind direction and force over the China Sea for each month of the year has been published under the authority of the Governor of Hong-Kong. There is a short introduction by the Director of the Royal Observatory, Hong-Kong. The observations were collected during the years 1900–1912 from ships calling at Hong-Kong, the stations of the Chinese Maritime Customs, and various observatories in the Far East. The observations were originally tabulated in one-degree squares, but this grouping being found unjustifiable except on the main sea routes, they were collected into two-degree squares. Pressures are shown in inches, wind forces are given on the Beaufort scale, and within the wind roses are given the number of barometric observations on which each has been determined and the percentage of calms. The maps extend to lat. 34° N., 8° S., and long 130° E. They are clearly printed, with land outlines in blue and isobars in red.

X-RAY EXAMINATION OF LONG-CHAIN COMPOUNDS.—In the *Annales de Physique* for July-August, M. Trillat contributes an important paper on the X-ray examination of long-chain compounds, and he gives values for the spacings of fatty acids containing as many as 32 carbon atoms. With the new data at his disposal he shows that the rate of increase in chain length with increase in the number of carbon atoms is slightly different for acids containing odd and even numbers of carbon atoms, although it is uniform in both cases. He also finds that by mounting a thin layer of a fatty acid on a strip of metal, a very fine

film of soap is usually formed immediately in contact with the metal surface. This film is amply sufficient for the purposes of X-ray examination by the reflection method, so that it is unnecessary, in general, to prepare a soap separately for X-ray examination. By examining the changes in the X-ray spectra of oleic, linoleic and linolenic acids in the course of drying in air, Trillat is the first to follow directly a complex chemical reaction by means of X-rays. Attention is directed to the importance of these long-chain compounds in the investigation of very soft X-rays.

THE PHYSICAL PROPERTIES OF GLASSES.—A large amount of information on the above subject is to be found in Prof. W. E. S. Turner's lecture on the relationship of the physical properties of glasses to chemical composition and mode of preparation, delivered before the Chemical Society on April 29, and published in the Society's *Journal* for August last. The preparation of commercial glass involves the fusion of a number of oxides or metallic salts, which may number as many as twelve or more, and the proportions of the constituents largely determine the physical properties. The most important properties are the transmission and absorption of light, the refractive index, the viscosity, the annealing temperature, electrical conductivity, and resistance to the action of water (which is partly a chemical process), thermal expansion and density. In many cases simple relationships are found which make it possible to prepare glasses of approximately known properties by fusing suitable oxides in the requisite proportions. A compromise is necessary in the manufacture of glass for chemical purposes, since the presence of alkaline oxides reduces the resistance to the action of acids. Modern chemical glass ware contains a high percentage of silica, with boric oxide and alumina, and only sufficient alkaline oxides to enable melting to take place fairly readily. The use of a high percentage of silica lowers the resistance of the glass towards alkalies, but the danger of breakage from sudden temperature changes is eliminated on account of its low thermal expansion.

THE USES OF TELLURIUM.—On account of its many industrial applications, tellurium is rapidly becoming of technical importance. Some notes on its uses are contained in a short article in the *Chemical Trade Journal* for September 10, and among the most important are: as a colouring agent in the glass and porcelain industry, in the preparation of organic dyestuffs, in the manufacture of electrical equipment, high resistance alloys and ultramarine, in the colouring of lithophone and the staining of silver, as a delicate test of sterilisation in bacteriology, and as a toning agent in photography. A compound of tellurium has been patented as an anti-knock constituent of motor fuels, and its use is said to lead to greater efficiency. Remarkable properties are shown by the alloys of tellurium; the tin alloys are extremely hard and have very great tensile strength, the aluminium alloys are very ductile, while the silver alloys have recently been used. The poisonous properties of the element, and its fairly ready absorption (*e.g.* from gold dental stoppings), are not mentioned in the article, but should not be overlooked.

LOW TEMPERATURE CARBONISATION.—The firm of Salermo Ltd., 17 Kingsway, London, W.C.2, has issued a brochure entitled "Low Temperature Carbonisation and the Salermo Process." It contains mainly a survey, sound in substance and temperately worded, of the processes hitherto proposed. The Salermo retort, which is new to Great Britain although tried already in the Sarre mines, is described. It consists of a series of troughs fixed adjacently and parallel and heated from below. The coal, pre-dried by waste heat, is mechanically propelled from one trough to the other, and the product is delivered in a semi-pulverised condition. High throughput is said to be associated with low capital and running costs. The product is, unfortunately, not fit for immediate domestic consumption, but might be suitable for steam boilers.

PROJECTION OF EXPLOSIVE FLAMES.—In a paper published by the Safety in Mines Research Board (No. 27) Mr. M. J. Burgess has described experiments on the distance over which a methane-air mixture, when exploded in a tube, projects its flame into the air filling a second tube attached to the explosion-tube. When the two tubes were 9 cm. in diameter the projection of flame into the air may be more than five times the length of the original column of explosive mixture. When the aperture between the two tubes is gradually reduced by an adjustable diaphragm, the first effect is an increase in the length of the projected flame—especially with mixtures containing an excess of methane. The experiments show to what a great distance flame may be projected along a gallery when a fire-damp explosion occurs in a mine.

SMOKELESS FUEL FOR POWER.—At the Conference on Smoke Abatement held at Birmingham recently, Mr. A. S. E. Ackermann read a paper on the "Engineering Aspects of the Smokeless Production of Power," a copy of which we have received. The various methods of generating power without smoke production are surveyed briefly. Pulverised fuel firing of steam boilers is favoured on account of high thermal efficiency and absence of smoke. The common view that water-power resources of Great Britain are negligible is contested. It is calculated that 500,000 H.P. might be developed by the erection of efficient installations. The combination of public hot-water supply with power stations is a means of increasing the thermal return of electricity generation. The waste heat from gas retort settings might be utilised to generate current in large quantities. Mention was made of the application to marine and locomotive work of the Still (internal combustion steam) engine, which now is the most efficient prime-mover available.

COAL TREATMENT IN THE UNITED STATES.—In the September number of the *Journal of the Franklin Institute* appears a series of papers on low temperature carbonisation, read at the "Oil and Gas Power Week" Conference at Philadelphia in April last. They reflect the growing concern as to the uncertainty of adequate supplies of mineral oil across the Atlantic. H. W. Brooks gave a general summary of European and American processes, and although unable to point to successful commercial achievement anywhere, he closed on a note of confidence that we are nearing the "Age of Coal Processing." W. H. Blauvelt read another general paper emphasising the desirability of subjecting coal to a process of fractionation and refinement analogous to that of the mineral oil industry. Perhaps the most interesting contribution technically was made by V. Z. Caracristi, who gave an account of experiences with the ingenious lead-bath carbonisation process which has aroused so much interest. This has been given trial by Henry Ford at his motor-works, where no expense has been spared in grappling with the problem of this pioneering effort. To those who speak lightly of the scientific treatment of coal, it may be a revelation to learn that already several million dollars have been spent on experiments on this one process. It is not clear whether commercial success is claimed, but it is stated that the practicability of the lead-bath as a medium for the transfer of heat has been fully demonstrated.

University and Educational Intelligence.

THE twenty-fifth session of the work of the Sir John Cass Technical Institute was inaugurated on October 4, when an address was delivered by Alderman Sir Charles Wakefield, Bart. Before calling upon Sir Charles to deliver the inaugural address, the chairman of the Governors, the Rev. J. F. Marr, referred to the resignation of Dr. Keane, who had been principal for almost a quarter of a century, the appointment of Mr. Geo. Patchin as his successor, the generous support given to the work by the important companies connected with the fermentation and petroleum industries, and the gratifying record of university successes; one student has been awarded a D.Sc. for a thesis on research work carried out in the department of chemistry. Further facilities for study are being provided during the session, including a more advanced course of lectures in colloids and an advanced course of lectures on petroleum technology.

ONE of the papers read at the recent conference at Balliol College, Oxford, of the Association of Special Libraries and Information Bureaux was entitled "Instruction in Bibliographical Technique for University Students," by Mr. Harold E. Potts, chairman of Convocation of the University of Liverpool. He urges that all students should be given some instruction in the art of using a library intelligently. It is not intended that they should spend the time when they should be working in the laboratories in reading in the library, but that they should acquire the habit of looking for the original sources of the information given in lectures and text-books. This matter is largely in the hands of the professors, who would do well, from time to time, to recommend their pupils to read certain original papers as an example of how discoveries are made. The habit of looking at original papers instead of at text-books and abstracts is one that cannot be acquired too early. The student will be astonished to find that some mis-statements have been quoted from text-book to text-book throughout long periods before the error was discovered. At the same time it must be confessed that a student may easily spend too much time in this way to the neglect of experimental work.

WHILE the universities and university colleges in Great Britain usually possess good libraries, the technical institutes and colleges are, as a rule, very poorly supplied. In most cases the sums allowed for the upkeep of their libraries are very small. Principal J. F Hudson, of the Huddersfield Technical College, in a paper contributed to the recent Conference of Special Libraries and Information Bureaux at Balliol College, Oxford, argues that the provision of a suitable supply of literature should be regarded as an essential part of the equipment of every scientific and technical department of a college. Most local colleges specialise in one or more departments, such as woollen textiles, rubber technology, or pottery. These schools should develop special libraries of peculiar value which should be made accessible to all who are interested in these subjects. Principal Hudson suggests that at least 1 per cent. of the annual expenditure on a technical institute should be assigned to the support of the library. He refers to a letter in NATURE for May 22, 1926, in which a correspondent asks what he can do with old scientific books which he no longer needs. As will be seen from Mr. Headicar's letter in our issue of July 3, the Universities' Library for Central Europe has taken up this problem and has arranged to act as a clearing house for the disposal of scientific periodicals.

Contemporary Birthdays.

October 15, 1884. Prof. Lewis Knudson.
October 16, 1859. Prof. James Playfair McMurrich.
October 17, 1872. Sir Cyril Reginald S. Kirkpatrick.
October 19, 1856. Prof. Edmund B. Wilson, For. Mem. R.S.
October 20, 1862. Prof. Thomas Hastie Bryce, F.R.S.
October 22, 1876. Prof. Harold Hilton.

Prof. KNUDSON, who occupies the chair of botany at Cornell University, was born at Milwaukee, Wisconsin, U.S.A. His informative lectures on plant physiology have been particularly welcomed in recent years by Spanish men of science, notably at such centres as Madrid and Barcelona. His botanical studies comprise researches in fermentation, the organic nutrition of plants, germination of orchid seeds, and the diseases of the banana.

Prof. McMURRICH was educated at Upper Canada College, Toronto, at the University of the city, and at Johns Hopkins University, Baltimore. He has occupied posts in several universities of the United States, but since 1907 he has been professor of anatomy at Toronto. In 1922 Prof. McMurrich was president of the Royal Society of Canada.

Sir CYRIL KIRKPATRICK was educated at Repton. His engineering studies were conducted, in the first instance, at the Crystal Palace School of Engineering; afterwards he entered the service of the old London and North-Western Railway. Sir Cyril was chief engineer of the Port of London Authority from 1913 until 1924.

Prof. E. B. WILSON, distinguished as a zoologist, was born at Geneva, Illinois, U.S.A., and educated at Yale University, New Haven, and Johns Hopkins University, Baltimore. In 1883 he was a lecturer in biology at Williams College, fulfilling afterwards various important duties elsewhere until 1891, when he was appointed professor of zoology in Columbia University. Prof. Wilson is a foreign member of the Royal Society of London, and of the Linnean Society. In 1914 he delivered the Croonian lecture before the former body, taking as his subject "The Bearing of Cytological Research on Heredity." A member of the National Academy of Sciences, Washington, and of several English societies, he is Hon. Sc.D., Cambridge. Prof. Wilson is the author of a standard work, "The Cell in Development and Heredity"; originally issued in 1896, it passed recently into a third edition.

Prof. BRYCE was educated at Edinburgh Collegiate School. He graduated later at the University of Edinburgh. Lecturer on anatomy in the University of Glasgow from 1892 until 1909, he was then appointed to the chair of anatomy. The Royal Society of Edinburgh awarded Prof. Bryce its Keith prize in 1906 for his memoirs on the histology of the blood of the larva of *Lepidosiren paradoxa*. He is the author of vol. 1 of "Quain's Anatomy" and joint author of a work on the development of the human ovum.

Prof. HILTON, an old pupil of Lancing College, graduated at Hertford College, Oxford. Sometime assistant lecturer in mathematics in the University of Bangor, he afterwards joined the teaching staff of Bedford College. Since 1912 he has been professor of mathematics in the University of London. Prof. Hilton is the author of many papers in crystallography, especially the theory of crystalline structures.

Societies and Academies.

SYDNEY.

Linnean Society of New South Wales, July 28.—C. T. **White**: On a small collection of plants from the Rigo district, Papua. Two species, one of Plectronia and one Jasminum, are described as new.—C. P. **Alexander**: The Trichoceridæ (Diptera) of Australia. One genus and four species are described as new. A key is given for the determination of the genera.—R. H. **Cambage**: Notes on the native flora of New South Wales. Part xi. Moree to Mungindi and Moonie R., with a description of a new species of Eucalyptus. The paper contains notes on the early exploration, topography, etc., and a list of the plants noticed. A comparison of this flora is made with that of Tasmania, in view of the dominating influence of climate on plant distribution.—G. H. **Cunningham**: Gasteromycetes of Australasia. (v.) The genus Calvatia. The genus may be separated from Lycoperdon by the method of dehiscence, which is effected in Calvatia by the irregular falling away of the apical portion of the peridium; whereas in Lycoperdon dehiscence is effected by means of a definite apical stoma. The genus contains about eight species, of which four are present in Australia and New Zealand.—G. D. **Osborne**: Stratigraphical and structural geology of the Carboniferous rocks in the Mt. Mirannie and Mt. Dyrring districts, near Singleton, N.S.W. There are two volcanic series with associated clastic rocks, and separating these series is a set of sediments called the Main Clastic Zone. The major volcanic series comprises andesites, dacites, rhyolites and keratophyres, while the lavas in the other group are chiefly toscanitic and dellenitic. The only glacial beds occur near the top of the Kuttung Series, and Rhacopteris-bearing strata are found on two horizons. The chief tectonic feature is the great Bridgeman Fault which separates the Kuttung Series from the Permian or Permo-Carboniferous Series. This is probably an overthrust. In addition there are many normal faults connected with the late Palæozoic diastrophism which folded the area and produced two basin-structures.

WASHINGTON, D.C.

National Academy of Sciences (Proc. vol. 12, No. 8, August). R. J. **Havighurst**: The absorption of X-rays in crystalline compounds. The mass absorption coefficient in a compound is the sum of the mass absorption coefficients of the individual atoms and has been calculated from various empirical formulæ. Measurements upon crystalline compounds are subject to large experimental error on account of "selective absorption" due to reflection of the primary ray from certain atomic planes. Compressed slabs of powders (and also Wingardh's data from solutions) give results in good accord with the calculated absorptions for sodium chloride and fluoride and calcium fluoride and carbonate. Carl **Barus**: (1) Acoustic pressures in case of soap bubbles. A series of soap bubbles were attached to the telephonic apparatus and pinhole probe. Pressure as measured by the fringe displacement of the interferometer always corresponded with the radius of the bubble. (2) Acoustic pressure promoted by co-operating quill tubes without pinholes.—Edwin H. **Hall**: Note on the temperature relations of photo-electric emission and thermionic emission of electrons. Hall's theory of "associated" and "free" electrons in metallic conduction indicates a slight increase with temperature in the work done in detaching completely an associated electron; this accords with the fact that

the lowest frequency producing photo-electric emission is nearly independent of temperature. Also the work done in detaching completely a free electron within the metal should diminish with rise of temperature; this has not been disproved.—R. de L. **Kronig**: The dielectric constant of diatomic dipole-gases on the new quantum mechanics.—F. L. **Mohler**: A photo-ionisation experiment with hydrogen. Using a double thermionic tube, one unit of which produced a discharge while the other detected photo-ionisation excited by the radiation from the discharge, no evidence was obtained that hydrogen emits radiation which can ionise the normal molecule.—Otto **Laporte**: Series and ionisation potentials in the iron spectrum. —Carleton C. **Murdock**: The location of the electromotive force in a photo-active cell containing a fluorescent electrolyte. Semi-transparent platinum films sputtered on opposite sides of a glass test-tube serve as electrodes. The electrolyte can be illuminated before it reaches the electrode, through it, or after leaving it, and is made to flow along the surface of the electrode. The photo-active electromotive force is due, in part, to the action of light on the fluorescent electrolyte.—Richard C. **Tolman** and Sinclair **Smith**: Remarks on Professor Lewis's note on the path of light quanta in an interference field. —L. R. **Maxwell**: The mean free path of electrons in mercury vapour. An electron stream passes through a chamber the end of which is a long Faraday cage. The electron current was measured with and without the presence of mercury vapour at a pressure of 3·12 bars in the chamber. The distance traversed by the electrons was varied by raising and lowering the cage. The mean free path is calculated for accelerating potentials up to 3000 volts; at 1120 volts and 3050 volts it is 73 cm. and 144 cm. respectively.—Edward A. **Birge** and Chancey **Juday**: The organic content of lake water. Large samples from Wisconsin lakes were examined. The quantity of organic material present is much greater than, and that of the inorganic salts is far less than, that found in sea water. The dissolved organic matter forms a potential food supply several times as large as that offered by the plankton.—Thomas Wayland **Vaughan**: (1) The stratigraphic horizon of the beds containing *Lepidocyclina chaperi* on Haut Chagres, Panama. The horizon is upper Eocene, virtually the same as that of the Ocala limestone of Florida and Georgia. (2) Foraminifera from the upper Eocene deposits of the coast of Ecuador. The horizon is about the same as that at Haut Chagres; the finds indicate that the same fauna existed on both sides of America during Eocene times.—T. J. **Webb**: On the free energy of hydration of ions. The energy of hydration depends on the dielectric properties of the solvent, as well as upon the charge and effective radius of the ion.—Curt **Stern**: An effect of temperature and age on crossing-over in the first chromosome of *Drosophila melanogaster*. Susceptibility is connected in some way with the localisation of the spindle fibre attachment.

Official Publications Received.

BRITISH AND COLONIAL.

Aeronautical Research Committee: Reports and Memoranda. No. 989 (Ae. 200): An Investigation of the Flow of Air around an Aerofoil of Infinite Span. By L. W. Bryant and D. H. Williams; with an Appendix by G. I. Taylor. (A. 3. a. Aerofoils, General, 132.—T. 1885.) Pp. 44. 1s. 9d. net. No. 995: The Behaviour of Single Crystals of Aluminium under Static and Repeated Stresses, Parts 1, 2 and 3. By H. J. Gough, Dr. D. Hanson and S. J. Wright. Work performed for the Engineering Research Board of the Department of Scientific and Industrial Research. (B 1. a. Metals, 40, a and b.—T. 1983, a and b.) Pp. 54+35 plates. 8s. 6d. net. No. 1015 (Ae. 218): On the Drag of an Aerofoil for Two-dimensional Flow. By A. Fage and L. J. Jones. (A. 3. A. Aerofoils-General, 154.—T. 2135.) Pp. 14. 7d. net. (London: H.M. Stationery Office.)

Leicester Museum, Art Gallery and Library. Bulletin No. 10. Pp. 12. (Leicester.)

County Borough of Warrington: Museum Committee. Report of the Director for the Two Years ending 30th June 1926; with a List of the Principal Additions to the Museum Collections. Pp. 21. (Warrington.)

Transactions of the Royal Society of Edinburgh. Vol. 54, Part 3, No. 14: Magnetic Quality in Crystals. Part i: Discrimination of, and Stability in, Magnetic Lattices; Part ii: Stability of Magnetic Lattices; Part iii: Twinning in Crystals. By Dr. J. Forrest. Pp. 601-701. (Edinburgh: Robert Grant and Son; London: Williams and Norgate, Ltd.) 12s. 6d.

Union of South Africa: Department of Agriculture. Science Bulletin No. 45: Physiological Studies of the Grape. By Dr. Francois Jean de Villiers. Pp. 97. (Pretoria: Government Printing and Stationery Office.) 1s. 6d.

Northampton Polytechnic Institute, St. John Street, London, E.C.1. Announcements, Educational and Social, for the Session 1926–1927. Pp. 176. (London.)

Decennial Index of *The Analyst*: the Journal of the Society of Public Analysts and other Analytical Chemists. Vols. 41-50 (1916 1925). Compiled by M. B. Elliott. Pp. 353. (Cambridge: W. Heffer and Sons, Ltd.) Paper, 21s. net; cloth, 25s. net.

Transactions of the Royal Society of Edinburgh. Vol. 54, Part 3, No. 16: On the Development of the Cranial Muscles in Protopterus and Lepidosiren. By Prof. F. H. Edgeworth. Pp. 719-734+9 plates. 5s. 6d. Vol. 54, Part 3, No. 19: The Petrography of Jan Mayen. By Dr. G. W. Tyrrell. Pp. 747-765. 2s. 6d. (Edinburgh: Robert Grant and Son; London: Williams and Norgate, Ltd.)

The Journal of the Royal Anthropological Institute of Great Britain and Ireland. Vol. 56, 1926, January to June. Pp. 206+15 plates. (London.) 15s net.

Diary of Societies.

SATURDAY, OCTOBER 16.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (Associates and Students Section) (at Neville Hall, Newcastle-upon-Tyne), at 3.—P. F. Hope: Steam and Electric Locomotives for Colliery Purposes.

BRITISH PSYCHOLOGICAL SOCIETY (at University College), at 3.—W. J. Messer: Conative Control.—R. J. Bartlett: Does the Psychogalvanic Phenomenon indicate Emotion?

PHYSIOLOGICAL SOCIETY (in Department of Physiology, Guy's Hospital), at 4.—Demonstrations on A Substitute for Blood Fibrin in Work on Digestion, by W. M. Clifford; and Peculiar Substance in the Central Nervous System of Cats kept on Autoclaved Meat, by C. Da Fano.—A. E. Clark-Kennedy and T. Owen: The Effect of Variation of Oxygen Pressure on the Respiratory Exchange during Exercise.—T. Lewis and Y. Zotterman: Reactions of the Skin to Ultra-violet Light.—T. Lewis and I. M. Harmer: The Release of Vasodilator Bodies in Response to Mechanical Stimulation of the Skin (preliminary communication).—W. Cramer: The Transplantation of Spleen.—W. W. Payne and E. P. Poulton: The Law of the Intestines as applied to the Œsophagus.—V. de Burgh Daly: The Effect of a Negative Pressure on the Heart-Lung Preparation.—A. D. Macdonald and W. Schlapp: Adrenaline Vaso-dilation.—K. Furusawa and R. M. T. Kerridge: The Buffering Powers of Cardiac and Skeletal Muscles of the Cat.—A. Levin: Fatigue, Retention of Action Current, and Recovery, in Nerves of the Spider Crab.—R. S. Creed and Sybil Cooper: A Reflex in the Knee Extensors caused by Active Contraction of the Flexors.—J. de B. Daly and E. B. Verney: The Site of the Receptors engaged in the Reflex Regulation of the Heart Rate.—E. B. Verney: Some Quantitative Experiments on the Secretion of Pituitrin in Mammals.—E. D. Adrian: Action Currents in the Optic Nerve.—E. T. Coxybeare, M. Maizels and M. S. Pembrey: Influence of Anæsthesia on Metabolism.—M. Maizels and A. C. Hampson: The Effects of Variations in PH on the Volume of the Red Cells (preliminary communication).

MONDAY, OCTOBER 18.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 4.—Sir John Rose Bradford: Harveian Oration.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—C. E. Shattock: Demonstration of Surgical Conditions of Lymphatic Gland.

ROYAL SOCIETY OF MEDICINE (Social Evening), at 9.30.—Sir Arthur Keith: John Bull: a Study in Anthropology.

INSTITUTION OF THE RUBBER INDUSTRY (London Section) (at Engineers' Club, Coventry Street).—W. H. Harford: Advertising.

TUESDAY, OCTOBER 19.

ROYAL SOCIETY OF MEDICINE, at 5.30.

INSTITUTE OF TRANSPORT (at Institution of Electrical Engineers), at 5.30.—Capt. F. L. Barnard: Commercial Flying.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—The Secretary: Report on the Additions to the Society's Menagerie during the months of June, July, August, and September 1926.—Dr. P. A. Buxton: Exhibition of Apparatus for the Measurement of Radiant Heat in the Tropics.—Miss Joan B. Procter: Exhibition of a White Example of the English Grass-Snake.—Prof. J. S. Huxley: Studies in Heterogonic Growth: the Annual Increment of the Antlers of the Red Deer (*Cervus elaphus*).—Dr. J. Waterson: On the Crop Contents of certain Mallophaga (Insecta).—J. R. Norman: A Synopsis of the Rays of the Family Rhinobatidæ, with a Revision of the Genus Rhinobatus.—Prof. D. M. Fedotov: The Plan of Structure and Systematic Status of Ophiocista (Echinodermata).—Dr. R. Anthony and G. M. Iliescu: Étude sur les Cavités nasales des Carnassiers.

ROYAL PHOTOGRAPHIC SOCIETY (Scientific and Technical Group), at 7.—T. Thorne Baker: The Use of Light-Sensitive Cells in Photometry, Wireless Picture Telegraphy and Television.

WEDNESDAY, OCTOBER 20.

SOCIETY OF GLASS TECHNOLOGY (at Leeds University), at 2.30.—General Discussion on Annealing and Lehrs.—E. A. Coad-Pryor: The Economics of the Annealing Process.—Dr. J. W. French: Glass Annealing.—Dr. S. English and Prof. W. E. S. Turner: The Relationship between Chemical Composition and the Upper Critical Annealing Temperature of Glasses.

ELECTRICAL ASSOCIATION FOR WOMEN, at 3.—Visit to London Electric Wire Co., and Smith's Ltd., Leyton.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Dr. W. J. O'Donovan: The Prevention and Treatment of Eczematous Conditions of the Skin of Occupational Origin.

ROYAL SOCIETY OF MEDICINE (History of Medicine Section), at 5.—W. G. Spencer: Review of the 'Proceedings' of the Section.—Dr. Le Roy Crummer: The Anatomical Plates for the work of Geminus.

NEWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING AND TECHNOLOGY (at Iron and Steel Institute), at 5.30.—R. Jenkins: The Rise and Progress of Manufacturing Industry in England (Presidential Address).

INSTITUTION OF AUTOMOBILE ENGINEERS (Birmingham Graduates' Section) (at Chamber of Commerce, Birmingham), at 7.30.—W. Evans: Engine Lubrication.

SOCIETY OF CHEMICAL INDUSTRY (Nottingham Section) (at University College, Nottingham), at 7.30.—F. H. Carr: The Manufacture of Organic Medicinal Chemicals.

MERSEYSIDE AQUARIUM SOCIETY (at 1 Falkland Road, Egremont), at 7.30.—W. Mallinson and A. G. This: The Construction of a Simple Aquarium.

INSTITUTE OF CHEMISTRY (London Section), at 8.

C.B.C. SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Essex Hall, Strand), at 8.—Dr. C. W. Saleeby: The Expectant Mother.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Prof. E. Ghosh: A New Classification of Ciliata.—Dr. J. E. McCartney: The Filterable Viruses.—B. K. Mullick: Notes on some Rotifers from India.—Dr. A. Piney: A Method of Silver Impregnation of Zenker-fixed Paraffin Sections.

ROYAL SOCIETY OF MEDICINE (Surgery Section), at 8.30.—W. Low: Surgery and the Workmen's Compensation Act (Presidential Address).

THURSDAY, OCTOBER 21.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Miss Margaret Morris: Dancing as Physical Culture.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Dr. W. H. Eccles: Inaugural Address.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 6.30.—W. R. D. Jones: Notes on Magnesium and some of its Alloys.

CHEMICAL SOCIETY, at 8.—Prof. H. V. A. Briscoe, P. L. Robinson, and H. C. Smith: The Density of Boron Trichloride, and the Suspected Variation in the Atomic Weight of Boron.—W. H. J. Vernon: The Formation of Protective Oxide Films on Copper and Brass by Exposure to Air at Various Temperatures.—W. H. Gray: The Action of Antimony Trichloride upon some Diazotised Diamines.—E. H. Farmer and J. Ross: The Formation and Stability of Associated Alicyclic Systems. Part III. The Change from 'Meta-' to 'Para-' bridged Rings.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, at 8.15.—Prof. N. H. Fairley: Studies in the Chemotherapy and Immunity Reactions of Schistosomiasis.

ROYAL AERONAUTICAL SOCIETY (Coventry Branch) (at Coventry).—Major F. M. Green: The History of the Aeroplane.

FRIDAY, OCTOBER 22.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Demonstration of the Anatomy of the Sacro-iliac Region and its Application to Practice.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—W. Reavell: Presidential Address.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—R. H. Kenyon: Boiler Accidents.

INSTITUTE OF METALS (Sheffield Local Section) (at Sheffield University), at 7.30.—Prof. H. C. H. Carpenter: Sorby Lecture.

ROYAL SANITARY INSTITUTE (at Town Hall, Dover), at 7.30.—Discussions on Diphtheria Immunisation.

OIL AND COLOUR CHEMISTS' ASSOCIATION.

PUBLIC LECTURES.

SATURDAY, OCTOBER 16.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Mrs. H. M. Dunn: Kashmir, the Country and its People.

SUNDAY, OCTOBER 17.

GUILDHOUSE (Eccleston Square), at 3.30.—Air Vice-Marshal Sir Sefton Brancker: The Scientific Problems of Commercial Aviation.

TUESDAY, OCTOBER 19.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. Abel: The Development and Present State of Public Health in Germany (Chadwick Lecture).

SCHOOL OF ORIENTAL STUDIES (London Institution), at 5.—Dr. L. D. Barnett: An Introduction to Indian Philosophy. (Succeeding Lectures on November 2, 16, 30; December 7; January 18; February 1, 15; March 1 and 15.)

KING'S COLLEGE, at 5.30.—Prof. C. Lloyd Morgan: The Place of Mind in an Organic Theory of Nature. (Succeeding Lectures on October 26 and November 2.)

UNIVERSITY COLLEGE, at 5.30.—K. Lansma: The Drainage of the Zuyder Zee.

WEDNESDAY, OCTOBER 20.

INSTITUTION OF ELECTRICAL ENGINEERS, at 5.30.—Prof. J. A. Fleming: The Interaction of Pure Scientific Research and Electrical Engineering Practice. (Succeeding Lectures on October 22, 27, 29; November 10, 12, 17, and 19.)

ROYAL SOCIETY OF MEDICINE, at 8.—Prof. Abel: The Development and Present State of Public Health in Germany (Chadwick Lecture).

THURSDAY, OCTOBER 21.

FULHAM CENTRAL PUBLIC LIBRARY, at 8.—H. T. Davidge: The Earth we Live on.

SATURDAY, OCTOBER 23.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—V. Gordon Childe: The Dawn of Civilisation in Europe.

SUNDAY, OCTOBER 24.

GUILDHOUSE (Eccleston Square), at 3.30.—Prof. W. A. Bone: The Economic Aspects of Coal.

CONGRESSES.

OCTOBER 13 TO 26.

GERMAN SOCIETY FOR THE STUDY OF DISEASES OF DIGESTION AND METABOLISM (at Berlin).

OCTOBER 20 TO 22.

TEXTILE INSTITUTE (at Town Hall, Buxton).—Sir William Bragg (Mather Lecture).—J. A. Robertson: Centralised Electricity Production.—P. Bean: Sizing of Artificial Silk Yarns, and Comparison with Sizing of Cotton Yarns.

OCTOBER 21.

COKE OVEN MANAGERS' ASSOCIATION (at Midland Hotel, Manchester).—Annual General Meeting.

OCTOBER 25 TO 28.

ITALIAN CONGRESS OF SURGERY (at Padua).

SATURDAY, OCTOBER 23, 1926.

CONTENTS.

Science and Religion.

AT the recent Church Congress held at Southport, several papers dealt with the relations between science and religion. This is a subject of the deepest interest to students of natural science, for the ultimate objects of religious study and of scientific research are the same. This was finely expressed by no less a person than Sir Ray Lankester, whom no one will accuse of a bias in favour of theology, when he was president of the British Association at the York meeting in 1906. In his presidential address he claimed the sympathy of the Church for the scientific student, saying that the churchman and the student agreed in this: both had turned aside their gaze from the fleeting and temporal and had fixed it on the enduring and eternal; both, in a word, sought for the absolute and everlasting beneath the never-ending flux of things.

There are, it is true, many students of science, and especially of biology, who consider religion to be a name for a mass of outworn and discredited superstitions, and think that the best hope for the progress of mankind lies in getting rid of such beliefs entirely. This, however, is a view which biologists of wider outlook find it impossible to accept. For they recognise, on one hand, that the progressive evolution of man is bound up with the evolution of society, and, on the other, that every society is, and always has been, held together by religious sanctions, even when those sanctions are submerged in the subconscious stratum of our existence. Hence the conclusion is inevitable that religious belief performs an important biological function, and that it will endure so long as society itself endures. But religion can only exercise its proper influence so long as it is believed in sincerely; and hence the importance of reconciling, if possible, such beliefs with the scientific view of the universe.

The functions of religion and science are, in fact, correlative: one strives to hold fast and preserve the flashes of insight into the real nature of things which have been granted to mankind in the past; the other is ever seeking to gain new light on Nature. The reverence of religion for what is old is justified, because great discoveries of truth, or, as our fathers preferred to call them, 'revelations,' come but very rarely, and between them are interposed many generations of ordinary men to whom no new light is vouchsafed.

Every 'revelation,' however, is necessarily framed in a background of the current beliefs of its time about the universe; and as this background changes the 'revelation' comes to be expressed in obsolete language. The reconciliation consists in finding appropriate modern language in which to express it, and in the

search for this expression the modernist school of Anglican theology will have the sympathy of every student who reflects deeply on the ultimate mysteries which he encounters in his study of science.

Amongst the papers read at the congress, none excited more interest than that from the pen of the late Dr. Adami on "The Eternal Spirit in Nature." Many of our readers and contributors to our columns were friends of Dr. Adami, and sadly miss his bright cheery optimism and his infectious scientific enthusiasm. It will surprise many of them to learn that Dr. Adami, whose interests they had imagined to be confined to the technicalities of science, had reflected so deeply on the ultimate nature of things. His paper attempted the stupendous task of trying to prove from a consideration of scientific facts that there was one God Who was the author of the universe, that the nature of God was good, and was ultimately expressed in the character and teaching of the Founder of Christianity, and that the human soul was immortal. Dr. Adami's method was not that of the *a priori* philosopher: like all true scientific men he was a pragmatist, and he felt that these beliefs were justified, because when applied to the phenomena they yielded satisfactory results.

If, indeed, Dr. Adami had been successful in his attempt, then the complete reconciliation of science and religion would have been achieved: we fear, however, that we are unable to go the whole way with him. His argument for the existence of God is the presence of order and law in Nature: this order must have its ground in one grand unifying Will. Was it not Huxley himself who said that "Law, order, and abiding Force are more stupendous miracles than any to be found in our mythologies," and who ridiculed that heterodoxy which regarded the world as "a mud-pie made by two blind children, matter and force." The argument really comes to this: the human intellect, through the action of which alone religion, science, or any other kind of knowledge is possible, recognises amidst phenomena an order and regularity which it feels to be akin to its own deepest nature. Either that recognition is valid or it is illusory. If it is valid, then the ultimate nature of everything must be a Mind in some ways akin to the human mind. If it is illusory, then we are thrown back on a total agnosticism, and conclude that we learn from phenomena nothing of the real nature of things, and that our intellect, as Bergson has maintained, is only a tool-making and food-getting mechanism.

Although it is persistently ignored by shallow thinkers amongst 'practical' scientific men, there is a subjective element in all knowledge which cannot be neglected. We do not begin with 'matter,' which is an abstraction, but with 'something presented to my mind,' and the 'mind' to which it is presented is as fundamental as the 'something.' The qualities with which we endow matter are all mental, and can be expressed only in terms of perception, which is a mental function. Surely no one imagines that 'redness,' 'hardness,' and 'sweetness,' for example, exist outside of and independently of us. To describe the mind as the mere result of molecular movement is to commit an error beside which the wildest Irish bull must sound like common sense.

Dr. Adami's argument that God must be good is that the evolutionary process has led to the production of human nature, the highest aspect of which is goodness. This, again, is the old argument that the stream cannot rise higher than the fountain. "He that planted the ear, shall He not hear? Shall not the judge of all the earth do right?"

Against this argument, however, there are ranged the terrible facts of the struggle for existence and the slaughter of the unfit. If God be the author of Nature, how is this condition to be accounted for? If with Dr. Adami we reply that there is some end to be gained by this which we cannot understand, then the objector justly rejoins that every conscious-suffering individual is an end in itself, and has rights which it is wrong to sacrifice even for the well-being of another.

If, indeed, not only the human soul, but also the soul of all that suffers, survives bodily dissolution, then the ultimate satisfaction of the individual may be enhanced by suffering in some of the preliminary phases of existence. We fail completely, however, to see how Dr. Adami can prove the immortality of the soul from the facts of natural science; the utmost that can be said is that the vitalistic conception of biology leaves the possibility open. It seems to us that the essence of religious faith is the hope that God may turn out to be good, and the resolve to order our lives on this assumption. We hope, but we do not and cannot know. Dr. Adami's assertion that the highest expression of the nature of God is to be discovered in the Founder of Christianity leads us into the realm of special theology, which it is outside the province of this journal to discuss. This much, however, all will admit: that so far no finer conception of God has been presented to the human intellect than that embodied in the sayings of Christ and of some of His early followers. In the field of natural science, it may not be necessary to postulate God; but in religion, as in science, the workings of an evolutionary process are now recognised. It is through the acceptance of the idea of evolution in the spirit as well as in the body of man that the partition which formerly separated religion and science is being dissolved.

The Evolution of Voles and Lemmings.

Monograph of the Voles and Lemmings (Microtinæ), Living and Extinct. By Martin A. C. Hinton. Vol. 1. Pp. xvi + 488 + 15 plates. (London: British Museum (Natural History), 1926.) 30*s*.

THERE is no group of mammals so likely to throw light on the manner in which new species arise as the Microtinæ, a subfamily of rodents represented by voles and lemmings, and there is certainly no one so well qualified as Mr. Martin A. C. Hinton, of the Zoological Department of the British Museum (Natural History), to bring together and to systematise all that is known concerning the distribution in space and time, the structure and habit, of this highly specialised group. It may be said at once that Mr. Hinton is producing a monograph—for the volume noted here is only the first part—of the very highest order, one which will serve the needs of systematic zoologists for many years to come. In the present volume 14 genera, including 120 species, are defined and described, a score of the species having been discovered and named by the author. Great and abiding as is the service which Mr. Hinton is thus rendering to systematic zoologists, he is doing even more for the student of evolution, and it is to this aspect of his inquiries which we desire to direct attention now.

In the common water vole, Mr. Hinton finds that although sexual maturity is attained at a comparatively early age, yet growth never ceases; growth changes are continued so long as the individual lives, so that aged animals may have the appearance of being specifically distinct from younger adults. There is, in particular, a continual transformation of all those parts of the skull which are concerned in mastication. In the water vole there is a tendency for the growth discs of long bones to remain open. More remarkable still are the growth changes in the teeth. As is well known, the development of a tooth begins with the formation of a crown and ends with the production of a root. The incisor or gnawing teeth of rodents remain perpetually young; they never proceed to the formation of a root but go on producing crown as long as the animal lives. This retention of an infantile stage in the growth of incisor teeth took place at an early stage in the evolution of rodent mammals. In the course of time this tendency spread from the incisor to the cheek or molar teeth of rodents. Mr. Hinton has demonstrated that a tendency to a delay in the formation of roots and an inclination to continue the growth of crowns has appeared in the molar teeth of various members of the Microtinæ, and at different horizons of the geological record. The molar teeth of the water vole never cease growing. Mr. Hinton also emphasises the fact that in the production of new specific forms the whole apparatus of mastication and of digestion—teeth, jaws, skull, temporal and masseter muscles, great bowel and cæcum—undergo a simultaneous and co-ordinated hypertrophy.

Now, changes of an exactly similar kind to those which Mr. Hinton has noted in the evolutionary history of voles and their allies have come under the observation of medical men. In acromegaly—a disorder of growth which occasionally overtakes men and women—jaws, muscles of mastication, skull and skeleton, and the various parts of the alimentary canal undergo just such changes as those which occur normally in adult water voles. Such growth changes in the human body are always accompanied by a disordered enlargement and action of the anterior lobe of the pituitary gland. Medical men also meet with cases in which the growth lines of bones tend to remain open, and although they cannot identify the exact part of the growth mechanism which is at fault, yet the evidence already collected leaves no doubt that the defect lies in the hormone system which regulates growth. These growth changes, with which medical men are familiar, have nothing to do with 'use and wont,' but are disordered manifestations of a growth mechanism which is resident in all living tissues.

Nowhere does Mr. Hinton mention the name of Lamarck, yet from statements he makes it is clear he must be placed amongst the followers of that great naturalist.

> "Every mammal," he writes, "is the product of two distinct and sometimes conflicting forces; a compound of relatively essential characters, fixed for the time being in each group by inheritance, and of more or less plastic characters which yield like potter's clay to the thumb of stern necessity. It is the special use which an animal makes of its various organs that results eventually in a more or less perfect adaptation of form and structure to particular functions, no matter whether the special use is called into being by tempting opportunity or by the compelling stress of circumstances. Use and habit, and all that goes to make environment in its widest sense, have thus made species what they are." (p. 4.)

In this extract Mr. Hinton leaves his readers in no doubt as to the factors which he conceives as being the most important in bringing about the evolution of new species. We may take one of his remarkable examples of adaptation in order that we may probe more deeply into what his beliefs imply. In a Greenland lemming (Dicrostonyx) the fur becomes very thick as winter sets in and at the same time the claws

> "of the third and fourth manual digits become highly modified for digging and subject to a remarkable and unique seasonal change; with the approach of winter these two claws grow to an extraordinary size and

develop a peculiar supplementary ventral portion which sometimes surpasses the main part of the claw in length; but with the return of spring this ventral portion is shed and the main part of the claw is then worn down to normal length. The bones of the fore-arm, particularly the ulna, are greatly strengthened for the attachment of the powerful muscles which move the fossorial hand."

Now the utility of all these changes, which permit Dicrostonyx to burrow in a frost-bound soil, is very apparent, but how 'use and wont' can bring about such a series of growth changes is not at all clear. The more we come to know of the machinery of growth, the less likely does it seem that 'use and wont' can effect any direct change on structure; use and habit can bring out of the claws of the Greenland lemming just such growth responses as are already resident in them. If these responses are lacking, no matter how the lemming-burrows or how hard the soil may be, its efforts will only wear the claws away. Here again we may fall back on observations made in the human body. If a hundred young recruits are submitted to the same course of hard physical training, a certain number will respond readily and fully, their muscles taking on a quite Herculean contour: others scarcely respond to the trainer's efforts. Between these extremes all intermediate stages occur. The environment has been the same for all; the response has depended on the degree to which the muscles and bones, heart and lungs, of the recruits have been endowed with the machinery which underlies the processes of growth. What is true of men is likely to hold for lemmings and voles. Environment can select, but there is no evidence that it can produce new forms.

Especially valuable is the contribution which Mr. Hinton makes to our knowledge of the evolution of the cheek teeth of the various members of the Microtinæ, for it is the characters of these teeth which give a clue to the identification of fossil species and to the evolutionary lines of their descent. The splendid series of drawings of skulls, jaws, and teeth by Mr. Terzi, and figures of the chewing surfaces of the teeth made by Mr. Hinton, render the reader's task easy. In interpreting the nature of the dental changes, Mr. Hinton has been influenced by the teaching of the late Dr. Forsyth Major, but most of his inferences are based on a first-hand study of extensive series of molar teeth. As to the accuracy of the facts observed by Mr. Hinton in the cheek or molar teeth of voles, lemmings, and their allies, there cannot be any doubt, but whether or not his interpretation of these facts will hold good, one may legitimately doubt. Indeed, Mr. Hinton has anticipated such a criticism, for in a footnote to p. 34 he states: "As long ago as 1914 Winge and I were comparing our views on this subject and he told me that I had got everything upside down. No doubt others will be of the same opinion to-day."

Voles and lemmings have three molar teeth on each side of their jaws; the middle molar is sheltered, and, in the opinion of the majority of students of dental evolution, would be regarded, on the evidence produced by Mr. Hinton, as the most conservative and primitive of the three. Mr. Hinton is of an opposite opinion. What he has demonstrated is that the free ends of the dental series, the front end of the first molars and the hind end of the last molars, are the plastic points of the dental series. One cannot see how an appeal to a multi-tuberculate theory of dental origin can explain the remarkable additions which have been made at the terminal points of the molar series of voles; the anterior 'loop' of the first lower molars and the hinder ends of the last upper appear to have in them the germinal properties possessed by the terminal sprout of a growing tree. From time immemorial crowns of teeth have been fully formed before they come into use. It is difficult to see how the manner of chewing or the degree of force exerted in this act can have brought about the changes noted by Mr. Hinton in the evolution of the molars of the Microtinæ.

We have reserved for a final paragraph a mention of the important contributions which Mr. Hinton has made, and is making, to our knowledge of the recent geological history of Britain. For the past twenty-five years he has searched the later geological deposits of England for fossil traces of the less conspicuous and smaller mammals. In the late pliocene deposits of East Anglia he has identified 13 species belonging to 4 genera of Microtinæ, the genus Mimomys being the oldest and Microtus the most recent of the pliocene forms. The high terrace of the Thames valley is evidently of the same age as the later Cromerian deposits, for in it Mr. Hinton has identified three of the genera of Microtinæ found in the late pliocene deposits of East Anglia. In the deeper or older deposits of the middle terrace of the Thames valley, fossil remains of three microtine genera occur, two of them—Evotomys and Microtus—being continued from the Cromerian horizon, while one—the genus Arvicola, to which the modern water vole belongs—appears for the first time. Mr. Hinton regards this genus as having arisen by modification from the pliocene genus Mimomys. In the upper or later deposits of the middle terrace an altogether different microtine fauna is found—one associated with a cold climate. Two forms of lemming make their appearance, and three forms of vole belonging to the genus Microtus, one being the snow vole.

No doubt this change in fauna corresponds with the maximum phase of glaciation; nowhere else in the recent geological deposits of Britain does Mr. Hinton

find any sudden faunistic change—only in the later deposits of the middle terrace and of deposits of the same age, such as those found at Ightham in Kent, and in the deposits of caves in the centre and west of England. In the lowest or third terrace of the Thames valley the microtine fauna of the cold period is continued. Traces of the modern water vole appear for the first time in quite recent deposits, but it is clearly closely related to a late pleistocene vole, distinguished by Mr. Hinton as *Arvicola præceptor*, which in turn is closely related to the late pliocene genus—Mimomys. Already the water vole of Britain is showing signs of breaking up into several local varieties the first phase in the production of new species. Clearly Mr. Hinton is justified in regarding the Microtinæ as being in a state of evolutionary plasticity, and he has also demonstrated that the fossil remains of this inoffensive and unobtrusive group of mammals supply geologists with trustworthy data on which to assign recent deposits to their proper horizons in time. The Microtinæ in their evolutionary history serve as geological clocks. Beyond a doubt the Trustees of the British Museum were well advised when they undertook the publication of Mr. Hinton's monograph.

Modern Photometry.

Photometry. By John W. T. Walsh. Pp. xxvii + 505. (London: Constable and Co., Ltd., 1926.) 40s. net.

IN his delightful book "With Nature and a Camera" Mr. Richard Kearton wrote (a few years ago): "It is wonderful to think that within the confines of the British Isles, on the eve of the twentieth century, it is still possible to find a man sitting on Friday night in a rude semi-underground house lighted only by the primitive stone lamp of his fore fathers of prehistoric times." He was referring to the primitive customs of Borrera in the Outer Hebrides. It is only yesterday that *light* of any sort, however feeble, was a great achievement. Then come demands for *more light*, and for *enough light*. Finally, the request is for *enough light of the right quality* which, by its approach to the properties of daylight, will show objects not only in form but also in their true colours.

In our modern world these questions of illumination are of the highest importance, and the relative illumination necessary for various purposes has been studied, so that in building a factory, say, it will be equipped with lamps so arranged as to yield the necessary light in the right quantity. The factory owner does not, of course, purchase light directly; he must pay for energy delivered by gas or electricity. Nevertheless, the study of the most economical production and distribution of the light calls for the development of accurate methods of measuring light quantities.

The human eye is, fortunately, a very accommodating organ. It will function more or less satisfactorily over a wide range of brightnesses. Hence the question of high precision in photometry is not likely to be of very much concern to the ordinary user, who will not experience much effect from a four or five per cent. variation of illumination unless he is trying to work with nearly the minimum of light. The demand for precision comes rather from the requirements of industrial competition in lamp manufacture; in testing various lamps for efficiency and the effects of ageing; in the investigation of the various reflectors and screens. Precision spectro-photometry is, however, of considerable importance to the user who requires light of daylight quality, and also it is important from many scientific and industrial points of view.

Photometry is by no means a purely physical operation. Although the modern tendency appears to be towards the elimination of visual methods, this can only be done by a thorough study of human vision. After all, the sensation of light is a purely subjective phenomenon, and it is not to be confounded with the radiation capable of evoking it.

Mr. Walsh's latest work on photometry reflects the enormous growth of the subject during the last few decades. In his capacities of senior assistant in the Photometry Division of the National Physical Laboratory, and of general secretary of the International Commission on Illumination, he has had unequalled opportunity of becoming acquainted with all sides of the subject; his treatise is in many respects the most complete and thorough-going which is at present in existence. The chapters include discussions of all the usual principles of photometry in addition to historical notes, the eye and vision, heterochromatic photometry, colour, physical photometry, and stellar photometry. Each chapter is concluded by a large and complete bibliography furnishing references to many original papers and books dealing with the subjects under discussion. Without doubt it will be of the greatest value as a work of reference for those who have to carry out photometric operations. The text is concisely and clearly written; the reader may place confidence in its accuracy. In addition, the diagrams are numerous and well drawn.

An adequate criticism of the book is extremely difficult to give on short acquaintance. The scope is probably wide enough to cover all the interests of a photometric laboratory, but it seems also to make a bid for the interest of the physicist and astronomer. These will, however, find the treatment of photographic photometry somewhat disappointing and brief.

One of the problems of greatest interest in modern spectroscopy is the measurement of the relative intensities of the lines in line spectra, and a fuller discussion of the photographic methods would have been very acceptable. On the other hand, the book includes many paragraphs which are quite out of place; such as those giving a highly condensed version of the derivation of Maxwell's electromagnetic equations, the thermodynamic discussion of radiation laws, and so on. Nobody turns to a book on photometry for matters of this kind, especially when they are discussed with the aid of complex equations written in the ordinary lines of text, where they are hard enough to see, let alone to understand.

The reader must not object to change. Spectrum diagrams are all plotted to wave number; in some cases the wave-length diagrams are given as well. There are obvious advantages for some physical discussions in using the 'wave-number,' but for many of the present purposes the familiar 'wave-length' is entirely suitable and adequate; there seems no obvious reason for the change from the familiar to the less familiar.

This is not the place to discuss fully the vexed question of nomenclature. The reader will, of course, find the terminology adopted by the International Commission, but in the writer's view the British section made a great mistake in translating the French 'intensité' by the English 'intensity.' In scientific English the word 'intensity' always connotes something analogous to 'energy per unit area,' but we are now asked to exchange the easily understandable phrase 'candle power' (as applied to a source) for the words 'luminous intensity.' Another recent innovation is the term 'luminous flux,' to be substituted for the term 'light.' Surely it would have been better simply to be more careful and definite regarding the use of the word 'light' rather than to introduce terms which, in the judgment of the present writer, show small signs of being generally adopted by the English-speaking scientific world, whatever is the case amongst photometric workers. Time and experience must decide, but evolution is preferable to revolution, even in this connexion. Cannot our specialists be a little more Fabian?

We may speculate in conclusion that the author of such a text-book has at the present time a very difficult task. He has a vast accumulation of material, very heterogeneous in composition, and a necessarily limited personal experience. Although some things stand out as secure and stable, there are many methods and ideas which are ephemeral and unsound. One plan is to include all the information possible, and leave it to the reader to take his choice; another is to adopt a severely critical attitude and reject all that is apparently non-essential. Mr. Walsh has at the present time avoided both extremes, but it may be hoped that the whole subject will henceforth gain in coherence and simplicity, and that this may be reflected in books of the future. The present book will, we feel sure, contribute materially to the healthy development of photometric theory and practice.

L. C. M.

Philosophy of Emergence of New Qualities.

Life, Mind and Spirit: being the Second Course of the Gifford Lectures delivered in the University of St. Andrews in the year 1923 under the general title of "Emergent Evolution." By Prof. C. Lloyd Morgan. Pp. xix+316. (London: Williams and Norgate, Ltd., 1926.) 15s. net.

THIS is the second course of Gifford Lectures delivered by Prof. Lloyd Morgan, and continues the first volume published under the title of "Emergent Evolution." It should be read in conjunction with the earlier volume, otherwise there are parts of the argument which might be found difficult to follow. Indeed, even with this aid, it is, it must be confessed, by no means easy reading. But the difficulty arises, in the main, from the difficulty of the subject and the profundity of the thought; and those who will make the effort to master the argument will find themselves amply rewarded. They will be encouraged in this task by the appeal that the tone and style of the writing must make to all readers, for the book, as a whole, is marked to an impressive degree by the dignity and urbanity of ripened wisdom.

Both books deal with that question of the emergence of new qualities which is so much in the centre of philosophical discussion at the present time. There are significant differences in Prof. Lloyd Morgan's treatment of the subject from that with which we are familiar in other writers, such as Prof. Alexander. We may, to begin with, get the impression that Prof. Lloyd Morgan recognises many more cases of real emergence than most writers. Even within the inorganic world he finds several stages. There are distinctively new modes of action in the behaviour of the molecule as compared with that of the atom, and again in the crystal as compared with the molecule. The novelty that occurs on the emergence of life is no different in principle from these cases. Then within the living organism we have the emergence of cognitive and reflective reference—we must not say mind—and, finally, the emergence of the spiritual or religious attitude, which consists in the acknowledgment of the working of Divine Purpose in

the universe. The differences in detail of these different levels are worked out with all the wealth of knowledge and reflection that we expect of the author.

If we continue our comparison with other writers we find that, for Prof. Lloyd Morgan, if there are more emergents, they are less emergent. What emerges in general appears to be rather a new pattern of what is already there than any positively new entity. We see this when we consider what is said about the place of mind in the process. Prof. Lloyd Morgan will not allow that mind emerges at any point in the evolution of life. On the contrary, mind is there from the beginning. He maintains the doctrine of "the unrestricted concomitance of life and mind," and will only allow the emergence of new types of action of mind and new relations between the mental and physiological sides of the vital process. Mind, by which he implies more particularly the enjoyment, apparently the conscious enjoyment, of the activity of the organism, is there at the lowest stages of life. But it is not there as a separate entity, with a substantial existence of its own, coming in, as it were, from outside and introducing new forms of energy. That is the animistic or 'hormic' theory, to which Prof. Lloyd Morgan is most resolutely opposed. As against it, he maintains that mind and body are merely two aspects of the same process, "two stories," as he phrases it, about the same series of events. This, in its turn, throws some light on what happens in the passage from the inorganic to the organic. It must be confessed that on this point we should like a good deal more information about Prof. Lloyd Morgan's point of view. But it is at least clear that there is, for him, no new entity or new form of energy which emerges.

The novelty of Prof. Lloyd Morgan's theory of emergence is seen most clearly when we come to deal with his view of the object of the religious consciousness. For Prof. Alexander and his followers, Deity is a new quality that emerges beyond the human level. For Prof. Lloyd Morgan, Deity does not emerge—though human acknowledgment of it does but pervades the whole from beginning to end. Divine Purpose *is* "the rational order of the cosmos." There is no supernatural and transcendent Being who intervenes at certain times or stages. But there is a purpose which is present in all that happens in the universe, and is none other than the "rational order" of the whole. Similarly, there is no particular point at which a naturalistic or scientific account becomes inadequate. That is always one way of looking at the facts. But, equally, there is always the other way of looking at the facts, which we call spiritual, and when we reach this point of view we have reached religion. We cannot pursue further the subtle, but difficult, argument in which Prof. Lloyd Morgan attempts to explain the sense in which he ascribes objective reality to the object of religious worship. Nor can we discuss here the degree to which his point of view is susceptible of being brought into accord with the ordinary assumptions of the religious consciousness.

The significance of the whole book is very great. To the philosopher it will, perhaps, lie mainly in the tendency which it shows not to remain contented with the simple acceptance of emergence as a mere brute fact, but to try to explain what is involved in it. Some might think that the explaining of it here comes very near to explaining it away. At any rate the main purport of the argument appears to be to reconcile the acceptance of some form of emergence with the monistic doctrine of the substantial identity of all that is, in which Prof. Lloyd Morgan is such a convinced believer.

Our Bookshelf

Reports of the Progress of Applied Chemistry. Issued by the Society of Chemical Industry. Vol. 10, 1925. Pp. 725. (London: Society of Chemical Industry, 1926.) n.p.

THE main impression conveyed by this compendious work is the enormous activity that is being displayed in applying chemistry and physics to the whole gamut of the arts and crafts. There may be signs here and there of radical advances, but, generally speaking, elaboration or *Ausarbeitung*, as the Germans say, seems to be the main feature of present-day work. The few who make a business of studying and card-indexing abstracts of technical literature may not require reports of this kind—for in the main they are little more than collated summaries of abstracts and patents—but the great majority of chemists who desire to keep abreast of the times will find them very valuable.

The present volume covers twenty-three of the somewhat arbitrary but necessary sections into which applied chemistry has been classified by the Society of Chemical Industry; reports on sanitation and water-purification and explosives are omitted, but the section on non-ferrous metals which was absent last year has been restored to its place in this year's volume. A considerable number of changes has been made in the authorship of sections, one of the most important being the collective contribution on paints, pigments, varnishes, and resins, by members of the Oil and Colour Chemists' Association. This innovation has much to commend it, and might usefully be extended to other sections of an omnibus character; but care must be taken that such contributions do not become inordinately long. The fact that every year sees an extension in bulk prompts the suggestion that it would be worth while to make the experiment of asking authors to deal more generally with their subjects: to lay aside their abstracts as they write, but refer to them for filling in gaps and necessary figures after writing. In this way, it is thought, the contributions would be more readable and savour more of original thought and treatment than of paraphrasing the abstract literature.

The book under review contains many contributions of high merit, and the general effect is undoubtedly good, though, as usual, there are minor points that evoke criticism. In altering the title of the first chapter by inserting the word 'General' before 'Plant and Machinery,' an attempt has been made to justify the inclusion in this section of information on beet-sugar and artificial silk production and on nitrogen-fixation, topics that are also treated in their appropriate chapters. If this report were labelled 'Chemical Engineering,' and the material of it were supplied by members of the Chemical Engineering Group, its value would be greatly improved, especially if line-diagrams were used to clarify, or obviate, verbal descriptions of plant. Unnecessary errors in spelling and hyphenation are less numerous than in previous reports, but the inclusion of such eccentricities as 'steam-line filter' (p. 12), 'electroultrafiltration' (p. 18), 'Pittsburg' for Pittsburgh (p. 14), and 'Haüsser' for Häusser (p. 189) show the need of better editorial supervision. The opinion (p. 87) that synthetic methyl alcohol "will solve the motor spirit from coal problem" appears to betray ignorance of the fact that methyl alcohol is a very poor motor-fuel; and the following statement (p. 59) bears witness to confusion of thought and style: "The decrease in the amount of tar now being distilled in the country may be gathered from the fact that the 1923 and 1924 quantities were approximately 326 and 353 million gallons respectively." In conclusion, we suggest that each volume should contain a list of the errors in its predecessor, and also the full titles of many, if not all, of the technical journals referred to in the text. How many chemists, for example, could decipher the abbreviations: S. & I. P., R., and J. Inf. Dis.?

Le magnétisme. Par Prof. Pierre Weiss et Gabriel Foex. (Collection Armand Colin: Section de physique, No. 71.) Pp. viii + 215. (Paris: Armand Colin, 1926.) 8·40 francs.

ALL who are interested in the important subject of magnetism must feel that they owe a debt of gratitude to the authors of this little book. They are both distinguished for the researches which they have carried out on the subject, and as their work shows, combine skill in exposition with the imaginative faculty which belongs to the successful investigator. In this volume they have aimed at putting the reader in touch with recent researches which for the most part are to be found only in the original memoirs. Consequently they have confined themselves to a rapid summary of the definitions and fundamental laws of magnetism, though even here the careful reader will find much to repay study. Questions, such as the experimental technique and industrial applications, which have been discussed in previous works, have been left on one side.

To present the results of research in a coherent form is no easy task when they cover such a wide domain, but the authors have been successful in a high degree, and have shown how the experiments are to be interpreted by means of thermodynamics, statistical mechanics, and the anisotropy of crystals. A study of the magnetic properties of matter leads inevitably to the problem of the constitution of the atom, and thus is related to the most fundamental questions of present-day physics. To a certain extent the phenomena of magnetism are in good agreement with the atomic models which are demanded by the facts of radioactivity and radiation, but there are still unsolved problems. The theory of quanta leads to an elementary magnetic moment which is almost exactly five times the magneton deduced by Weiss from the experimental results. As the volume under notice bears the date 1926, we might have expected some account of the recent work of Sommerfeld and others, which serves to throw some light on the discrepancy. The final chapter does, however, contain a description of the quantisation of orbits in three dimensions and the confirmatory experiments of Gerlach and Stern. Though most students of physics are able to read scientific works in French, an English translation, if accompanied by some additional matter, would probably be welcome.

Kalkfrage, Bodenreaktion und Pflanzenwachstum. Von O. Arrhenius. Pp. vii + 148. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1926.) 8 gold marks.

A LIST of those who have set forth their views on some aspect or other of the reaction between lime and soil would be an almost complete list of the world's soil chemists. It is not only—perhaps not chiefly—because of the economic importance of the liming of soils that so much scientific work and thought have been given to the matter. Economic considerations undoubtedly brought about the inception of the work (and still remain in some quarters the diplomatic excuse for its pursuit), but the enormous development of the work is in large measure the result of the sheer fascination of an elusive problem, which seems to be more complicated with each step taken towards its solution.

In his survey of the problem, Dr. Arrhenius gives a brief and somewhat critical review of the opinions held by soil chemists and ecologists on the relation between plant growth and soil acidity, and of the multiplicity of experimental methods which have been invoked in the study of the subject. We recognise the difficulty of giving an account of a subject with so many aspects, particularly when there is great divergence of opinion about the relative significance of those aspects, but it is not easy to understand the omission from the book of an account of the work of Hissink and of Gedroiz on the relation of exchangeable calcium in the soil to the liming problem. The conceptions which have arisen from this work are well known to be playing a prominent part both in the scientific study of the liming question and in the solution of economic problems of farming. It is to be hoped that in a future edition some account of this aspect of the work will be given and the appropriate additions made to the otherwise valuable and extensive bibliography.

A feature of the book is a concise account of the work—to which the author has himself made important contributions of the observed relation between the weight of crop and the hydrogen ion concentration of the soil. Not all soil chemists and ecologists are able to agree with Dr. Arrhenius about the significance of this work and the validity of the conclusions drawn therefrom, but this account will be valuable both to its exponents and its critics. N. M. COMBER.

Colloid Chemistry: Theoretical and Applied. By Selected International Contributors. Collected and edited by Jerome Alexander. Vol. 1: Theory and Methods. Pp. 974. (New York: The Chemical Catalog Co., Inc., 1926.) 14.50 dollars.

MR. ALEXANDER, with the aid of sixty contributors of a dozen different nationalities, has made a gallant attempt to produce a comprehensive treatise on colloid chemistry in English. His success may be measured by the mass of useful material which is here presented, though the arrangement does not always make it readily available. The more general papers, for example, Harkins on surface energy, Hardy on lubrication, Freundlich on adsorption, Gibbs on aerosols, and Hatschek on viscosity, are models which might with advantage have been followed by some of the less eminent authors. The detailed discussion of any particular piece of experimental work is only permissible in a book of this kind when some very general principle is thereby illustrated, and on these grounds some half-dozen of the papers here printed should be relegated to the ordinary journals; their inclusion tends to produce the atmosphere of a *Festschrift*. Again, the actual matter of some of the articles is already available elsewhere; for example, that of Millikan on measuring the electrons, and the unduly long account given by Von Weimarn of his theory of the colloidal state. It is to be hoped that in the two volumes to follow the editor will be less merciful, even though his contributors write without hope of reward.

The ingenuity with which this mosaic of essays covers the field of theory and method is remarkable, but it is curious to find that the fundamental process of dialysis receives only a casual mention in two places. Recent developments in the use of electrodialysis are also neglected. No pains have been spared to provide adequate bibliographies, diagrams, and indexes, and with some patience in use this volume will form a valuable addition to the shelves of the colloid chemist.

P. C. L. THORNE.

Pflanzen als Gesteinsbildner. Von Julius Pia. Pp. viii + 355. (Berlin: Gebrüder Borntraeger, 1926.) 10·50 gold marks.

THIS book, which is founded in part on lectures delivered at the University of Vienna, aims at providing a comprehensive treatise on plants as rock-builders. It is intended both for geologists and botanists, but the whole mode of treatment is botanical rather than geological. The account of the Bacteria and Algæ, with which the book opens, will be useful to many students, though the amount of botanical detail included seems scarcely relevant to the main purpose of the book. Indeed, before the Cormophyta are reached, the reader can scarcely fail to become aware of a certain lack of proportion in the scheme of the work; nearly half the volume is devoted to the Bacteria and Algæ, while about the same amount of space is deemed sufficient for the higher plants from Bryophyta to Angiosperms. Even within the latter section of the book, the space assigned to different topics seems to have been allotted with little regard to their relative importance. Less than a dozen pages, for example, are assigned to the Coal-measure flora, whereas more than forty are devoted to marsh and moorland plants of the present day, which are included on the strength of their function as peat-formers.

The book is lavishly illustrated, the figures being mostly taken from well-known sources, which are cited. It may seem ungrateful to quarrel with such a wealth of excellent drawings in a book which has, to a certain extent, a popular aim, but one cannot but regret the space consumed by figures of some fifty flowering plants of the present day. The student, whether of geology or botany, would willingly have dispensed with some of these pretty pictures in favour of fuller bibliographies, especially in connexion with the chapter dealing with coal and its origin.

The Psychology of Social Institutions. By Prof. C. H. Judd. Pp. ix + 346. (New York: The Macmillan Co., 1926.) 8*s.* 6*d.* net.

"THE purpose of this book is to concentrate attention on the fact that social influences are of the highest importance in determining the character of human thought and conduct." To instincts and other inborn traits the author attributes little importance. This point of view now meets with widespread approval, and it is not proposed to quarrel with it here. There can be little doubt that the older social psychology, founding itself upon observation of the individual, over-emphasised the rôle of the so-called instincts of gregariousness and acquisition and the like. Whatever may have been the case with regard to the origin of institutions in respect to the part played by instinct, there is no question but that the vast accumulation represented in our social heritage now predominates in determining social conduct in general. Prof. Judd's book is to be welcomed in that it provides for the student an examination of certain social institutions at some length, during the course of which this point of view is kept continuously to the fore. But it cannot be said that the book contributes anything definite towards the solution of the numerous problems connected with the whole subject. It may be replied that this was not its purpose, and if this is so, then it has certainly fulfilled its limited object in driving home this one important lesson.

A. M. C.-S.

British Birds. Written and Illustrated by Archibald Thorburn. New edition. In 4 vols. Vol. 3. Pp. x + 168 + 48 plates. (London: Longmans, Green and Co., Ltd., 1926.) 16*s.* net.

THE third of the four volumes of Mr. Thorburn's new book on "British Birds" has now appeared, and fully comes up to the standard of its predecessors. It contains a further series of coloured plates of high merit, although a few, such as that of the lapwing, are decidedly less happy than the majority. We are glad to see that the female plumage is portrayed in very many cases, as is certainly necessary with such birds as ducks and game-birds, two of the principal groups dealt with on this occasion. Both sexes of the ptarmigan are shown in each of their three seasonal plumages. We could wish, however, that the nestlings also had more often been included in the plates, as has here been so successfully done in the case of the ringed and golden plovers.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Early History of Gaseous Adsorption.

THE publication in a recent part of *Proc. Roy. Soc.* (A, Sept. 1) of excerpts from the memoir of 1863 by Dr. R. Angus Smith of Manchester, on "The Absorption of Gases by Charcoal—(i.)," by the initiative of Mr. S. Lenher, calls to mind Angus Smith's service in collecting, with the help of James Young of Kelly, the scattered scientific papers of his friend Thomas Graham, in 1876. No more attractive account of the history and philosophy of the atomic theory exists than the short introduction which he prefixed to that volume. Physical chemistry was then being born, and the relevant ideas about atoms and the aether were in the foreground.

The John Hunter whose paper (*Journ. Chem. Soc*, 1865) is referred to by Mr Lenher was, I doubt not, the assistant trained to this kind of work by Thomas Andrews at Belfast, who died young In Andrews' address to the Chemical Section of the British Association in 1871 ("Scientific Papers," ed. Tait and Crum Brown, p. 318), which was a survey of the main recent advances, he devotes a paragraph to the work of his assistant.

"Hunter has given a great extension to the earlier experiments of Saussure on the absorptive power of charcoal for gases. Cocoanut-charcoal, according to Hunter's experiments, exceeds all other varieties of wood-charcoal in absorptive power, taking up at ordinary pressures 170 volumes of ammonia and 69 of carbonic acid. Methylic alcohol is more largely absorbed than any other vapour from 90° to 127°: but at 159° the absorption of ordinary alcohol exceeds it. Cocoanut-charcoal absorbs forty-four times its volume of the vapour of water at 127°. The absorptive power is increased by pressure."

One recalls that the late Sir James Dewar, who presented to science the technique of charcoal absorption at low temperatures, spent his earlier years at Edinburgh, where the work of Andrews would be familiar through his friends Crum Brown and Tait.

JOSEPH LARMOR.

Cambridge, October 1

The Structure of the Continents.

IN his letter on this subject published in NATURE of September 25, Dr. Harold Jeffreys cautiously favours the possibility that "the basaltic layer below the granite may be in a glassy state, as Daly has suggested," and he goes on to add that the underlying layer may well be dunite The evidence in favour of this view is based on:

(*a*) Earthquake records which show that compressional waves are transmitted through the upper layer with a velocity of 5·6 km./sec., through the lower layer with a velocity of 7·8 km./sec.; and through an intermediate layer with a velocity (measurable in one case only) of 6·2 km./sec.

(*b*) The work of L. H. Adams and R. E. Gibson (*Proc. Nat. Acad Sci*, May 1926, p. 275), which gives the velocities calculated from the observed compressibilities and densities, at pressures corresponding to depths of about 30 km., as 6·45 km./sec. for tachylyte (basaltic glass) and 8·2 km./sec. for dunite (peridotite composed mainly of olivine). As these results refer to ordinary temperatures, those corresponding to the temperatures below the granitic crust would be a little less.

The possibility of a layer of basaltic glass between granite and dunite—both crystalline rocks—seems improbable on general grounds. If the basaltic layer be glassy, then one would expect the dunite also to be glassy, in which case the velocity of compressional waves would probably be less, instead of greater, than that within the lower layer of the continents. On the other hand, if the dunite be crystalline, then the basaltic layer should also be crystalline, particularly as its existence is referred to differentiation due to the crystallisation and sinking of olivine; for if olivine could crystallise it is difficult to imagine conditions which would inhibit the crystallisation of pyroxenes and felspars (or a high-pressure equivalent). But in this case the velocity of compressional waves would be 6·9 km./sec. or more. Evidently all that can be safely deduced from the evidence is that the basaltic layer is not mainly composed of gabbro.

There is, however, an alternative interpretation of the intermediate velocity recorded by Jeffreys which should not be overlooked. L. H. Adams and E. D. Williamson (*Journ. Franklin Inst.*, April 1923, p. 520) have calculated the corresponding velocities in syenite and granodiorite at 6·2 km./sec., and in diorite at 6·4 km./sec. If, therefore, the granite of the upper levels of the continents passes down into diorite, a reasonable explanation of the intermediate layer is forthcoming In a recent paper (*Geol. Mag.*, July 1926, p. 317) I presented chemical and petrological evidence supporting the hypothesis that the continents were originally of granodiorite composition, and that as a result of igneous processes, mainly in pre-Cambrian time, the upper levels have become more granitic, leaving a complementary differentiate of diorite in depth This hypothesis is in accordance with the great abundance of diorites and andesites in zones of later mountain folding, and with the absence of any widespread intrusions of post-Cambrian granites comparable in their regional extent with those that preceded them in pre Cambrian time

If the intermediate layer of Jeffreys be identified with diorite instead of with basaltic glass, then the basaltic layer should exist in the high-pressure crystalline facies of eclogite. Unfortunately, the compressibilities of garnets or eclogites at different pressures have not yet been determined, but it seems probable that the velocity of compressional waves in eclogite would not differ seriously from that in dunite. A layer of eclogite passing gradually down into dunite at some unknown depth would then satisfy the seismic, petrological, and isostatic evidence In view of the great importance of testing this interpretation in the most direct possible way, I have expressed to Dr. L. H. Adams and his colleagues my hope that they will add to their work on basaltic glass and dunite a similar investigation of the elastic properties of eclogite.

A further objection to the identification of the intermediate layer with basaltic material, whether glassy or otherwise, arises from its shallowness in the crust. If, as Jeffreys suggests, it extends from a depth of 10 or 15 km. to a depth of 20 or 30 km., then it is difficult to understand how it could ever be raised to the high temperatures implied by the great extrusions of plateau basalts which from time to time in geological history have overwhelmed enormous areas in different parts of the world. This difficulty is relieved by the conception of an eclogite layer extending downwards from a depth of 20 or 30 km. into a region where the temperature is higher and heat of radioactive origin can be accumulated.

ARTHUR HOLMES.

The University, Durham, September 25.

Science and Psychical Research.

As I shall be shortly leaving for New Zealand, perhaps a little space may be granted me to reply to a number of letters which have appeared in the recent issues of NATURE, from the pens of Sir Bryan Donkin, Mr. Campbell Swinton (3), and Mr. E. J. Dingwall.

Some of the confused thinking represented in these letters may perhaps be stopped if I explain the genesis of the original article which has provoked the discussion. The editor of NATURE asked me to write a review of Sir Arthur Conan Doyle's book *from a scientific viewpoint*, and I said I would try to do it. After reading through the two volumes very carefully, I concluded that there was nothing scientific about the book. I do not care for merely destructive criticism, as I think that a badly written book is its own worst condemnation. Also I am not yet so far removed from youthfulness as to have forgotten what I owe to the talented author, for giving us, long ago, "The White Company" and the adventures of the immortal Sherlock Holmes So I told the editor that I had decided not to undertake the task He then suggested to me that I should write an "essay review"; that is, using the book as a peg, I should hang upon it a dissertation on a cognate subject of scientific interest, namely, psychical research. I accepted this offer, and chose the subject which has started the present discussion. Apparently it sufficed for some minds to draw the conclusion that, because my essay was hung upon a spiritualistic peg, therefore psychical research is the same thing as spiritualism! No doubt, if I had written an essay review on the subject of evolution, hanging it upon a book on neo-Lamarckism, let us say, as a peg, the same type of mind would deduce that this indicated that evolution was the same thing as neo-Lamarckism!

That psychical research and spiritualism are not at all the same thing can be easily demonstrated, I think, if we take the cases of two famous exponents of psychical research already more or less discussed in these letters. I refer to Lodge and Richet Both are admittedly psychical researchers of the first rank. Lodge is also a spiritualist, having come to the conclusion that survival is proved from his interpretation of the facts of psychical research Richet, admitting the truth of the same set of facts, but interpreting them from a very different viewpoint, is still a kind of 'super-materialist,' absolutely and irrevocably opposed to the spiritistic hypothesis, which he holds is disproved by some of the very facts of psychical research! Could anything be plainer, then, than that psychical research and spiritualism are two entirely different things? What should we say of the mentality that confused biology with neo-Darwinism or with neo-Lamarckism? What are we to think of those who confuse a line of experimental research with one of the hypothetical conclusions which, in the opinion of only a portion of the researchers, arises out of it?

Let me now reply more particularly to Mr. Campbell Swinton, who has been a fair and, on the whole, courteous opponent, though sadly tempted at times, I fear, to let out and say what he really feels. Perhaps I may be ready to meet him half-way in his criticism that the medium is not absolutely comparable with the microscope or the chemical balance; I ought perhaps to have used a closer simile and likened the medium rather to the catalytic agent, the presence of which is essential to the production of the phenomena in certain types of chemical change. What I wanted to bring out, and what I still maintain, is that a genuine medium is not *actively* a participant in the experiments; the phenomena are produced *through some extended action of his subconscious mind*, but not by active volition on his part.

Mr. Campbell Swinton ought to know that a set of negative results in an experiment does not prove anything when confronted with even a single well-authenticated positive result from the same experiment. How many times have we, who have taught chemistry in schools, seen some of the most carefully prepared experiments fail to succeed, to the great delight of the assembled class? Yet, once the positive result is obtained, the acute mind of the boy knows at once that the negative results are cancelled, and one good demonstration is enough for him. It is only muddled thinking of the adult mind which persists in quoting a series of negative results as decisive.

As regards psychic photography, the decisive positive result, in my opinion, has never yet been obtained So, in this particular case, I entirely agree with Mr. Swinton that there is *a high probability* that there is nothing in it. Many psychical researchers think the same; but spiritualists, on the whole, believe the opposite The question could be settled once for all, to everybody's satisfaction, if one of the alleged photographic mediums would consent to experiment under absolute test conditions in which he would not be allowed to handle the plates or to have access to them at any stage of the proceedings But I venture to think that it will be a very long time before any such thing as this is likely to happen

I think it is rather hard that all my critics should waste so many words on trying to prove that I am a spiritualist and that spiritualism is a delusion. If any of them had come to the National Laboratory of Psychical Research last week they would have heard my address on this very subject, in which I took the stand that the spiritistic hypothesis does *not* fit in with all the known facts of the case, and pleaded for a more thorough and scientific study of the phenomena, with the view of finding a general theory "which should harmonise all the discoverable facts in the same way that Darwin's great theory of Evolution harmonised all the known facts of biology" Surely Mr. Swinton, at any rate, will concede that I have never diverged from that view in the whole of this long discussion?

I am sorry that Mr. Swinton departed a little from the high level of his debate in the last paragraph of his letter in NATURE of September 25. The words *suggestio falsi* sound, to my ears, somewhat offensive, especially as the idea behind them has been derived from the second-hand information of mischief-makers, and has not been verified by Mr. Swinton himself. There are more than six hundred firms, associations, and companies in the London Telephone Directory having names beginning with the word 'national'. I think I need say no more than that we can justly claim to be quite as national in our organisation and outlook as most of them But as an excuse for refusing my invitation the objection to the word is surely puerile. Why does not Mr Swinton say that he has never in his life been to a séance and never intends to go to one? I would have preferred this direct statement to the somewhat unkind and unworthy innuendo which he makes instead. But, in any event, Mr. Swinton stands self-confessed as an illustration of the type of scientific man about whom I wrote my article, namely, the man who presents "an unscientific attitude to the subject of psychical research." I claim that the letters written by him and my other correspondents fully prove my point.

Mr. Swinton's remarks in his last letter, published in NATURE of October 9, are entirely correct and in agreement with my own views, except for his last paragraph. I never classed Richet with Crookes and Lodge "as a spiritualist" but only as a psychical

researcher. To do so would be "most misleading" if I had been dealing with spiritualism, but I was not. The title of my essay was "Science and Psychical Research," not "Science and Spiritualism." My plea to men of science is for a more scientific attitude of mind *towards psychical research*, not towards spiritualism.

Sir Bryan Donkin has gratuitously given his own interpretation to the words "supernormal phenomena," thereby ruling out all those manifestations which I consider to be the key to the whole situation. I have more than once stated that I do not know the difference between trance and sleep. If Sir Bryan does, will he please tell us? If he does not, why does he take up an attitude which will forever prevent the problem being solved? If some of our leading medical men would spare a little time, even though they be, as I am, hard-worked to the very limit, we should soon know something about this mediumistic state. But I have seen excellent supernormal phenomena produced with the medium wide awake and absolutely controlled and immobilised in good light, so the question as to what trance may or may not be does not touch the essentials of my argument. Sir Bryan cannot have it both ways. If he is opposed to the scientific examination of the trance state, then he takes an unscientific attitude towards this phenomenon and is another of those to whom my article was addressed. But if he thinks it ought to be studied, then he should range himself on my side in this discussion.

Mr. Dingwall, I can surely claim, agrees with me, for he uses my very words in his last paragraph. He says, "There is a good case for the scientific study of what are called supernormal phenomena." That is exactly what I said too! But the rest of his letter shows clearly what he wanted to imply, namely, that Dr. Tillyard had not seen enough supernormal phenomena to enable him to judge rightly. I concede readily that I have not seen anything like so much as Mr. Dingwall; if he were logical, he would *a fortiori* exclude Mr. Swinton and most other men of science from this discussion, as they have not even seen as much as I have seen. Why pick me out and leave them in?

Mr. Dingwall asks, very pertinently, "Can Dr. Tillyard tell us of any single medium who can produce some simple raps, under conditions which render their normal reproduction impossible?" Yes, I can. Stella C. has repeatedly, both in my presence and in that of many others, produced such raps inside a close Pugh Table at a distance from herself. Mr. Dingwall will doubtless criticise this experiment, as he has done to me personally, on the ground that, as the box is closed, nobody could really see what was going on inside it. Yet, in his report on the Margery mediumship he says that he particularly requested that the phenomena should be done inside a closed box, and, when this request was refused, he regarded it as highly suspicious. In other words, Mr. Dingwall is always ready with an argument *against* any particular experiment, even though his objections mutually destroy one another.

I would like to assure Mr. Dingwall that it is not the number of séances that a man attends, but his capacity to draw definite conclusions, which really matters. Mr. Dingwall has attended hundreds, but he is still in a mental fog, just like the schoolboy whom we all know, who may be given an experiment to do many times over, but can never make a clear deduction from it. I am quite content with the eight séances which I have attended. In two of them, undoubted evidence of fraud was easily discoverable. In one other there was no analysable result. In the other five, with three different mediums, definite supernormal results followed under strict test conditions. In other words, I have obtained, *five times over*, a definite proof that supernormal phenomena do undoubtedly occur, and so I join the ranks of those who, like Lodge and Richet, are convinced of this fact. No amount of negative evidence can outweigh these positive results. Let me also assure Mr. Dingwall that I am not very likely to add largely to my psychic experiences, not being a hunter after sensations. I have seen Sir Ernest Rutherford's experiment on the bombardment of the atom demonstrated twice. It is enough. I accept the fact that the atom can be broken up, and no longer desire to go on attending lectures which keep on proving the same thing. I have seen supernormal phenomena in abundance produced at five controlled séances. It is also enough to convince me that they occur. What is the true explanation of them remains still to me at least a partial mystery; according as the evidence may unfold itself in the future, I may yet find myself with either Sir Oliver Lodge or Prof. Richet.

Finally, let me again plead for a more scientific attitude of mind on the part of men of science towards psychical research. Perhaps I may live to see it, if I succeed in attaining the allotted span.

R. J. TILLYARD.

REFERRING to the discussion on this subject in previous issues of NATURE, might one ask: Is there not confusion regarding the aims of science and of psychical research, which at present are fundamentally dissimilar? We know that the object of experimental science, as distinct from philosophy and mathematics, is to obtain control over the energies of Nature by learning the laws inherent in matter; that science has never set a limit to the varieties of matter; that, consistent with its purpose, it accepts facts as it finds them; and that its function, *qua* science, has never been to prove *a priori* conceptions. Some of us forget, however, that the elementary conditions essential for the pursuit of its object are not compatible with the objects and conditions of psychical research. By way of contrast a simple statement of scientific requirements might be made as follows:

1. The first two indispensable and interdependent factors in any scientific problem are the trained research worker and *something to be examined*. The thing to be examined may not have been contacted by all the physical senses, as, for example, electricity; but it must have been experienced by means of one sense-faculty, at least, before it will come to the attention of human beings or within the range of scientific research. (Scientific instruments are merely the extension of our physical senses.) It was not necessary to prove the existence of electricity; the problem was first, how to induce, and second, how to control or direct it.

2. It is essential for real scientific research that the matter investigated be, to some extent at least, under the control of the investigator, and this is possible only through his knowledge of the laws which describe the action of energy under certain specified conditions.

3. Science has advanced each step in its progress on the knowledge of laws already ascertained. Much was known concerning the chemical elements and conductive materials before electro-chemical phenomena could be investigated. Every factor in an experiment cannot be new.

4. Science requires for each advance a working hypothesis or theory about what is next to be discovered. The theory may be proved wrong, but nothing at all can be attempted in fresh fields without

a tentative supposition, a temporary theory which suggests a particular line of investigation, or some reason for doing one thing rather than another.

Now, the phenomena described as 'psychic' cannot come within the purvey of science if we accept the conditions given above. Men of science cannot examine something non-existent to them, and of which, consequently, no data exist, for there is then no basis for a beginning. It is impossible to undertake to 'test' that about which we know absolutely nothing. Thus a Gilbertian situation arises when it is proposed to examine 'psychic phenomena' scientifically: (1) The matter to be tested has as yet no existence; therefore (2) we know no laws by which its action could be induced; (3) we have no theory regarding its nature, laws, or cause; (4) we cannot control its production; (5) we do not know the nature of the medium through which it is proposed to attempt to induce the phenomena; and (6) the investigator cannot control or direct the energies which supposedly must operate to produce results.

Before science can enter this field there would have to be (1) an acknowledgment, derived from experience, of the reality of psychic phenomena, (2) the formulation of a scientific theory or working hypothesis of the possible laws inherent in the matter of the phenomena, and (3) some means found by which the experimenter could control the operations of the experiment. One does not by this preclude the possibility of prediction by mathematical science of the existence of a kind of matter hitherto unknown, a hypothetical state of organic matter, acting under electro-magnetic laws, analogous to inorganic states of invisible electro-chemical matter. Such a prediction could arise only from a more exact knowledge of physiological and psychological activities, but the first step in a true scientific investigation of 'psychic phenomena' cannot be taken until some deduction or other is attempted. It is necessary, therefore, for serious investigators of this phenomena, who affirm its existence, to state a case, to enunciate a working hypothesis not contradictory of the fundamental principles of exact science. The collection of instances and theories thereon, or hit-and-miss experiments in the vague expectation that something will be discovered, have never, and could never, in themselves, evolve a science. Terms used should be defined in such a way as to conform to the 'uniformity of Nature,' which is the one great deductive theorem of science. We know, however, that, although man is included in Nature in the largest sense of that term, science has as yet gained control only of energies latent in the mineral forms of existence and of *states preceding mineral precipitation*. The energies of the forms that *succeed*, *i.e.* of plants, animals, and man, have not been made subject to exact science. We have no practical knowledge of the laws that originate organic forms and govern their growth. Further, no man of science can alter the temperament or constitution of a human being, nor can he *isolate sensations, emotions, or thoughts from exterior influence and regulate them according to prescribed formulæ*. Hence, scientific attempts to isolate a 'medium' are childish. Equally puerile are 'tests' by measuring instruments. The *vacuum tube* preceded the measurements of the phenomena of modern physics. What is to be the vacuum tube for psychical investigation?

W. W. L.

How can the methods of scientific research be applied to the subject of the spirit world, which is of such post-vital interest to us all? To do so under existing conditions is generally impossible and always difficult. Faraday wrote to a friend: "I have been busy turning the tables on the table-turners." That statement was based on the results of definite experiments carried out under his own conditions.

In present circumstances, to follow Faraday's example and apply science to psychics is not easy. Would any manager of importance take his medium to the Royal Institution and submit without reserve to laboratory conditions?

Cannot the difficulty, if it does exist, be overcome by the use of scientifically trained mediums? Suppose, for example, prominent spiritists were engaged, in the first instance, to examine the staffs of colleges and scientific institutions throughout the country. It is probable that from such plentiful material a sufficient number of mediums of even moderate power could be obtained, when it is remembered that from one family alone a father, two daughters, and a son-in-law were all able to practise successfully as mediums. It would be desirable to exclude all who already have committed themselves intensely, those whose interest is mercenary, writers of imaginative articles for profit, those who seek prominence, and those imbued with the spirit of mischief.

Given the willing medium whose sole interest is science, and given suitable laboratory conditions, it should be possible to test the scientific basis of the claims of spiritists. It might even be possible to entice a ghost between crossed Nicols.

Transmission of Stimuli in Plants.

THE transmission of stimulation past a discontinuity has been demonstrated in Mimosa by Prof. Ricca and confirmed by Mr. Snow and others. On the other hand, Sir J. C. Bose has stated (NATURE, vol. 115, Jan. 10 and March 28, 1925, and also *Proc. R. S.*, Series B, **98**, p. 290) that he was unable to obtain this result.

I have for some time past been engaged in work on the transmission of stimulation in *Mimosa pudica*. Apart from my main line of work, and more as a matter of interest than from any doubt as to its validity, I have attempted to repeat this experiment. The method used was that described by Mr. Snow (*Proc. R. S.*, Series B, **96**, p. 349) in which the two parts of the shoot are connected together by a piece of water-filled rubber tubing.

The directions given by Mr. Snow were followed carefully, but for a long time I was not successful in obtaining the transport of the stimulus past the cut, although the experiment was repeated on a number of different occasions. The cause of the failures was finally found to be due to minute bubbles of air which emerged from the pith as the tension in the water increased. These bubbles collected in the space between the cut surfaces and interrupted the continuity of the water separating the two portions of the shoot. In Mr. Snow's experiments this effect does not seem to have been encountered, but possibly Sir J. C. Bose's failures are to be attributed to this cause. It may be of interest to describe a method which I have found successful in avoiding this difficulty.

A shoot was cut into two halves under water and the portions placed in a beaker of water in such a way that the two freshly cut surfaces were completely submerged. The beaker was then put into a large empty desiccator from which the air was exhausted by means of a vacuum pump. In this way air was removed from the intercellular spaces of the pith of the cut internode and, when air was readmitted to the desiccator, these spaces became injected with

water. The two portions of the shoot were removed and connected with water-filled rubber tubing in the usual way, the two cut surfaces being brought very close together. The whole shoot was then supported in air in a horizontal position, the basal end being immersed in water. After a resting period of two hours, to enable the shoot to recover its normal condition, it was stimulated by the application of a flame to a basal internode.

On the two occasions on which the experiment was tried, using the above-mentioned method, the stimulus affected, first of all, the leaves on the basal portion of the shoot, and then, after a pause of more than one minute, it traversed the water-gap and affected the leaves in the apical portion. For example, in one case, the two leaves in the basal part moved after 4 sec. and 8 sec. respectively, while beyond the discontinuity the times at which the leaves moved were 1 m. 16 s., 1 m. 49 s., 2 m. 21 s., and 2 m. 29 s.

If Sir J. C. Bose will repeat his experiments, using the precautions mentioned above, I am sure that he will be able to convince himself of the need of modifying his statements (NATURE, vol. 115, Jan. 10, 1925) "that the transpiration-current has nothing to do with the conduction of the excitatory impulse" and that "*the conduction is a phenomenon of propagation of protoplasmic excitation.*" There is no doubt that the stimulus can be carried across a discontinuity by means of the transpiration current, and that in this case, at any rate, the conduction has nothing to do with "the propagation of protoplasmic excitation."

It is somewhat surprising that Sir J. C. Bose (*Proc. R. S.*, Series B, **98**) should have failed to obtain stimulation by applying extracts of the stem to the basal end of a cut shoot. This result, which was obtained originally by Prof. Ricca and amply confirmed by others, strongly favours the hormone theory. Personally, I have not found the least difficulty in obtaining stimulation in this way.

Electric Television.

INVENTION appears to be multiplying in regard to this interesting subject, and I hear that more than one inventor in Paris is employing, for receiving, the cathode ray arrangement that I believe I was the first to publish in a letter to NATURE of June 18, 1908. The ideas embodied in this arrangement had occurred to me several years prior to that date, indeed not long after the production of the Braun cathode ray oscillograph invented in 1897. I actually tried some not very successful experiments in the matter of getting an electrical effect from the combined action of light and cathode rays incident upon a selenium-coated surface, in which I was assisted by the late Prof. G. M. Minchin, himself a great authority on electric cells sensitive to light, and also by Mr. J. C. M. Stanton. The transmitting apparatus consisted of a home-made Braun oscillograph in which a metal plate coated with selenium was substituted for the usual fluorescent screen, the image to be transmitted being thrown by a lens upon the selenium surface, and the end of the cathode ray beam being caused electromagnetically to traverse the projected image. Experiments were also tried in receiving with a Braun tube which I purchased in Germany, but in its then 'hard' form it proved very intractable.

My ideas in regard to this cathode ray arrangement for the production of television were further detailed and illustrated in an address I gave to the Röntgen Society on November 7, 1911, and still further elaborated and brought up-to-date, with wireless methods applied, in a paper I read before the Radio Society of Great Britain on March 26, 1924.

My idea, which was to use cathode rays as employed in the Braun oscillograph, instead of moving material parts, both in the transmitting and in the receiving instruments, is, as I understand, only at present being applied for receiving, mechanical apparatus being still used for transmitting. I desire, however, to point out that when the cathode ray is also applied to transmitting it will be possible to dispense entirely with all moving material parts, as the alternating or intermittent electric currents employed for moving the two cathode ray beams synchronously at the transmitting and receiving stations respectively can be supplied by oscillating thermionic valves supplied by batteries.

In this way it should prove possible to have electric television of a satisfactory fine-grain description without the employment of any mechanical motion of material parts whatever, as cathode rays are practically without weight and inertia, and can be deflected with perfect accuracy and synchronism at almost incredible speeds, while the accuracy of oscillating valves properly tuned is also wonderful.

Active Nitrogen.

IN the "Research Items" in NATURE for September 18, reference is made to the paper by Willey and Rideal in the *Journal of the Chemical Society* for July, in which the energy of active nitrogen is found to be 42,500 cal. per gm. mol. Now Strutt's photographs of the glow produced when active nitrogen acts upon iodine show that the iodine line 2061 Å.U. is produced, and this needs an amount of energy of at least 150,000 cal. It is unlikely that a series of successive impacts could give to the iodine a higher level of energy than that possessed by the nitrogen, or that simultaneous collisions of the iodine with more than one nitrogen molecule would suffice. The nitrogen glow is destroyed by iodine vapour in an exceedingly small fraction of a second, which indicates the probability of exchange of energy taking place directly between the active nitrogen molecule (if it *is* the molecule and not the atom) and the molecule of iodine.

Copper at Low Temperatures.

IN the August issue of the *Proceedings of the Royal Society* (A 112 [1926], pp. 136-151) a paper by Messrs. Lambert and Hartley on "An Investigation of the Effects of Variations in the Radiation Factor on the Efficiency of Dewar Vessels" records some interesting experiments which suggest that copper has unique radiating properties at about the temperature of liquid oxygen. In this connexion a peculiar phenomenon came to my notice some months ago, and it is possible that the two sets of observations may be related.

When present at a public lecture on 'Liquid Air,' delivered at the beginning of this year, I made the following observation during one of the lecture experiments. A small solid copper cylinder was immersed in liquid air contained in an unsilvered glass Dewar vessel in order to cool it down prior to its immersion in water to demonstrate the formation of ice. During the cooling of the cylinder in the liquid air, the usual rapid evolution of gas occurred on immersion, which lasted for some time, after which the liquid air became quiescent and it appeared that temperature

equilibrium had been reached. However, instead of remaining quiescent, as one would expect, after a few seconds a sudden re-evolution of gas took place, which was of short duration, and then a state of equilibrium was apparently attained.

I have recently confirmed this observation, and some experiments have been carried out to see whether this phenomenon is of general occurrence with metals, or whether it is specific for copper. It has only been possible, so far, to examine the following metals: lead, iron, tin, platinum and aluminium, and in these cases no such action was observed under similar conditions.

It appears from these experiments that either:

(1) Copper undergoes an allotropic change with heat evolution at a temperature slightly above that of liquid air. One is reminded of the phenomenon of recalescence in the case of iron at higher temperatures.

Or (2) a surface action peculiar to copper comes into play

Such an effect must cause a considerable loss in filling copper Dewar vessels with liquid air.

I have so far been unable to trace any record of this peculiar behaviour of copper in the literature.

The Reaction to Flea Bites.

IT does not seem to be generally appreciated that the irritating wheals which may follow the bites of various insects are anaphylactic in origin. The first time that a person is bitten by a species of insect which has never bitten him before, nothing or next to nothing may happen, but when he has become sensitive to the proteid in the liquid which the insect injects in the process of biting, he develops the local irritable swelling which is familiar to most people.

Some years ago (*J. Path. Bact.*, **17** (1912), 110) I showed that my wife, who gave a violent reaction to the bite of the human flea (*Pulex irritans*), did not respond at all to bites of the rat flea (*Xenopsylla cheopis*) until they had been fed on her five times during six weeks, when she developed extensive wheals. We have recently got the same results with the rabbit flea (*Spilopsyllus cuniculi*). Single fleas were fed on June 6 and June 18, and four fleas on July 11, without any result; after feeding two on August 13 red papules developed seven days later; single fleas were fed on August 22 and September 1, and in each case a moderate reaction developed about 36 hours later. It is rather remarkable that the minute quantity of foreign proteid injected by the fleas in four bites should be enough to make a person sensitive. Lack of sensitisation is not, of course, the only reason why people do not react. Some persons who are extensively flea bitten seem to become immune. Others are naturally immune: however often I am bitten by them, I give no response to fleas of any kind, though midges and some mosquitoes irritate me extremely. At least that is so in Hertfordshire; from my only experience of Scotch midges, in which I was bitten very freely, I had no trouble, they were probably a different species.

The rabbit flea does not in my experience bite man very readily; in some trials I have quite failed to get them to do so even after several days' starvation. When they do, they take a long time to get their feed, and if undisturbed may remain attached for so long as an hour. Brumpt ("Précis de parasitologie," 3rd ed., 1922, p. 829) notices this peculiarity, which seems to apply to their feeding on rabbits as well as man.

Zoological Nomenclature: Hübner's (1806) 'Tentamen.'

THE secretary of the International Commission on Zoological Nomenclature has the honour to invite attention of the zoological profession to the fact that application has been made for the suspension of the International Rules, in the case of Hübner's (1806) 'Tentamen' in order to establish its nomenclatorial availability.

Briefly summarised: The formal nomenclatorial status of this document, involving about 100 names admitted by some authors as of generic rank, has been under controversy for many years, and opinion of specialists in Lepidoptera is still divided.

The arguments, as submitted, in favour of suspension of rules, maintain that: (1) there are sound reasons both for admitting and for denying recognition to the 'Tentamen' from the viewpoint of interpreting the Rules; (2) the evidence *pro* and *con* is not sufficiently conclusive to remove the question from debate; (3) the rejection of the 'Tentamen' will produce greater confusion than uniformity, will necessitate a vast amount of undesirable labour and economic loss of time and work; (4) if, on the ground of expediency, the rules can be suspended in this case, the nomenclature of the Lepidoptera, as used for the past thirty years, can be largely maintained.

The 'Tentamen' is one of the most important and most controversial cases ever submitted to the Commission. A discussion, with essential bibliographic references, will be found in *Smithsonian Misc. Coll.*, v. 73 (4) (now in press).

The Commission will delay announcement of vote, on the requested suspension, at least until September 1, 1927, in order to give interested authors, and especially entomological societies, opportunity to study the premises and to present to the Commission their views and arguments, *pro* or *con* regarding the action requested.

In order to protect groups other than Lepidoptera, a prerequisite to suspension of rules would be that representative specialists in Lepidoptera agree upon and furnish to the Commission definite bibliographic references to the 107 names which they view as genotypes.

C. W. STILES,
Secretary to Commission.

The Problem of the Origin of Species as it appeared to Darwin in 1859 and as it appears to us To-day.

I HAVE discovered two errors in my recent paper which appeared under this title in NATURE of August 21, 1926. These errors were due to the hurried assemblage of facts and citations under the heading "Geographic Isolation and Speciation"; they will be carefully corrected in a sequel to this paper which is now in preparation for the *American Naturalist*, to be published under the title "The Origin of Species, V.: Speciation and Mutation." Meanwhile, I desire to point out as inaccurate the following statement in my paper:

"As an example of wide isolation without speciation, the house wren of Florida, *T. ædon ædon*, exhibits the same characters as those of Tierra del Fuego, but in the intermediate regions another species, *T. musculus*, exhibits a large amount of subspeciation and several complete intergradations."

On the contrary, the house wren is not known to breed in Florida and does not occur in Tierra del

Fuego. The species occurs in Patagonia and in the southern United States, but the birds from these two areas are specifically distinct.

The second erroneous statement is in the final paragraph of the same section, where (2) and (4) contradict each other:

"(2) . . . a desert subspecies, *P. m. sonoriensis*, reared for eight years in a humid environment, is entirely unmodified in the direction of the humid subspecies *P. m. gambeli*.

(4) Similar results from transplantation of *P. m. rubidus* and *P. m. sonoriensis* are obtained: reared in an entirely new environment, they do not converge toward each other but toward local humid subspecies *P. m. gambeli*."

Here (4) should read:

"Similar results from transplantation of *P. m. rubidus* and *P. m. sonoriensis* are obtained: reared in an entirely new environment, they do not converge toward each other or toward the local humid subspecies *P. m. gambeli*."

I regret having made these erroneous statements in a zoological field outside my own, and I trust that this correction will prevent their wider circulation.

The Spectrum of Zinc.

IN the course of an investigation for the British Non-Ferrous Metals Research Association, which it is hoped will prove successful in applying the spectroscope to the quantitative assay of the impurities in zinc, the following observations of more special scientific interest were noted.

A zinc line, which does not appear to have been measured, occurs at λ2147·36 I. Å. (±0·02) near the cadmium line at λ2144·39 Å. Close to the 'raie ultime' of cadmium λ2265·04 Å is a zinc line the wavelength of which is λ2265·35 I. Å. (±0·02). This should be taken into account when searching the zinc spectrum for lines due to impurities, as with spectrographs of comparatively low dispersion, such as the Hilger quartz spectrograph size E. 31., the zinc and cadmium lines are indistinguishable. Hagenbach and Schumacher (*Z. wiss. Phot.*, **19**, p. 129, 1919) give the following as zinc lines: λλ2265·08 (8) and 2265·40 (2), and it is highly probable that the former line is a cadmium line.

Spectrograms were taken on a Hilger quartz spectrograph size E. 1. and the zinc lines measured on a photo-measuring micrometer size L. 1. using various samples of zinc.

The samples of zinc supplied by the British Non-Ferrous Metals Research Association included one sample from the New Jersey Zinc Co., prepared by fractional distillation after electrolytic refining, and was considered to be spectroscopically pure.

Observed Relative Intensities of Stark Components in Hydrogen.

ATTRACTED by the singularly large observed variations (*Astrophys. Jour.*, **62**, 229, 1925) from estimated intensities of certain strong Stark components of H_β (H. A. Kramers, Copenhagen, 1919) we have recently made quantitative measurements from a suitable source by means of a neutral wedge. It is interesting to compare the results with the new theoretical calculations by Schrödinger (*Ann. d. Phys.*, **80**, 437, 1926). Following are the observed, calculated, and estimated ratios of intensities of components having polarisations and displacements as indicated. The displacement Δ is expressed in the unit which appears in the quantum theory of the Stark-effect.

Components Compared.	Ratio of Intensities		
	Obs.	Calc.	Est.
p components of H_β, $\frac{\Delta = +8}{\Delta = +10}$	1·00	1·06	0·40
s components of H_β, $\frac{\Delta = +4}{\Delta = +6}$	1·59	1·55	0·54

The much weaker components, p, $\Delta = +6$ and s, $\Delta = +2$ appear somewhat stronger than the theory indicates. This is possibly due in part to superimposed secondary spectrum lines, which could not be detected by the present method. Owing to the increased interest in this research, the measurements are now being extended to the weaker components and to H_γ and H_δ with such modification in method as to permit the detection of any seconday spectrum lines.

Absorption Spectrum of the Hydrogen Molecule.

WITH the continuous spectrum described by Lyman (*Astrophysical Jour.*, **60**, 1) as a background, and with hydrogen flowing through the receiver of the spectrograph, it was found possible to photograph the absorption spectrum of molecular hydrogen in the extreme ultra violet. More than twenty absorption bands were observed between λλ1245 and 840. Most of the bands were clearly resolved and show the characteristic structure of the emission bands in the ultra-violet. The most striking feature of the spectrum is a progression of strong absorption bands beginning with λ1105. At least twelve bands of this progression were easily recognised. This adds a new electronic level to the three already obtained (Dieke and Hopfield, Oakland Meeting of the American Physical Society, June 1926) from the hydrogen emission spectrum. A continuous absorption spectrum begins sharply at λ840. This continuous absorption corresponds to the dissociation of the molecule into a normal and an excited atom. The long wave-length limit of the continuous absorption compares well with the theoretical value 14·4 volts. Complete details will be published later.

Sterility in the Vegetable Marrow.

THE vegetable marrow appears to have been affected by a form of sterility this season. I have been told of cases both in Gloucestershire and Surrey where the plants have produced an enormous number of male flowers and only one, or possibly two, female flowers. In the case of one marrow to a plant the resulting fruit has been a large one. Every plant was affected in the same way. No disbudding had been practised. In my own case I have had, as usual, an abundant crop, including about three dozen well-ripened fruits for winter use. The season has been favourable for half-hardy plants. Can any reader suggest a reason for this occurrence in a monœcious plant?

The Analysis of Line Spectra.[1]

By Prof. A. FOWLER, F.R.S.

RATHER more than sixty years ago, when the spectroscope became an effective instrument of scientific research through the work of Kirchhoff and Bunsen, it was regarded essentially as providing a new and powerful method of chemical analysis. It soon had brilliant results to show in the discovery of a number of new elements, but this kind of discovery could not go on indefinitely, and the interest of chemists as a body in spectrum analysis would appear to have declined rather rapidly. Spectrum analysis, as was soon realised, was not so simple a matter as it first appeared, and called for so much study that its pursuit was mainly left in the hands of a small band of specialists.

Some of the most important developments of spectroscopy have been closely associated with attempts to interpret the spectra of celestial bodies. The introduction of photographic methods by Huggins led almost at once to the discovery of new lines apparently belonging to hydrogen in the spectra of Sirius and other white stars, which were afterwards of great value in the establishment of Balmer's law of the hydrogen spectrum. Perhaps the greatest contribution of early astrophysics to our stock of knowledge, however, was that which so clearly pointed to the essential identity of matter throughout the universe.

With the discovery that the spectra of certain elements were modified by varying the character of the exciting source, chemical analysis of the sun and stars was supplemented and eventually overshadowed by investigations of the physical conditions which prevail in those bodies. The sun and stars thus came to be regarded as natural experiments on generally similar masses of matter at various high temperatures—experiments ready prepared for observation and always in operation. Thus many laboratory researches were directly instigated by astrophysical observations. To take one example, the fragmentary observations by Lockyer and by Liveing and Dewar of what were afterwards called *enhanced lines* were extended and systematised through an attempt by Lockyer, in which I myself took part, to interpret the spectrum of the solar chromosphere as photographed during the total eclipses of the sun in 1893 and 1896. The immediate result was an important correlation of the changes in the laboratory spectra of the elements with the succession of types in stellar spectra,[2] from which it appeared that enhanced lines were especially characteristic of stars which, on other grounds, were believed to be hotter than the sun. These investigations laid the foundations for a true interpretation of the spectra of the hotter stars, and led to the more extended studies of enhanced lines which have proved of such great importance in the development of the theory of the origin of spectra and the structure of atoms.

The remarkable developments of spectroscopy in the direction of atomic physics have resulted from discoveries relating to regularities in spectra. In the representation of series spectra the wave-number of a line always appears as the difference of two *terms*, and a series of lines appears as a regular succession of differences between a limiting term and a sequence of terms, the limit itself being a term of another sequence.

Much of the early work on series regularities in spectra is summarised in the now well-known symbolic representation of a series system, namely:

Principal series . . .	$1\,S - mP_i$
Sharp series	$1\,P_i - mS$
Diffuse series . . .	$1\,P_i - mD_i$
Fundamental series . .	$2\,D_i - mF_i$

where 1 S, for example, represents an individual term, and mS a sequence of terms of S type. The S terms are always single, but the others are complex in all but singlet systems; so that $i=1$ for singlets; 1, 2 for doublets; and 1, 2, 3 for triplets (in the older numeration). A sequence of terms may be represented by an approximate formula such as that of Hicks, in the form $R/[m+\mu+\alpha/m]^2$, where R is the Rydberg constant, m a serial number, and μ and α constants (usually proper fractions) to be determined from the observed lines. The possible combinations of terms in the production of lines are restricted in accordance with selection rules which have since been extended to more complex spectra, as will appear later.

It should be understood that these studies of the structure of spectra were pursued with the clear conviction that they would ultimately reveal the secrets of atomic structure, and the analysis of spectra, as distinct from spectrum analysis, gradually became one of the principal objects of spectroscopic research.

With the advent of Bohr's theory of spectra in 1913, spectroscopy entered on a new phase of activity. The theory and its immediate explanation of the spectra of hydrogen and ionised helium are now so well known as to call for little more than mention. Adopting the Rutherford conception of a neutral atom, spectroscopic terms were translated by the theory into 'energy levels' of the atom, so that a spectrum line is considered to represent the energy emitted by an excited atom when it passes from a non-radiating state of a certain energy to another of lesser energy. The terms are, in fact, proportional to the energies of the corresponding 'stationary' states.

The theory in its first form also gave a definite significance to the enhanced lines occurring in the spectra of other elements besides helium, and predicted that such lines would form series systems for which the series constant would be 4 R, 9 R, 16 R, and so on for atoms at successive stages of ionisation.

Bohr's theory proved a great stimulus to experimental spectroscopy as well as to theoretical investigations. Among the first fruits was the experimental verification of the predicted 4 R value for the series constant in the spectra of ionised magnesium, calcium, and strontium.[3] Next, Sommerfeld's well-known extension of the theory of the hydrogen spectrum by taking account of the relativistic variation of the mass

[1] From the presidential address delivered to Section A (Mathematical and Physical Science) of the British Association at Oxford, on August 9.

[2] Lockyer, *Roy. Soc. Proc.*, vol. 60, p. 475 (1897).

[3] A. Fowler, *Phil. Trans.*, A, vol. 214, p. 225 (1914).

The verification of 9 R for doubly-ionised aluminium by Paschen (*Ann. d. Phys.*, vol. 71, p. 142, 1923), and of 16 R for trebly-ionised silicon by A. Fowler (*Roy. Soc. Proc.*, A, vol. 103, p. 413, 1923), followed in due course.

of the electron with its orbital velocity predicted a fine structure of the lines of hydrogen and of ionised helium which was almost immediately verified by Paschen's remarkable observations of the structure of ionised helium lines under very high resolving power.

A general explanation of the existence of several types of series S, P, D . . . in the spectra of more complex atoms immediately followed, namely, that such types of series are to be attributed to the action on the series electron of a perturbing field due to the presence of other electrons in the atom, producing a precessional motion similar to that associated with the relativity effect, but of very much greater value.

Apart from the first two groups and the aluminium sub-group of the periodic table, the spectra of the elements, with few exceptions, are extremely complex and long defied analysis. It was not until 1922 that a key to the structure of complex spectra was furnished by the investigations of Catalán, who was then working at the Imperial College of Science. The essential feature of Catalán's work was the discovery that in the arc and spark spectra of manganese, and in the arc spectrum of chromium, there were terms of greater complexity than the triple terms which had previously been recognised. It was this discovery that opened a way to the analysis of complex spectra in general. It has been pursued with amazing success by Catalán himself, Walters, Laporte, Meggers, Sommer, and others, and the main features of the structure of many spectra as complicated as that of iron have been revealed.

It is not necessary to go into all the intricate details of the spectra, because the general results can now be very simply summarised in consequence of the theoretical developments which have gone hand in hand with the experimental investigations. Bohr and Sommerfeld had already established certain 'selection rules' for the combination of the terms of the simpler spectra on a quantum number basis, and immediately following the work of Catalán, Sommerfeld showed that the scheme of 'inner quantum numbers' which he had devised for the simpler spectra could be extended so as to fit the observations empirically. As other spectra came to be disentangled, an assignment of quantum numbers which appears to be adapted to all spectra was completed by Landé.

In accordance with the work of Bohr, Sommerfeld and Landé, a spectral term may be represented by four quantum numbers, written in the form n^r_{kj}. Here n is the *principal* quantum number, increasing by unity for successive terms of the same sequence; k is the *azimuthal* quantum number and has the values 1, 2, 3, 4, 5 . . . . . . for the term types S, P, D, F, G . . . .; j is the *inner* quantum number, having one or more values according as the term is single or multiple; r represents the *maximum multiplicity* of terms in the system to which the term belongs, so that $r=1$ for singlets, 2 for doublets, 3 for triplets, and so on.

The selection rules regulating the term combinations of most general occurrence are:

For different types of terms: $\Delta k = \pm 1$.

For individual component terms: $\Delta j = \pm 1$ or 0, with $j=0$ to $j=0$ forbidden.

For systems of terms: $\Delta r = \pm 2$ or 0.

Apparent exceptions to the first selection rule, $\Delta k = \pm 1$, are of very frequent occurrence. In the spectra of the alkaline earths there are several groups of lines—some of them of great intensity—which do not belong to the regular series, but are related to them through the characteristic separations of the respective triplet systems, as was first recognised by Rydberg more than thirty years ago. Groups of this type were further investigated by Popow and by Götze, and their real structure was deduced from observations of Zeeman effects. It then appeared that such a group was derived from combinations of P terms of the regular series with another set of P terms, or of ordinary D terms with a second set of D terms. The additional types of terms, which are usually distinguished as 'anomalous terms' and designated by P', D' . . ., have the same inner quantum numbers and show the same Zeeman effects as ordinary terms of corresponding types; but in their combinations with the regular terms they mostly follow the rule $\Delta k = 0$, giving the combinations PP', DD' . . . . Among themselves, however, the anomalous terms combine in accordance with the ordinary selection rule, $\Delta k = \pm 1$, giving such combinations as P'D', D'F' . . . . Such terms are not restricted to the spectra of the alkaline earths, but have been found to be of very general occurrence in all but the simplest spectra.

In the actual analysis of a spectrum, the selection rules which have been indicated for the combination of terms are supplemented in a very practical way by Sommerfeld's 'intensity rule' and to a less degree by Landé's 'interval rule.'

The whole question of intensities in related groups of lines has recently been placed on a quantitative basis through photometric measurements initiated by Ornstein, Burger, and Dorgelo at Utrecht. It results that the intensities in such groups are in the ratio of integers, and it may accordingly be concluded that intensities, like frequencies, are determined by quantum considerations.

Unfortunately, the analysis of a spectrum does not always lead to a knowledge of the actual values of the terms, or energy levels. These can be determined for any of the relatively simple spectra, in which comparatively extended series can be traced and their limits calculated. In most of the complex spectra, only the relative values of the terms have been deduced, since extended sequences in these spectra are apparently of rare occurrence. Even for these, however, the term of highest numerical value, representing the lowest energy level, can often be identified, and this is of special value in view of its association with the normal state of the atom.

This completes the story of spectroscopic terms and their possible combinations on what might be called a purely numerical basis; that is, in so far as the analysis of a spectrum can at present be based merely on a table of wave-lengths and intensities. Especially as regards the more complex spectra, however, advantage has to be taken of every possible experimental aid to the classification of the lines—particularly, in the first instance, as a means of sorting out the lines characteristic of an element at different stages of ionisation.

Thanks to the industry of numerous workers, many

of the complex spectra have now been partially analysed, and two of the principal generalisations foreshadowed some years ago have been greatly strengthened. The first of these is expressed by the so-called 'alternation law,' according to which the arc spectra of the elements are alternately of even and odd multiplicities in passing from the first to the higher groups of the periodic table. No exceptions to the rule have yet been found.

The second generalisation is expressed by the spectroscopic 'displacement law,' which states that the first spark (enhanced) spectrum of an element has a structure similar to that of the arc spectrum of the element which precedes it in the periodic table. To make this generally applicable, however, it is necessary to qualify the rule by restricting the meaning of similarity to a common odd or even multiplicity.

These rules have by no means been proved for all elements, but they are true for all spectra which have been disentangled up to the present time, and may safely be adopted as a starting-point in the analysis of further spectra. They have been almost completely verified for the elements of the two short periods Li (3) to Cl (17), but may be more effectively illustrated by the arc spectra of the elements K (19) to Ni (28) by the use of data collected by Catalán, which are given in Table I. The table includes references to the 'ground term,' *i.e.* the highest term or deepest energy level:

TABLE I.

TERM SYSTEMS IN ARC SPECTRA, K-NI.

Group	I	II	III	IV	V	VI	VII	VIII		
Element.	19 K	20 Ca	21.Sc	22.Ti	23 V	24.Cr	25.Mn	26 Fe	27 Co	28 Ni
Multiplicities	2	1, 3	2, 4	1, 3, 5	2, 4, 6	3, 5, 7	4, 6, 8	3, 5, 7	2, 4, 6	1, 3, 5
Ground term	^2S	^1S	^2D	^3F	^4F	^7S	^6S	^5D	^4F	^3F

A very striking relation, to which attention appears to have first been directed by Hund, is that, as regards the ground term, the spark spectrum of each of the elements Ca to Ni is more closely related to its own arc spectrum than to the arc spectrum of the preceding element. This may be shown as follows:

	20.Ca	21.Sc	22.Ti	23 V	24 Cr	25.Mn	26.Fe	27.Co	28.Ni
Arc . .	^1S	^2D	^3F	^4F	^7S	^6S	^5D	^4F	^3F
Spark . .	^2S	^3D	^4F	^5F	^6S	^7S	^6D	(^3F)	(^2F)

It is not improbable that such systematic relations will be of considerable assistance in the unravelling of the numerous complicated spectra which remain to be investigated.

The more recent results of the analysis of complex spectra have provided an ordered knowledge of a multitude of facts which have an important bearing upon the development of the theory of spectra and the arrangement of electrons in the outer parts of normal atoms. Theoretical workers have not been slow to utilise the new data, and have, indeed, frequently been able to forge ahead of experimental results.

The principal problems immediately resulting from the analysis of the more complex spectra resolve themselves into two—first, the distribution of the electrons among the various possible types of orbit; and, second, the deduction of spectroscopic terms from a given distribution of electrons.

In the consideration of the first problem we are not confined to the evidence afforded by optical spectra. Other data towards this end are furnished by X-ray spectra and by the variations of the chemical and physical properties of the elements according to their positions in the periodic classification. Bohr's well-known table of electron orbits (1922) was built up by taking account of these properties and considering the formation of atoms by the successive capture and binding of electrons. The orbits themselves were distinguished by the quantum numbers n_k ($k \leq n$), and it was assumed that the orbits of the earlier bound electrons were essentially unchanged when another electron was introduced into the system.

These ideas of Bohr have been remarkably developed in recent years, especially through the work of Main Smith[4] and Stoner,[5] who independently arrived at similar conclusions, chiefly from the consideration of chemical and physical properties respectively. In the new scheme the inner sub-levels are completed at an earlier stage than in Bohr's arrangement, and there is a greater concentration of electrons in the outer sub-levels of each group. The nature of the modification will be sufficiently indicated by comparing the electron distribution among the sub-levels in helium, neon, argon, and krypton, according to the old and new arrangements (Table II.).

TABLE II.

ARRANGEMENT OF ELECTRONS IN RARE GASES.

Bohr.

	Atomic Number.	K 1_1	L 2_1	2_2	M 3_1	3_2	3_3	N 4_1	4_2	4_3	4_4
He	2	2									
Ne	10	2	4	4							
A	18	2	4	4	4	4					
Kr	36	2	4	4	6	6	6	4	4		

Main Smith and Stoner.

	Atomic Number.	K 1_{11}	L 2_{11}	2_{21}	2_{22}	M 3_{11}	3_{21}	3_{22}	3_{32}	3_{33}	N 4_{11}	4_{21}	4_{22}
He	2	2											
Ne	10	2	2	2	4								
A	18	2	2	2	4	2	2	4					
Kr	36	2	2	2	4	2	2	4	4	6	2	2	4
	n_k	1_1	2_1	$\underbrace{\quad}_{2_2}$		3_1	$\underbrace{\quad}_{3_2}$		$\underbrace{\quad}_{3_3}$		4_1	$\underbrace{\quad}_{4_2}$	

The new scheme of electron distribution was shown by Stoner to be supported by a consideration of the intensities of X-ray lines, the absorption of X-rays, chemical and magnetic properties, and optical spectra. It retains all the essential features of Bohr's picture of the building up of atoms, and is equally in accord with chemical considerations, as is especially shown by the work of Main Smith. The electronic arrangements of all the elements from 1 to 92, in their normal states, may now be specified with considerable confidence.

[4] "Chemistry and Atomic Structure," London, 1924; *Review of Chemistry and Industry*, March 28, 1924.
[5] *Phil. Mag.*, vol. 47, p. 719 (1924); vol. 49, p. 1289 (1925).

With the attainment of a definite conception of the electronic structure of the various atoms it becomes possible to approach the second of the two problems referred to above, namely, the determination of the spectroscopic terms associated with a given distribution of electron orbits. The first steps were taken by Russell and Saunders, and independently in part by Wentzel, who, in a discussion of the so-called 'anomalous' terms, which have already been mentioned, made one of the most illuminating contributions to spectroscopy of recent years. To the three $^3PP'$ groups of calcium already known two more were added by Russell and Saunders, who were thus able to show that the five groups formed a series which could be approximately represented by a Ritz formula. The surprising result then appeared that, as referred to the regular triplet limits, the later P' terms were numerically negative. The earlier P' terms, having positive values, certainly originated in the neutral atom, and it could scarcely be doubted that the later terms also had the same origin.

The existence of these negative terms implies a greater equivalent energy than that required for ionisation of the atom, and it follows that it is possible for the atom to remain neutral while absorbing more energy than that necessary to remove the series electron. Hence, in accordance with a previous suggestion made by Bohr, but unknown to them, Russell and Saunders concluded that the energy must be divided between two (or more) electrons, each of which is displaced to a higher energy level, without the removal of either of them. The detailed numerical evidence led inevitably to the conclusion that both valence electrons might jump at the same time from outer to inner orbits, and that the net loss of energy would then be radiated as a single quantum, *i.e.* as monochromatic emission.

Arising out of the work of Russell and Saunders, together with further contributions by Pauli, Goudsmit, and Heisenberg, a general theory of complex spectra has been developed in a practical form by Hund.[6] The theory enables the deeper spectrum terms corresponding to any specified configuration of electrons to be determined with considerable certainty.

It is a fundamental feature of the new theory that, in a complex spectrum, the quantum numbers which specify an electron orbit are quite distinct from those which specify a spectroscopic term. The former are five in number, namely, n, k_1, k_2, m_1, m_2. The latter, which number three, are represented by r, l, j. The theory consists of semi-empirical rules for deducing r, l, and j for the deeper lying terms from the quantum numbers of the electrons in uncompleted groups.

The assignment of five quantum numbers to each electron orbit is due to Pauli, who supplemented it by a hypothesis—generally known as Pauli's principle—which asserts that no two electrons in an atom can occupy orbits having the same values for these five quantities. This principle can be shown to lead immediately to the scheme of electron distribution suggested by Main Smith and Stoner.

The extraordinary theoretical developments in recent years, leading to the prediction of certain features of the spectra of elements and the structure of atoms, have possibly overshadowed the progress in experimental spectroscopy. Nevertheless, much experimental work of immediate importance to theory has been carried on, and much more is urgently called for.

The present resources of experimental spectroscopy would appear to be adequate for the elucidation of the majority of the outstanding problems. For most elements the conditions of excitation can be so modified that the spectrum is well under control, so that all the lines, or only a selection of them, can be produced at will.

The old, well-tried methods of exciting substances to luminosity—the flame, arc, spark, and vacuum tubes—have by no means been superseded. They have, however, been supplemented by numerous other experimental arrangements. Some of these, like the electric furnace so effectively employed at Mount Wilson by A. S. King, have brought the spectrum of an element under more gradual control, so that a valuable aid in the classification of the lines of a complicated spectrum is provided by the order of their appearance as the temperature is raised. Other methods have definitely brought additional spectra within the range of laboratory experience.

One class of 'experiments,' as I have previously mentioned, is provided by the heavenly bodies. Saha's theory of high-temperature ionisation, further developed by Fowler and Milne and by Miss C. H. Payne, has already been utilised in the prediction of the ionisation potentials of certain multiply-ionised atoms for which the structures of the corresponding laboratory spectra have not yet been sufficiently determined to indicate the energies of the normal states. In this way it is conceivable that we may obtain approximate values of the actual energy levels in some of the complex atoms for which only relative values can at present be directly determined from the spectra.

Enough has been said, I hope, to give some idea of the main lines of development and present trend of spectroscopy. The analysis of spectra with which I have been chiefly concerned is a fascinating pursuit, and the establishment of a beautiful order out of an apparent chaos of spectrum lines brings great satisfaction to the investigator. I have endeavoured to show, however, that the analysis of spectra is not an end in itself, but that under the guidance of quantum theory it has fundamental contributions to make to our understanding of atomic structure and of the periodic classification of the chemical elements. It appears not at all improbable that some of the mysteries of chemical valency may also find a solution in the classification of spectrum lines, and there are indications that the conceptions of spectroscopy may ultimately extend our knowledge of the structure of matter in the liquid and solid states.

It may be that in the future the theory of spectra will be so far developed that it will become possible to calculate the positions and intensities of the lines composing the spectrum of an element with greater accuracy than they can be observed. We are, however, still very far from this ideal, and meanwhile experiment and theory must go hand in hand towards a better understanding of the problems that lie immediately before us.

Scientific and Industrial Research in Australia and New Zealand.

AT the Imperial Conference now in session, among other important problems for discussion is that of Imperial co-operation in scientific research. By far the most promising schemes for advancement in that direction, in Australia and New Zealand respectively, are those recently evolved by Sir Frank Heath, Secretary to the Department of Scientific and Industrial Research, London, as the result of his recent visit to those countries, at the invitation of their Governments, which have now unanimously adopted the proposals he has laid before them.

In addition to internal development, the importance of the protection of new countries against the accidental introduction of insect pests alone, not to mention plant pests, has lately been emphasised by Dr. Edward M. Ehrhorn, the well-known entomologist of Honolulu. He has stated that the losses caused by insect attack on the principal crops of the United States amount to upwards of 1,000,000,000 dollars a year, "a sum more than sufficient to meet the entire cost of the Federal Government's annual expenditures." Most of these pests were accidentally introduced, and many could have been excluded by a scientifically controlled quarantine.

Already in Australia rust and other fungoid diseases have attacked the wheat, but their ravages have been greatly lessened by the breeding of rust-resisting varieties, as initiated by Farrer of New South Wales, and by the disinfecting of the seed wheat with copper compounds. Formerly the seed wheat was dipped, before being sown, in a weak solution of copper sulphate. This poisoned the fungoid spores and so saved much loss from rust, but it somewhat damaged the seed wheat. Now, in lieu of this the seed wheat is dusted with finely powdered copper carbonate, and this process alone, as compared with the earlier one, is increasing the value of the Commonwealth wheat yield by about 2,200,000*l*. per annum.

This discovery, of vast value to Australia, the United States, and other wheat-growing countries, has been the result of 'team work,' partly by native-born Australian workers, partly by men trained in the best schools of the homeland, and the whole improved by American investigators. If the increased value of the American and other wheat crops throughout the world, accruing from this discovery, be added to the 2,200,000*l*. a year gained by Australia, the total sum realised would repay, many times over, all cost of agricultural research. A far greater gain will follow when, as the result of scientific breeding of wheat, both rust-resisting and drought-resisting types, are evolved. In view of such research, particularly in Australia, Prof. J. D. Watt, of the University of Sydney, considers the desired end is already in sight. What is true of scientific team-work applied to wheat, is true also of all the primary and secondary industries.

The key-note of the Australian and New Zealand research schemes is 'team-work': team-work within Australia and New Zealand themselves, and team-work within the Empire, but such team-work, to attain the best, must not be spasmodic. In Sir Frank Heath's words: "What the industries want is a steady long-sighted policy of help and advice from the State in a national movement for the co-operative attack on scientific problems similar to that successfully initiated here [New Zealand] in the marketing of products overseas." Again, the report on the Australian proposals refers to the distribution of the Commonwealth's activities among the States according to their suitability for different sections of the work as "a means of convincing them that the national effort in scientific things is a pervasive instead of a centralised and bureaucratic influence."

In order to give effect to the proposals of the Commonwealth Government for the reorganisation of the Institute of Science and Industry, an Act was passed by the Commonwealth Legislature in June last which provides as follows:

A Commonwealth Council of Scientific and Industrial Research to be constituted, consisting of not less than nine members, three nominated by the Prime Minister, and appointed by the Governor-General, and including the official chairman of the council. This body is to be the executive during the six-monthly interval between the meetings of the full council. The remaining six members of the council come from the six States of the Commonwealth, each of these members being the chairman, for the time being, of the State Committee (advisory to the Council of Scientific and Industrial Research) in the particular State to which he belongs. In addition, the council may co-opt such other members as may be approved by the Minister on account of their special scientific knowledge. In order to give continuity to the policy of the council, the scheme provides that each of the three executive officers shall hold office for several years.

The Act provides for the State Committees to be constituted "as prescribed." Under the Government scheme, the chairmen are to be selected by the Commonwealth Government after consultation with the State authorities: three members appointed by the State Governments from the staffs of their scientific departments; three members representative of pure science, of which at least two must be from the local universities —such men to be selected by the National Research Council; these six members and the chairmen to co-opt three (or, exceptionally, more) other members representative of primary and secondary industries within the State.

The Commonwealth Council has already held several meetings, and consists of the following:

Executive	G. A. Julius, *Chairman*, President last year of the Institute of Engineers in Australia.
	Prof. A. C. D. Rivett, Professor of Chemistry, University of Melbourne.
	W. J. Newbigin, Managing Director of the firm of W. J. Adams & Co., Ltd., an engineer and member of the Chamber of Commerce.

The remaining members are:

Queensland. Prof. H. C. Richards (Geology).
New South Wales. Prof. J. D. Watt (Agriculture).
Victoria. Sir David Orme Masson (Chemistry).
Tasmania. Mr. Keam (Pastoralist).
S. Australia. Prof. T. Brailsford Robertson (Physiology).
W. Australia. Mr. Perry (Industrialist).

In addition, the following two members have been co-opted:

Queensland. Prof. E. J. Goddard (Biology).
Melbourne. Prof. H. A. Woodruff (Veterinary Science).

Thus, both the Commonwealth Council and the State Committees are widely representative. Great freedom of action is given to the council by placing it immediately under the Prime Minister, not as one of his departments, but as an advisory council to him.

Annual estimates for the special work of the year have to receive the sanction of the Commonwealth Parliament in the usual manner, but the financial provision, of far-reaching importance, adopted by the Parliament is as follows: The appropriation from the consolidated revenue fund of the sum of 250,000*l.* to form a trust account, the capital and interest to be used for the purpose of scientific and industrial investigations. A further sum of 100,000*l.* has been appropriated out of the consolidated revenue fund as an endowment fund (of which the executive of the council are trustees), the interest on which is to be used: (1) to assist persons in their scientific research; and (2) to train students for scientific research. The Commonwealth Parliament also voted 29,000*l.* to clear off all debts left by the old Institute of Science and Industry. In addition, the sum of 50,000*l.* was asked for by the council for the particular work to be undertaken within the present financial year.

At the instance of the Prime Minister, the Right Hon. S. M. Bruce, the Cabinet gave immediate effect to Sir Frank Heath's recommendations for facilitating the further training in the homeland of the most promising young Australian scientific workers by sending four such, at once, to be trained for two years in research institutions, chiefly those attached to the Department of Scientific and Industrial Research, London. Four additional students are about to be nominated for training abroad. An allowance of 150*l.* is made to these students for their passages to and from Australia, and the salary is 300*l.* a year with an additional provision of a sum up to 100*l.* for each student for travelling while abroad. Reciprocal arrangements have now been made for the reception of students from the homeland at centres of research in Australia and New Zealand. This excellent provision is not the least important of the plans for securing good team-work within the Empire.

The field work of the council this year will be as follows: Cold-storage problems in co-operation with the British Food Investigation Board, with special reference to beef; liquid fuels, treatment of fuels for saving oil and other products by low-temperature distillation, Bergius process, etc.; forest products, continuation of researches on making paper pulp out of timber, utilisation of gums, resins, tannins, etc.; animal diseases and pests, blow-fly and buffalo-fly pests, diseases of cattle, sheep, and horses; plant diseases and pests, researches for checking the spread of prickly pear (29,000,000 acres in Australia now overrun by this pest).

The chairman of the council, Mr. Julius, is expected to arrive in England next year to discuss scientific and industrial problems of mutual interest to the homeland and to Australia. Thus, so far as Australia is concerned, the new council is already going strong.

In regard to New Zealand, on the recommendation of the Prime Minister, the Right Hon. J. G. Coates, the Parliament has adopted practically all of Sir Frank Heath's scheme as follows: An Advisory Council of Scientific and Industrial Research is to be formed, under the Prime Minister, for the general utilisation of science for the advancement of New Zealand's industries. It is also to co-ordinate and see to the proper maintenance of the Geological Survey, Magnetic Survey, Meteorological Office, the Hector Observatory, the Samoan Scientific Service, and a State Laboratory for Standards and Tests to include the present Dominion Laboratory. An agricultural college is to be built and an institute of dairying to be established to collaborate with it. Expensive buildings are not suggested, but much of the initial research work is to be done at the college laboratories. It is suggested that the Dairy Products Control Board share with the Government the cost of maintaining such a research institute.

In regard to forestry problems, of great importance to the Dominions and the Empire, in view of the alarming decrease in the supply of soft woods (Great Britain now imports 40,000,000*l.* of timber annually) it is recommended that a forestry institute be created, later, by the Government, assisted by the timber milling companies, and that meanwhile a general report on the whole question of the New Zealand forests be obtained from the ablest forester available. With regard to fuel resources, and how best to utilise the somewhat friable coals of New Zealand, a research student is to be sent at once to the Fuel Research Station of the Department of Scientific and Industrial Research at Greenwich. Then there is the hydro-electric problem: it is estimated that New Zealand has a potential supply of no less than five million continuous horse-power.

So much for the primary industries. For the secondary industries, two technical field officers are to be appointed to assist co-operative research associations, and particularly to advise the smaller industries. Arrangements are to be made for a scientific library to comprise the chief public and university libraries as well as some private libraries. New Zealand is advised to link itself up with the International Research Council by establishing a local National Research Council; and to found National Research Scholarships and grants to professors and others for research work.

The total grants for the last-named services are not to exceed 2000*l.* a year, while the initial cost of the council, apart from office charges, etc., is estimated to be about 7000*l.* a year. A scientific officer is to be attached to the Office of the High Commissioner of

New Zealand in London to act as a liaison between the Department of Scientific and Industrial Research and the new department in the Dominion.

The universities, the New Zealand Institute, and the Cawthron Research Institute all find places in the scheme, as well as the Department of Industry and Commerce. The Advisory Council is to be constituted much as in the Commonwealth, with this important exception, namely, that in view of the smaller distances to be travelled in New Zealand as compared with Australia, the meetings of the council are to be held monthly, the executive being left in the hands of the secretary of the council, a well-trained man of science, Dr. E. Marsden, until recently assistant director of education, formerly a fellow of the University of Manchester and professor of physics at Victoria College, University of New Zealand. A bill to give statutory effect to the above recommendation has recently been carried by the New Zealand House of Representatives.

Thus, in New Zealand, as in Australia, in the future application of science to the development of industry, the watchword is 'team-work,' as for the nations around the Pacific who meet triennially in the Pan-Pacific Science Congress, no less than for the League of Nations. For any work worth the doing the first essential is to find the man, and surely in the selected teams of Australia, and in the leader of the New Zealand Councils for Scientific and Industrial Research, the men have been found.

News and Views.

THE preliminary programme of the third Pan-Pacific Science Congress, which is to be held at Tokyo from Saturday, October 30, until Thursday, November 11, contains a provisional scheme and time-table of the work of the congress, a list of the excursions which have been arranged, lists of sailings, and other matter useful to those who propose to attend the meeting or to contribute to its proceedings. His Imperial Highness Prince Kotohito of Kan-in has consented to act as patron, and H.E. the Prime Minister of Japan will be president of the congress. There is a long and distinguished list of honorary vice-presidents, which includes the diplomatic representatives of the chief Powers, a number of the Japanese Ministers of State, and heads of universities. The arrangements for the meetings have been in the hands of an organising committee appointed by the Japanese National Research Council, under the auspices of which the congress is held. A change has been made in the organisation of the meeting itself to promote solidarity of feeling and action. There is no doubt that the change will also greatly facilitate the conduct of business in a congress covering so wide a field. The different branches of science have been classified into two broad divisions, the physical sciences and the biological sciences, instead of into sections and sub-sections for each branch of science as in previous congresses. Divisional meetings and joint divisional meetings will take the place of the sectional meetings. At these, discussions will take place between allied branches of science on subjects of more or less common interest, in other words on border-line problems. Sectional meetings will continue to be held, but taking quite a subordinate place — for the contributions of a special nature which from their scope are unsuitable for discussion at a divisional meeting.

THE character of the discussions at the congress must, to a great extent, depend upon the number and nature of the communications offered, but the organising committee has drawn up a provisional list of subjects. In the joint divisional meetings it is proposed to hold a symposium on certain plans for international co-operation in the study of the more important scientific problems of the Pacific, and, secondly, to survey the present state of knowledge of the physical and biological oceanography of the Pacific. The subjects suggested for divisional or sectional discussion cover a wide range in all branches of science, from astronomy to economic geography, agriculture, and medicine, in all cases with special reference to the Pacific. It is noticeable that there is a considerable bias in favour of topics which have a practical application. In the physical section meteorology, earthquakes, and the study of volcanoes take a prominent place. In the biological sciences the fauna and flora of the Pacific are to be discussed in relation to distribution, as well as from the practical point of view of protection, and, where appropriate, in relation to economic development. Anthropology is well represented in the discussion of the antiquity of man in the Pacific, the anthropometry of races of the Pacific, the study of Ainu, Papuans, and pygmies, the culture of the East Indies in relation to the question of 'diffusion,' and the relation of food, clothing, and houses to climate. A series of excursions has been arranged to suit the special interests of members of the congress extending from October 18 until November 19, which will include visits to Ainu villages, the famous shrine and temple at Nikko, Hakone volcano, Fuji, coal and copper mines, hot springs, cretaceous, tertiary, pliocene, and other geological formations in various localities, the old Imperial Palace and the University at Kyoto, as well as other places of importance for the study of the fauna and flora or the commercial and industrial activities of Japan. After the official excursions are over, facilities will be afforded for a longer stay if desired.

PROF. R. RUGGLES GATES, who has just returned to London after a visit to Russia, gives us some interesting information as to the position of some scientific work and institutions there. In the course of his letter he says that much valuable work is being done in the various plant-breeding stations which he visited. These included Tammisto, near Helsingfors, Finland, as well as Khibiny in Russian Lappland, north of the Arctic circle, which is devoted chiefly to the production of northern vegetables and oats for fodder; Peterhof and Desto Selo, near

Leningrad, where extensive genetical, biometric, cytological, and physiological investigations are being carried on, especially with cereals, under the direction of Profs. Philiptschenko, Vavilov, and Levitsky, and Drs. Pissarev and Karpetschenko; Petrovsky-Razoumovsky, where extensive experiments, particularly with oat-breeding, are being made by Dr. Schegalov; and Saratov, where the greatest interest attaches to a series of unique wheat-rye hybrids of Prof. Meister, and where Dr. Plachek is improving the varieties of sunflowers, which are extensively grown as a crop in Southern Russia.

IN Moscow, the Institute of Experimental Biology is one of several laboratories under the direction of Prof. Koltzoff, in which a great range of genetical and cytological as well as other experimental work in animal biology is being done. The genetical section is in charge of Prof. Tschetverikoff. Much eugenical work is also being done in Moscow and Leningrad, especially in the collection of pedigrees, and a *Russian Journal of Eugenics* is edited by Profs. Koltzoff, Liublinsky and Philiptschenko. The Timiriazev Institute in Moscow, under the direction of Prof. Navashin, is chiefly devoted to research in plant cytology and genetics. Prof. Gates also visited the Botanical Gardens in Leningrad, Tiflis, and Batoum, the chief interest of the Tiflis garden being its large collection of Caucasus plants. A study was made of the tundra vegetation in the far north and the steppe region in Southern Russia and the Caucasus. While in Moscow Prof. Gates was present at the opening of a small museum of Metchnikoff relics in the Institute of Experimental Pathology Madame Metchnikoff came from Paris for the occasion.

CONSIDERABLE interest has been aroused among archæologists by discoveries at Glozel, on the right bank of a rivulet called Le Vareille, about twenty miles south-east of Vichy, of which little had been heard in England until attention was directed to them by Prof. S. Reinach in a letter to the *Times* of September 27, in which he referred to their bearing upon the date of the Magdalenian culture. The excavations, which began in 1924 and were carried out by Dr. Morlet, assisted by a young peasant Émile Fradin, yielded last summer a curious combination of objects in association which is at least puzzling. The objects were of stone, bone, and more or less baked clay, without a particle of metal or Celtic or Roman pottery. They consisted of (1) a few polished axes and small flints (there is no flint in the neighbourhood): (2) very thick hand-made vases, one of them decorated with a human head (eyes and nose but no mouth), a fiddle-shaped figurine representing a woman, without a mouth and recalling the so-called owl-vases of Troy, (3) pebbles engraved with outlines of animals or inscriptions or both, in the most degraded Magdalenian style, (4) a large number of clay tablets covered with inscriptions, some long and well engraved. Of these inscriptions some are described as being like the Phœnician, but the greater number are quite different.

INSCRIPTIONS from so remote a period are not known if we except some of Piette's earlier painted pebbles from the Mas d'Azil and a few (apparent) graffiti on reindeer horn. The only similar inscriptions of anything like so early a date were found in Portugal in 1894; but these aroused some suspicion and have not been universally accepted. Prof. Reinach, to whom we are indebted for these details of the find, is of the opinion that we have here a religious deposit of early neolithic age associated with a degenerate Magdalenian culture which is thus brought down so late as 4000–3000 B.C., he holds that it points to the western origin of writing. Prof. Elliot Smith, in his presidential address to the Anthropological Society of University College, London, on October 15, referred to this curious association in one deposit of neolithic objects with Cretan affinities, Magdalenian objects, and a linear script. He suggested that if the neolithic phase did not begin in western Europe until the second millenium B.C., there was nothing inherently improbable in the association, but it necessitated cutting off one millenium from the dating on Prof. Reinach's view, that the close of the Magdalenian period might have been so late as 3000 B.C. Further, if the Ægean origin of the pottery was admitted, the claim for the western origin of writing was unjustifiable.

AT the Imperial College, South Kensington, on October 13, Dr. W. H. Keesom, professor of physics and director of the Cryogenic Laboratory in the University of Leyden, described the experiments by which he succeeded in solidifying helium in June and July last. The methods of refrigeration employed by the late Dr. Kamerlingh Onnes made it possible to attain a temperature of less than one degree above the absolute zero, and by applying great pressure at this temperature, Dr Keesom found it possible to reduce helium to the solid state Under the most favourable conditions a pressure of the order of 100 atmospheres was sufficient for the purpose. In the earliest experiments, in which the use of much higher pressures was contemplated, the solidification took place in a German silver tube, and was demonstrated by the indications of a differential manometer showing that the tubes had become blocked. In later experiments a glass vessel was employed, so that the solid helium could be seen. It was not distinguishable from the liquid to the eye, having apparently the same refractive index and density, but the existence of the solid was proved by the fact that a metal stirrer immersed in the substance became fixed. By means of a simple device for melting the helium in immediate contact with the stirrer, the latter was released, and could be hammered against the unmelted solid a short distance away. A curve of melting-point against pressure was drawn, and it was found that, unlike the corresponding curve for other substances, it did not meet the vapour pressure curve, and there was therefore no triple point. By extrapolation the melting-point curve was shown to become parallel to the axis of temperature at the absolute zero, in accordance with Nernst's heat theorem.

RECENTLY the International Education Board, founded by Mr. John D. Rockefeller in 1923, made an offer of 30,000*l.* towards the cost of erection,

equipment, and endowment of new premises for the Department of Animal Breeding in the University of Edinburgh, on condition that a similar sum was obtained in Britain. It was announced by the Principal of the University, Sir Alfred Ewing, on Thursday last that Lord Woolavington had given a sum of 10,000*l.* towards the endowment of a chair of animal breeding in the University, and that the Development Commission would make a substantial grant, so that the condition laid down by the International Education Board might now be regarded as fulfilled.

THE Board of Agriculture first suggested in 1913 that research in animal breeding should be undertaken in Edinburgh, and a joint committee, representative of the University and the College of Agriculture, was appointed to consider the matter in conjunction with the Board and the Development Commission. The organisation of the work was interrupted by the outbreak of the War, but was resumed in 1919, and towards the end of 1920 the Department of Animal Breeding was established with Dr F. A. E. Crew as director. It was first housed in the immediate neighbourhood of the Old College, but for the last two years has occupied laboratories in the new Department of Chemistry at West Mains, adjacent to which ten acres of pasture belonging to the University have been made available. The financial arrangements now announced will enable the Department to be provided with premises specially equipped for work on animal breeding, and as a site at West Mains is available, it is anticipated that the building of the new Department will soon be undertaken.

AT a meeting of the Society for the Study of Inebriety on October 12, Dr. J. D. Rolleston read a paper on alcoholism in classical antiquity in which he stated that, in view of the fact that the scientific study of inebriety dates only from the middle of the nineteenth century, very little is to be gleaned from contemporary medical writers as to the prevalence and effects of alcoholism in ancient Greece and Rome. The main sources of information are the poets, especially the gnomic writers and satirists, philosophers, moralists, and encyclopædists such as Pliny the elder and Athenæus. Though there is some indication of the existence of chronic alcoholism, as is shown by passages in Pliny and Seneca, alcoholism in classical antiquity was mainly of a convivial character, and industrial alcoholism, apart from that associated with prostitution, was unknown. Dr. Rolleston quoted numerous passages from the classical writers dealing with the dysgenic influence of alcohol and other evil effects of drink on the community and the individual, especially the relation of inebriety to insanity, crime and poverty, and the measures, often of a fanciful character, recommended by the ancients for the prevention and treatment of drunkenness. In conclusion, Dr. Rolleston pointed out that the alcoholism of classical antiquity differed from that of to-day by its predominance among the upper classes, the lack of legislative control, the absence of distilled liquors and the non-existence of syphilis, which is now often contracted as the result of alcoholic indulgence and runs a severe course in alcoholic subjects.

THE Innwerk Aluminium Co. has built an electric power station at Töging in Germany in order to utilise the various falls on the river Inn. It is the largest hydro-electric power station in Germany. It is estimated that the annual average output will be 465 million kilowatt-hours. A description of the equipment of this station appears in the July number of *A E G Progress*. A peculiarity of the scheme is that no provision is made for storage. The hydraulic energy is immediately converted into electrical energy. There is never waste due to water flowing uselessly over the weir. The amount of power available is so large that it cannot always be utilised for power and lighting. At the time the station was built it was doubtful whether it would be more economical to manufacture aluminium or nitrogen. Hence the electrical equipment was designed so that either direct current or alternating current could be obtained. At the Töging station there are 15 nine-thousand horse-power turbines. The first eight of these machines drive three-phase generators, whilst the other seven drive direct current dynamos, the output of which is used for the manufacture of aluminium, the furnace rooms for which are near the station. The alternating current is carried on overhead wires at 100 kilovolts pressure to the Hart carbide factory, which is ten miles away. Special precautions have been taken to prevent the pole wheel from bursting should a turbine 'run away.' They are made of steel cast in one piece, and two rings of Siemens Martin steel are shrunk on to them. The strength of this steel is 78,000 lb. per square inch.

THE fiftieth annual meeting of the Conchological Society of Great Britain and Ireland was held at the City Museum at Leeds on October 16 under the presidency of Mr. J. W. Taylor, the doyen of the Society. There was a large gathering of members, and a number of delegates from related societies attended with messages of congratulation and good wishes. The president in his address dealt with the evolution of the Mollusca, and there were various exhibits of interest, including the Stubbs Collection which has been recently acquired by the Museum. The Society was founded in Leeds fifty years ago within a few days by Messrs. W. Nelson, W. D. Roebuck, H. Crowther, and J. W. Taylor, and the last two were happily present at the jubilee, which was appropriately celebrated at Leeds, though the Society has had its headquarters at the Manchester Museum for some years past. Mr. Hugh Watson, of Cambridge, was elected president for the ensuing year.

THE newly-created Society of British Foresters held its inaugural meeting during the recent meeting of the British Association at Oxford. The object of this Society is to help in the technical development of forestry in Great Britain. Forestry is coming more and more into prominence, and it is felt that the time has now arrived for the establishment of an

association of those engaged in it and in allied sciences. A journal will be published, and this will provide a place for the publication of the results of forestry investigation and practice in Great Britain, and for the dissemination of results obtained elsewhere. The officers of the Society are: *President*, Mr. R. L. Robinson, *Vice-President*, Prof. R. S. Troup; *Members of Council*, Mr. C. O. Hanson, Major F. M. Oliphant, Mr. R. S. Pearson, Mr. Frank Scott, Mr. J. D. Sutherland, Dr. Malcolm Wilson; *Editor of Journal*, Dr. H. M. Steven; *Business Editor*, Mr. J. Lyford Pike; *Secretary and Treasurer*, Mr. R. Angus Galloway, 8 Rutland Square, Edinburgh.

THE following courses of lectures have been arranged at the Royal Institution during November and December. The Tyndall Lectures will be delivered by Dr. G. W. C. Kaye, who will commence a course of three lectures on the acoustics of public buildings on Tuesday, November 2, at 5.15, and on Tuesday, November 23, Sir William Bragg begins a course of four lectures on the imperfect crystallisation of common things. On Thursday afternoons, beginning on November 4, there will be two lectures by Sir Edgeworth David on Antarctic exploration of the past and future; three by Dr R. R. Marett on the archæology of the Channel Islands; and two by Sir Squire Sprigge on (1) early medical literature and (2) medical literature in relation to journalism. On Saturday afternoons, November 27 and December 4, at three o'clock, Dr G C Simpson will give two lectures on atmospheric electricity. The Juvenile Lectures this year, the hundred and first course, will be delivered by Prof A. V. Hill on nerves and muscles, how we move and feel: (1) Nerves and the messages they carry (Dec 28); (2) muscles and how they move (Dec. 30), (3) the heart and some other muscles (Jan. 1), (4) the lungs and blood (Jan 4); (5) nerves and muscles working together (Jan. 6), (6) speed, strength, and endurance (Jan. 8).

THE ninth annual Streatfeild Memorial Lecture will be delivered by Mr F C. Robinson at the Institute of Chemistry on Friday, November 19, at 8 P.M. His subject will be "The Chemist in the Non Ferrous Metallurgical Refinery," and Prof. G. G. Henderson, president of the Institute of Chemistry, will take the chair. Tickets of admission are obtainable on application to the Registrar, Institute of Chemistry, 30 Russell Square, London, W.C 1 Frederick William Streatfeild was on the staff of the City and Guilds Technical College, Finsbury, from its foundation until his death in March 1918, as a teacher of applied chemistry. He won the esteem and affection of several generations of Finsbury students, who established a fund for the provision of an annual memorial lecture to mark their appreciation of his work and worth. Previous Streatfeild Memorial lecturers have been: Sir William Pope (1918), Prof. G. T. Morgan (1919), J H. Coste (1920), W. P. Dreaper (1921), Prof C. H Desch (1922), E. M. Hawkins (1923), Julian L. Baker (1924), and Francis H. Carr (1925). On the closing of Finsbury Technical College, the administration of the Fund and the arrangements of the lecture were entrusted to the Institute of Chemistry.

FARADAY House Testing Laboratories, Southampton Row, London, W.C.1, have issued a scale of fees for testing mechanical, electrical, and chemical materials, instruments, and machinery. Arrangements are also made for the loan of instruments, workshops, for investigations and reports, and for advice and assistance to inventors.

Two of the best signs of activity and vigour of the optical industry in Great Britain are the number and importance of the scientific papers which are published by optical firms. We have before us a list of fifteen or sixteen publications which have appeared in scientific and technical journals during the last two years from Messrs. Hilger's workshop. Of these, nine were papers read at the recent Optical Convention, two deal with the lens interferometer and its use, two with spectrum analysis and spectrographs, and one with a new measuring micrometer.

WE much regret the appearance of a misprint in Dr. K R. Ramanathan's letter in NATURE of September 4, p 337. Observations at Simla referred to near the end show that polarisation for the red reaches values so high as 87 per cent, and not 30 per cent as printed.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A lecturer in organic chemistry and an assistant lecturer in geography in the University of Birmingham—The Secretary (October 30) A lecturer in electrical engineering at the Chesterfield Technical College—The Director of Education, S. Mary's Gate, Derby (October 30) A lecturer in agricultural botany at Armstrong College, Newcastle-upon-Tyne—The Registrar (November 6) An assistant lecturer in botany in the University of Birmingham—The Secretary (November 6) A scientific officer for, primarily, research in connexion with electrical ignition appliances at the Royal Aircraft Establishment, South Farnborough—The Chief Superintendent, R A E, South Farnborough, Hants (November 10, quoting No. A. 81). A professor of zoology in the University of Birmingham—The Secretary (November 22). An engineer to take charge of the section of wood preservation of the Forest Products Research Laboratory at Princes Risborough—The Secretary, Dept of Scientific and Industrial Research, 16 Old Queen Street, S.W 1 (December 1). A reader in wireless telegraphy and high-frequency technology at the Indian Institute of Science, Bangalore—Dr. W H. Eccles, Institution of Electrical Engineers, Savoy Place, W C.2. A woman B.Sc., biology, physiology, and biochemistry, and preferably physics or mathematics, for work at the Wellcome Physiological Research Laboratories, Beckenham—The Director. An assistant agricultural botanist under the Linen Industry Research Association—The Secretary, Research Institute, Lambeg, Co. Antrim. A head of the physics department of Huddersfield Technical College—The Director of Education, Education Offices, Huddersfield.

Our Astronomical Column.

RECENT SUNSPOTS AND MAGNETIC STORM.—Although no unusually large spot has appeared as yet this month, the sun's disc has presented a striking feature, consisting of a procession of four large groups of spots in the northern hemisphere. Some of the spots were occasionally naked-eye objects to keen vision, but as they kept just on the limit of visibility they have not been included in the list of the largest spots given from time to time in these columns. Their approximate positions will be of interest to observers, however, and are tabulated as follows:

Group.	Central Meridian Passage.	Longitude.	Latitude	Area.
a	Oct 9·2	232	15° N	700
b	11·2	205	18 N	900
c	13·7	173	16 N	600
d	16·7	133	24 N	650

(The areas, corrected for foreshortening and expressed in millionths of sun's visible hemisphere, were measured on Oct 13.)

Group *d*, comprising a roughly circular spot with small companions, represents the return of the large September spot No. 10.

On Oct. 14, at 20^h, the commencement of a magnetic disturbance was recorded at Greenwich, which continued for about 12 hours, the greatest deflexion of the declination needle being about 0·5°. At 19^h on Oct 15 a recrudescence of the disturbance took place which rapidly developed into one of great magnitude, the declination traces showing extreme deflexions of more than 1°. Serious difficulties in telegraphic transmission were experienced at the same time, and a display of the aurora was reported from America. At the time of the commencement of the preliminary disturbance, the longitude of the sun's central meridian was 157°, and at the commencement of the great disturbance it was 145°. As will be seen from the above table, the present instance is an example of the considerable uncertainty in ascribing a relation between a particular sunspot and a magnetic storm, judging merely from the position and appearance of the spot. Spectroscopic observations may, of course, come to hand which will throw some light on the matter.

It may be added that the general activity of the sun is still increasing. Apart from the occurrence of spots and faculæ, this fact is shown by the prominences during the last three months. Mr Newbegin reports that, for the past three weeks, the average number per day he has observed spectroscopically at the sun's limb is 20.

UNUSUAL DISPLAY OF LARGE METEORS.—Mr W. F. Denning writes that during the three nights Oct. 9 to 11 four brilliant meteors were observed by himself or friends at Bristol, and that three recorded paths indicated a well-defined radiant in Corona at 230° + 33°.

On the evening of Oct. 9 at 20^h 30^m G.M.T. a bright meteor, equal to twice the apparent magnitude of Jupiter, was seen in Draco moving from 244° + 47° to 261° + 59°, motion rather swift. On the same evening at 22^h 20^m a fireball, three or four times the brightness of Venus, appeared in Auriga, falling approximately from Auriga to low in the N.W. It left a long vaporous trail which remained visible for ten minutes or more. Near the end of its flight it gave a great outburst of light which illuminated the sky and land. This brilliant object had a radiant at about 262° + 55° and was probably a fragment of Giacobini's comet of 1900. The comet has a radiant at 253° + 56° as computed by Rev. M. Davidson, and its orbit is nearest to the earth (distance $5\frac{1}{2}$ millions of miles) on Oct. 9.

On Oct. 10 at 20^h 20^m a slowish meteor equal in brightness to Venus traversed part of Cygnus, crossing the stars ϵ and ξ Cygni, the path being from 318° + 30° to 333° + 32°. It left a bright streak for several seconds and burst with a strong flash when between the two stars mentioned.

On Oct. 11 at 21^h 17^m a meteor as luminous as Jupiter appeared in Perseus, and shot from 53° + 43° to 53° + 23°.

It is an unusual circumstance to get a radiant from brilliant meteors alone. A singular abundance of fireballs has, however, diversified the present season since September 6. They have been directed from a number of different showers, though several have apparently had their origin in radiants near the N.E. and N.N.E. region of the horizon. Corona, as a radiant of meteors in October, is quite unknown, for that constellation is low in the N.W. in the evening hours and sets before 23^h at this time of the year.

COMETS.—The comet Giacobini-Zinner, discovered in 1900, and seen again on its second return in 1913, has been detected by Dr. Schwassmann at Bergedorf on Oct. 16, 17^h 50^m U.T., in R.A. 17^h 24^m 52^s, N. Decl. 2° 32′, magnitude 14·0. The indicated value of T, the perihelion passage, is Dec. 11·77, 1926, about four days later than Mr. Cripps's predicted date. His other elements are: ω 171° 44′ 8″, Ω 105° 56′ 35″, *i* 30° 43′ 4″, ϕ 45° 47′ 29″, log q 0·90726, equinox 1926·0.

EPHEMERIS FOR 0^h U.T., CORRECTED BY ABOVE OBSERVATION

	R.A.	Decl	log *r*.	log Δ
Oct. 24	17^h $15·1^m$	0° 35·1′ N	0·0836	0·1358
Nov. 1	18 9·9	1 38·5 S	0·0618	0·1212
,, 9	18 37·9	3 55·9	0·0415	0·1061
,, 17	19 8·6	6 15·3 S	0·0239	0·0908

This makes the sixth comet to pass perihelion in 1926, four being periodic and two parabolic.

Neujmin's Comet is expected to pass perihelion on January 2 next; however, if a doubtful object observed by Mr. Neujmin in 1920 was really his comet, the date will be 22 days later. The following ephemeris for 0^h is by Mr. B. F. Bawtree, on the earlier assumption:

	R.A.	N. Decl.
Oct 23	9^h $59·3^m$	18 34′
,, 31	10 23·3	15 48
Nov 8	10 47·3	12 45

As two revolutions have taken place since discovery, there is considerable uncertainty in the positions. The comet is likely to be faint.

Mr. J. Polak, of Saratov, had investigated the perturbations of Holmes's comet, discovered in 1892, and seen again in 1899 and 1906, but not since then. Dr. Zwiers calculated its perturbations up to 1906, but after his death no one continued the work. Mr. Polak shows that the Jupiter perturbations in 1908 were very large, increasing the period by 6 months, and diminishing the eccentricity from 0·412 to 0·379. This explains the failure to find the comet in 1913 and 1919. The return in the former year was a very favourable one, and an ephemeris is given in *Astr. Nach.* 5465. The general region is Aug. 4, R.A. 1^h 0^m, N. Decl. 20°; Oct. 3, R.A. 0^h 34^m; N. Decl. 30°. Plates of that region taken in 1913 should be examined for images of the comet.

The perturbations since 1908 have been small and the next perihelion passage will be near March 12, 1928. The comet may be seen (especially by southern observers) in the autumn of 1927. As this is one of the few comets discovered in England it is satisfactory to find that work on it is resumed.

Astr. Nach. 5466 contains an interesting study of the brightness of comet Tempel II in 1925. During the month of July it brightened up four magnitudes, from 10·5 to 6·5, log *r* changed from 0·14 to 0·12, and log Δ from 9·58 to 9·51. These changes are so small that it is clear that the brightening was mainly due to physical change in the comet. One may conjecture that at greater distances the sun's physical effect on the cometic envelopes is insignificant, but that it becomes important at a certain point (not apparently the same for all comets), and henceforth develops rapidly with approach to the sun. It is, however, difficult to frame laws that will cover all cases.

Research Items.

ESKIMO ENGRAVINGS ON WALRUS IVORY.—Three examples of Eskimo art from Alaska of a type rarely seen in Europe are described by M. L. Giraux in the *Journal de la Société des Américanistes de Paris*, N. Sér. T. 18. The objects in question are made of walrus ivory, measuring 31 cm., 33 cm., and 36 cm. in length respectively, and are engraved and painted or stained in colour with human and animal figures. Among the human figures is that of a male in European clothing. All the figures are realistic, but the animals in particular exhibit an intimate acquaintance on the part of the artist with their characteristic attitudes and habits. Although all the Eskimo of Alaska show considerable dexterity in carving wood, bone, ivory, and reindeer horn, the inhabitants of the coast from the Yukon delta to the lower Kuskokwin river are particularly noted for their artistic skill. The technical methods employed in dealing with the ivory of a walrus tooth in the days before the introduction of iron and steel implements, are of considerable interest, especially in view of the marked resemblance of the objects under consideration to palæolithic engravings. Four grooves were made in the tooth with a piece of quartz or other siliceous stone. When these had been made as deep as the form of the cutting edge of the stone implement allowed, the two pieces were flaked off either by simple pressure of the hand or by means of a wooden knife-blade-like implement, which was inserted in the groove. The central piece of ivory thus obtained was rubbed down to the required shape by a freshly broken stone. The perforation found in some of the objects was then made by a stone drill and sand, working in a slight depression previously made, and actuated by a cord or strap. The polishing was done either with a very fine-grained stone (soapstone) or by the hand used with very fine-grained sand. Lastly, another piece of ivory was employed to produce a high polish. The gravers were sharp pieces of stone, flint, quartz, schist, or soapstone, usually fixed in pieces of wood, each material requiring a special method in manufacturing the graving tool. The colours employed were black (plumbago and charcoal or gunpowder mixed with blood), red (oxide of iron or ochreous earth), yellow (ochreous earth), white (argillaceous clay), and green (oxide of copper). A dark reddish brown used for staining seal skin was obtained by macerating the inner bark of alder in urine for twenty-four hours.

AN ENDEMIC FLORA.—An unusual analysis of an endemic flora will be found by F. Lewis in the *Annals of the Royal Botanic Gardens, Peradeniya*, vol. 10, part 1. With the data given in Trimen's "Flora of Ceylon," and from his own observations as to altitude, the author has analysed the distribution of the large endemic flora in relation to its distribution at different altitudes. The result is that the greater number of endemics are to be found at the foot of the hills instead of at the highest altitudes, a conclusion which the author briefly discusses, assuming that in the more densely populated lower levels the struggle for existence is greater, and natural selection has thus operated more vigorously.

JAPANESE BOTANY.—The botanical output of Japan proceeds apace, and fortunately abstracts will be found of practically all publications in the *Japanese Journal of Botany*. A brief notice of some of the interesting papers is all that can be attempted here. Yoshiji Yoshii has published a very extensive study of the maturation of the seed of *Pharbitis Nil*. The process of maturation can be divided into a series of stages; the chemical changes, water content, etc., of the seeds were studied and also their capacity to germinate when tested at these different stages. (*Journ. of Faculty of Science, Tokyo*, Section III. vol. 1, Part i.). Isaburo Nagai publishes four papers upon mutations in *Oryza sativa* L. in the *Japanese Journal of Botany*, Vol. 3, No. 2; in the same journal Kametaro Oharo has a paper upon Japanese fossil conifer woods, which he has been studying at the palæobotanical institute at Berlin, and there are two cytological papers upon pollen development, that by Tetsu Sakamura and Isamu Stow, dealing with the experimental production of pollen grains with abnormal chromosome numbers in *Gagea lutea*. In the previous issue of the same journal, Ichiro Ohga has an interesting paper upon the structure of ancient but still viable fruits of the Indian Lotus. The author began these studies in Manchuria, and continued them at Tokyo and then at the Johns Hopkins University, at Baltimore. These old lotus fruits occurred in a peat bed in the Pulantien Basin, in South Manchuria, and are probably at least three or four hundred years old. The retention of viability for such a long time is probably due in large part to the approximate maintenance of the water and gas content in the tissues of the embryo, due to the structure of the fruit coats and their maintenance in the undisturbed condition of the peat bed. A very full account of the life history, fertilisation and cytology of the fungus *Plasmopara Halstedii*, is given by Prof. Makoto Nishimura in the *Journal of the College of Agriculture*, Hokkaido Imperial University, Sapporo, Vol. 17, Part I, with five plates of drawings which are well reproduced. Koki Masui has a paper upon the mycorhizal relation of the fungus *Cantharellus floccosus*, Schw. with the roots of *Abies firma* in the *Memoirs of the College of Science, Kyoto Imperial University*, vol. 2, No. 1, 1926. It seems clear that this fungus is definitely parasitic on the tree, in many cases killing branches of the root.

CORALS AND SEDIMENTS.—Problems of sedimentation and rock formation in tropical, coral-bearing regions constitute the subject-matter for research in vol. 23 of the papers from the Department of Marine Biology of the Carnegie Institution of Washington. M. N. Bramlette, in dealing with some marine bottom samples from Pago-Pago harbour, Samoa, describes the nature of present sedimentation processes in and around the harbour. Chemical and mechanical analyses of the samples are given and discussed and, in some cases, a detailed analysis of the organic constituents has been made. Borings from the reef were also examined and, on comparison with the bottom samples, shown to be relatively richer in magnesium carbonate. A study of reef-sand from the Bahamas by M. I. Goldman is concerned chiefly with the problem of dolomitisation. The chemical composition of the sand was determined directly and also by calculation from a count of the different constituents of known composition, mainly calcareous skeletons. The difference found is taken to represent a change in chemical composition, the results in the present case indicating a relative decrease in the amount of magnesium carbonate. The results are not considered conclusive, however, and suggestions are put forward for other methods of investigation. N. R. Smith, reporting on a bacteriological examination of 'Chalky Mud' and sea water from the Bahama Banks, classifies the bacteria found and describes an experiment to show that calcite is precipitated from sea water as a result of bacterial growth when food is supplied and when the supply of calcium in solution is maintained by the addition of calcium sulphate. He states also that calcite is formed from natural sea water by the strong ammonifying vibrios found in the mud, the only addition required being organic

nutritive matter. J. A. Cushman supplies a list of some recent Foraminifera from Porto Rico with notes on their distribution. An account of some late Miocene or early Pliocene mollusca and sharks' teeth from the Fiji and Tonga Islands by W. C. Mansfield, is accompanied by a useful annotated bibliography of the geology of the Fiji Island. T. W. Vaughan and J. E. Hoffmeister describe some Miocene corals from Trinidad, mostly new species.

Vortex Distribution behind an Aerofoil.—Lanchester, in his "Aerodynamics," vol. 1, indicated from general theoretical considerations that the flow in the wake of an advancing aerofoil of finite span should comprise a layer of vorticity immediately behind the trailing edge and two general circulatory motions of opposite directions of rotation, one at each tip. Broadly speaking, this prediction has stimulated investigations at Gottingen, in America, and at the National Physical Laboratory at Teddington, receiving ample verification. In Aeronautical Research Committee Report, R and M. No 951 (H.M. Stationery Office, 1s. net), Messrs. Fage and Simmons have subjected this theory to an accurate quantitative test and mapped out the changes which occur in the vortex distribution in the wake of an aerofoil. The result provides an experimental verification of the theoretical relation given by Lanchester, that the total strength of the vorticity leaving a semi-span of an aerofoil, as obtained by integration over the transverse plane close behind the aerofoil, is equal to the circulation around the median section, and that the distribution of vorticity is in close association with the distribution of lift along this span. At 13 chords behind the aerofoil the rolling up of the vortex band is practically complete and, within the limits of experimental error, at a distance of 0·57 chords in front of the aerofoil the flow is irrotational The theory thus verified has undoubtedly given a new impetus to aeronautical developments.

Cathode Sputtering.—In the *Ann. der. Phys.*, No 15, p 672, 1926, A. von Hippel describes a new method for the investigation of cathode sputtering, and he shows that sputtered metal particles consist, at any rate to a very large extent, of uncharged atoms. In his experiments a cadmium cathode was usually employed, but experiments were also carried out with silver and zinc cathodes. The particles emitted from the cathode collide with ions and electrons, and if they were atoms they would emit their resonance lines Thus, if the resonance lines of the cathode material are observed close to the plate, which lies outside the dark space, on which the sputtered particles are deposited, then we have evidence of the atomic nature of the particles. Clear proof of this was obtained, however, by comparing the intensity of the cadmium 3261 line with the intensity of the mercury 2537 line, when the vapour pressure of the mercury inside the sputtering chamber was known. From these observations the vapour pressure of the sputtered particles was calculated, and the value thus obtained agreed, within the limits of experimental error, with the value obtained from calculations based on a knowledge of the thickness of the sputtered film and on the assumption that the particles were atoms. Incidentally it was found that sputtered cadmium absorbed mercury vapour very rapidly.

Age-hardening of Aluminium Alloys.—It has been shown that the alloys of aluminium with manganese and silicon possess the property of age-hardening after quenching from a high temperature, and also that alloys of aluminium with copper show age-hardening to a lesser degree. In the first part of a paper by Kathleen E. Bingham read at the Liège meeting of the Institute of Metals on September 3, and entitled "The Constitution and Age-hardening of some Tenary and Quaternary Alloys of Aluminium containing Nickel," it is shown that the tenary alloys of aluminium with copper and nickel do not possess this property of age-hardening in any appreciable degree. This suggests that the addition of nickel to the alloys of aluminium with copper suppresses the phenomenon of age-hardening. This is explained by the constitution of the alloys, since the property of hardening depends on the precipitation of one or more of the constituents, and it has been shown that with 2 per cent. of nickel and about 6 per cent. of copper there is no $CuAl_2$ present, either at 500° C. or on cooling slowly to 200° C.; *i.e.* 2 per cent. of nickel increases the solubility of $CuAl_2$ in these alloys at both high and low temperatures. Finally, it is shown that the addition of 1 per cent. manganese to the alloys of aluminium with copper and nickel causes the precipitation of a large amount of magnesium silicide on cooling from 500° C. to 200° C., and also affects slightly the solubility of $CuAl_2$ and $NiAl_3$. In the series containing 4 per cent. copper, 2 per cent. nickel, and 1·5 per cent. magnesium, marked age-hardening takes place, and it is suggested that it is due chiefly to the precipitation of magnesium silicide, since it has been seen that any due to the $CuAl_2$ is very slight. One per cent magnesium is already in excess of the amount required for the formation of the compound Mg_2Si, as there is only about 0·13 per cent. silicon in the aluminium used.

Testing of Hardened Steel.—The testing of high carbon tool steel has hitherto been carried out almost entirely in the form of actual machine tests on tools made from the steel. Axel Lundgren, in a paper read at the Stockholm meeting of the Iron and Steel Institute describes a simpler test. The type of test adopted was a bend test, carried out in a machine specially designed for this work. Steels with more than 1 per cent. of carbon annealed in such a manner that the cementite was in a fine-grained form, show, after subsequent hardening and tempering, a higher bend strength and a higher resistance to impact than specimens which, before hardening, have been so annealed that coarse-grained cementite has developed. An annealing which yields a cementite in a spheroidised condition will, after hardening, yield a steel consistently tougher than will a treatment which resulted in the cementite appearing in the form of a network, and this despite the fact that the cementite has afterwards disappeared. Steel with the highest percentage of carbon, 1·3 per cent., shows, after hardening and tempering, a higher bend strength than do lower carbon steels. Annealing so as to produce a fine-grained cementite results, when the steel is hardened and tempered, in the production of a higher bend strength than is obtained from an unannealed steel. The steels quenched at too high a temperature and then tempered at a temperature of 150° to 200° C. show a reduced bending strength, particularly when the tempering temperature is lower. So far as hardness is concerned, the steel with 1·3 per cent. of carbon is slightly harder after heat treatment than the 0·9 per cent. carbon steel. The difference is not great, but with lower carbon contents a rapid decrease in hardness is recorded. Similarly, a slightly greater hardness has been observed in the specimens which were not annealed before hardening, than from those which had been annealed. The influence of the rate of cooling upon the ultimate bending stress, after tempering, has been tested with a tempering temperature of 300° C. In this connexion it has been found that in the case of very rapid cooling in benzene, a much lower bending strength was obtained, than in the case of a less rapid cooling in air.

International Congress of Psychology.

THE eighth International Congress of Psychology was held at Groningen on September 6-11. Nearly 250 psychologists attended. All appreciated the arrangements made by the national committee, consisting of Profs. Heymans (president), Wiersma, Roels (secretary), Brugmans (2nd secretary), Bouman, Buytendijk, Zwaardemaker, and the late Prof. van Wayenburg, and especially by the local reception committee. On the social side, concerts and other entertainments and excursions were arranged, and the reception by the Municipality of Groningen in the Stadspark was a brilliant function.

More than eighty papers were read Mention may be made of a symposium on intensity differences of sensation, which was opened by Dr. C. S. Myers (London), and Prof. Werner (Hamburg).

Dr. Myers showed how the study of spinal reflexes contributed to our knowledge of intensity differences. As the strength of a stimulus increases, not only does each muscle contract with greater vigour, but *additional* muscles are also brought into play. Moreover, when the stimulus becomes strong enough, the original reflex may be suddenly transformed into another. Thus if the skin between the pads and cushion of the dog's hind foot be pressed or stretched in the spinal animal, the leg is reflexly *extended*. But if the stimulus becomes sufficiently powerful, this reflex changes into one totally different, and the leg is reflexly *flexed*. Instead of inducing contact with the stimulus-object, the stimulus now evokes escape from it. Instead of being, as before, related to the act of walking, the reaction now has reference to that of flight. The sensation passes from one of touch to one of pain. Corresponding to such an abrupt change in type of reaction, the whole pattern of events in the spinal cord must be supposed to undergo an equally abrupt change. The evidence thus points to sensational intensity being in actual experience inevitably an impure variable. Just as with increase of a reflex stimulus the latter spreads to other reflexes, so, as we increase the strength of a tonal stimulus, new sensations inevitably arise, it alters not merely in intensity but also in timbre. It is indeed seldom, if ever, possible that a stimulus is so weak (or so pure) as not to affect mixed sensory elements.

Yet another feature of reflex action is that, when a stimulus provokes reflex flexion of a limb, it simultaneously inhibits antagonistic reflex extension of that limb. If proven applicable to the sensory field, this means that increase of one sensation is accompanied by decrease of an opposite sensation, *e.g.* warmth and coolness, red and green, blue and yellow, white and black. In the white-black pairs there is even a gradual transition from one pure pattern to the other pure pattern through every degree of admixture. It is therefore not surprising that so much discussion has been evoked as to whether changes in the white-black series of sensation are to be regarded as changes in quality or in intensity of sensation. The true answer is that both are inevitably simultaneously changed; or, as Dr Myers long ago pointed out (*Brit. Journ. of Psychology*, Oct. 1913), intensity differences may be regarded as neither qualitative nor quantitative, but strictly *sui generis, i.e.* intensive.

Prof. Spearman (London) communicated some results obtained from his well-known doctrine of noegenesis, according to which all cognitive operations can be analysed into a system of ultimate laws and processes. These processes were sharply divided into two kinds, the insightful and especially the *eductive* processes, and those which are merely *reproductive*. Thus in the study of individual differences of ability, all current tests of intelligence may be analysed into their eductive and reproductive constituents. The former has shown itself to involve one single general factor, and if anything is to be given the title of 'general intelligence,' it can be nothing else than this. As for the other or reproductive kind of process, this has proved to be wholly independent of the general factor. Thus eduction and not reproduction is the only trustworthy basis of a successful mental test. In the same way the operations involved in the so-called learning by trial and error admit of analysis into the two kinds of constituents, eductive and reproductive, and are far from being 'mechanical,' as generally supposed. The topic of error is another field illuminated by this doctrine. An exhaustive examination of every sort of belief that can unquestionably be regarded as erroneous—from the highest chains of reasoning down to the merest tricks of illusion—every one of them prove to rest primarily upon the law of retentivity and the process of reproduction. All purely noegenetic processes are incapable of error in the slightest degree.

The doctrine of noegenesis also enables the whole range of cognition to be surveyed, and such ancient 'faculties' as 'memory,' 'imagination,' 'attention,' and so forth, as well as such modern ones as 'the power of censorship' or 'keenness in breaking up a complex'—always resolve themselves without the smallest remainder in terms of ultimate psychological laws.

Demonstrations were given by Dr. Godefroy (Amsterdam) on the principles of electrotachography. His method of investigating the psychogalvanic reflex is essentially the transformation of the galvanogram obtained by the Veraguth-Waller method into its first differential or speed curve. Into the circuit which is led through the person tested, the primary coil of an alternating current transformer has been introduced, while the secondary is connected directly with the galvanometer. Thus whenever a change of intensity of the primary current takes place the galvanometer shows a deflexion, and the ordinates of the curve obtained are proportional to the rapidity of the changes in intensity of the primary current. There is also the advantage that the galvanometer returns to zero after each tachographic deflexion. There is, however, at present considerable difference of opinion as to the cause of the psychogalvanic reflex. Dr. Godefroy's experiments lead him to support the hypothesis of the emotional genesis of the phenomenon. Dr. Aveling (London), however, after elaborate experimentation, concludes that the psychogalvanic phenomenon is characteristically the consequent of conation.

Several interesting exhibits and demonstrations were given of various apparatus, designed by Prof. Zwaardemaker of Utrecht, which are well-known to psychologists and to nose and ear specialists, namely, various kinds of olfactometers, an apparatus for demonstrating the presence of odorous molecules in the air, etc.

Prof. Zwaardemaker has recently designed an apparatus for the reinforcement of speech on behalf of the deaf by audions and thermotelephones. The choice of the microphone, the valves and the transformers is a matter of knowledge of modern radio

telephony, but Zwaardemaker, not content with subjective listening at the thermotelephone, secured objective measurements by employing the Rayleigh principle of the acoustic mirror.

In conclusion, the records of the Congress point to activity along lines already initiated, and there was little evidence of the breaking of new ground. Thus the researches of the 'configurationists,' useful as they are, as a contrast to the work of some 'atomists,' could yet be assimilated by many outside their camp without sacrificing any psychological principles. LL. W. J.

Coal Blending.

THE gradual exhaustion of the more easily mined seams of coal in Great Britain, and other factors which are resulting in increasing costs of mining and transport, are combining to focus attention on the necessity of employing more scientific methods in the preparation and utilisation of coal. In coal carbonisation, the main object of the coke oven is to produce coke possessing the special properties required by the metallurgical industries; whereas the chief aim of the gas industry has been to manufacture gas of the quality required for domestic and industrial purposes, and coke as a secondary product has not received the attention it deserves. The possibility of producing coke with the qualities desirable in a solid smokeless fuel for domestic use is now being realised, and coke quality and structure are consequently being given much more consideration.

Many attempts have been made to manufacture a solid smokeless fuel, containing a comparatively high percentage of volatile matter, by the carbonisation of coal at low temperatures, and satisfactory products have been obtained, but the costs of the processes have been so great that it has not yet been possible to establish them on a sound commercial basis.

In high temperature carbonisation processes, largely on account of the low thermal conductivity of coal, the charge adjacent to the retort walls is fully carbonised before any marked decomposition of the coal in the centre of the charge has commenced. The exposure of the coke to high temperatures for long periods, and the small amount of volatile matter, both operate in the direction of rendering the product difficult to ignite. The work of numerous investigators, however, has led definitely to the conclusion that these are not the only factors which influence the quality of coke as regards relative ignitability, combustibility, and reactivity. Other factors of importance include the character of the coal carbonised, the state of division of the coal, the method, speed, and duration of heating and the temperature of carbonisation.

The character of the coal to be carbonised may be controlled by grinding and mixing coals of different coking properties with one another or with coke breeze or other substances, in predetermined proportions. The main effects of efficient blending are more rapid heat penetration of the charge and the production of a harder and more easily combustible coke. The method, speed, and duration of heating are largely determined by the design of carbonisation plant.

In a recent paper to the Iron and Steel Institute,[1] Mr. David Brownlie presents a useful survey of the subject of coal blending; that is, the mixing of coals with one another and with other carbonaceous materials, such as low temperature fuels, coke, pitch, etc., especially in connexion with carbonisation. A summary of the paper is not attempted in this article, since the paper, although extending to forty-two pages, is in itself a summary, and the titles of the sections alone occupy more than one page.

Some coking coals are so constituted that they do not require blending for the production of good high temperature coke, but the amount of coal of this type is limited. Scientific blending would render many more coals available for use in the carbonisation industries. It must be emphasised, however, that the blending of coals on a commercial scale requires close attention, as the correct blend for a particular process and temperature of carbonisation would not necessarily be suitable for other processes or temperatures. Other factors, in addition to the amounts of resinous material in the coals constituting a blend, must also be taken into account. For example, the investigations of the Joint Research Committee of the University of Leeds and the Institution of Gas Engineers have shown that the degree of fineness of the coal carbonised exerts important influences. Further, the work of C. B. Marson and J. W. Cobb has demonstrated that the character of the coke may be influenced considerably by the nature of the ash constituents. Iron oxide, calcium oxide, and sodium carbonate have marked beneficial effects, but certain other substances examined were apparently inert.

The application, on a commercial scale, of the results obtained in laboratory investigations of coal blending presents certain difficulties. In addition to the installation of grinding and mixing machinery, increased bunker capacity would be required. It would also be necessary to ensure that only small variations in the quality of coal from a particular colliery occurred in different consignments. The advantages obtained by blending must also compensate for the additional cost of the preparation of the blends, and in this connexion it must be pointed out that the depreciation of grinding machinery, when coke is one of the constituents of the blend, may be considerable. A. PARKER.

[1] Coal Blending: A General Review of Principles as Applied both to High and Low Temperature Carbonisation, by D. Brownlie. Iron and Steel Institute, June 1926.

Physical Phenomena and Molecular Orientation at Interfaces.

THE behaviour and properties of interfaces were discussed at a conference arranged by the Faraday Society on October 1. The subject is of fundamental importance in the science of colloids, and it is only by a better appreciation of the former that we can hope to unravel the peculiarities of such complex systems as are to be found in natural colloidal materials. The liquid-gas and liquid-liquid interfaces are more simple than those containing a solid surface, since liquids present equipotential surfaces. There is little doubt that the concept of a unimolecular layer of orientated molecules as constituting the surface layer of an insoluble oil on the surface of water is correct, and many investigations are being made on the conditions of formation and stability of these orientated, two-dimensional systems in their solid, liquid, vapour, and gaseous states of aggregation. All the usual three-dimensional phase phenomena, such as allotropy or the process of vaporisation, have been shown to have their two-dimensional prototypes. For soluble substances the surface composition can only be calculated by means of the Gibbs' equation, a

thermodynamic process which gives no information as to the dimensions or orientations of the surface phase. That within certain ranges of bulk concentrations, however, the Gibbs' layer is unimolecular, is made probable by experiments on sparingly soluble fatty acids and the analogy between the properties of the surfaces of solution and three-dimensional gases.

This simple idea, however, does not appear to be applicable to all types of binary mixtures; it is possible that in some solutions the Gibbs' layer is thicker than one molecule, but reasons for and against are founded as yet on but slender arguments. The kinetic interpretation of the lowering of the surface tension by two-dimensional liquids, vapours and gases does not, however, meet with universal acceptance, and we find the concept of a negative surface tension developed on the assumption of a molecular halo or wide zone of molecular attraction. This idea is based upon the view that a material spread upon the surface of water will cover but a definite area, and not expand indefinitely, as is assumed on the kinetic hypothesis, a problem clearly susceptible of experimental solution.

As is the case in solutions, the adsorption of ions at liquid interfaces is attended with the operation of electric forces resulting in an ordered distribution of the ions in the interfacial phase. The nature of this distribution is of great importance in an interpretation of the phenomena of electric endosmose and electric cataphoresis. Freundlich has shown quite definitely that the potential difference or electro-kinetic potential of which those phenomena are manifestations is in no way related to the total potential difference across the interface, the one considered by Nernst in his development of a mechanism of operation of electric cells. It is thus necessary to conceive an ionic distribution the total amount of which can be calculated by Gibbs' method, such as will give rise to those two well-defined potential differences. Whilst this problem still awaits a detailed solution, it appears clear that the old and well-known conception of Helmholtz of a condensed double layer, as well as the idea of a diffuse double layer developed by Gouy, must both be rejected in favour of some composite type combining the advantages of both.

Attempts have not been lacking to show that the free surface of a liquid presents an ordered arrangement. Whilst consideration of the mean life of a molecule on the surface of a liquid, as well as the dependence of the surface energy and the Eötvös constant on the molecular structure, show that some orientation does in fact exist, it is clear that the total surface energy of a liquid is not defined entirely by the nature and orientation of the surface layer of molecules.

The nature of the free surface of a solid and the phenomena attending adsorption are more complicated. Whilst unimolecular films are the rule rather than the exception on liquid surfaces, the building up of secondary films, *i.e.* multi-molecular in thickness, is quite frequent on solid surfaces, although the loss in free energy attending the formation of each molecular layer is greatest for the first layer. It is not, however, a simple matter to calculate the film thickness from the amount of material adsorbed, since the surface of a solid is by no means uniform in character, and breaks in the adsorption isotherm may indicate merely the covering up of a fresh portion of the surface possessing a different surface energy. The variation in surface texture, dependent upon the presence of different crystal facets and edges, as well as the presence of broken crystals, is accompanied by a variation in surface energy, the interrelationship for heteropolar materials having been investigated by Born and Lennard Jones. For metals, however, we are not yet in a position to make the necessary calculations. Whilst both catalytic activity and adsorptive powers are dependent on the nature of the surface, the almost specific nature of many of these processes shows that both surface energy and surface structure are necessary factors to be taken into consideration in dealing with these problems.

The Faraday Society is again to be congratulated in promoting a highly successful meeting, at which it was possible not only to listen to a number of distinguished foreign visitors, but also to obtain the point of view which has led different investigators in certain fields to diametrically opposed conclusions.

E. K. R.

The Wellcome Historical Medical Museum.

AFTER closure for nearly a year for reorganisation and enlargement, the Wellcome Historical Medical Museum, Wigmore Street, London, W.1, was reopened on October 14 by Sir Humphry Rolleston, in the unavoidable absence abroad of the founder, Mr. H. S. Wellcome. Sir Arthur Keith delivered a short address, and Sir Frederic Kenyon and Sir D'Arcy Power also spoke in proposing and seconding a vote of thanks to the previous speakers. A brief tour of the Museum discloses the great variety and interest of the collection, but does little more than whet the appetite for return visits on future occasions, when selected objects could be more fully studied.

The visitor first enters the Hall of Primitive Medicine, in which are displayed the paraphernalia of the medicine-man, including his masks and costumes; a reconstructed skull-hunter's hut from south-east New Guinea is here a prominent feature. In the same section are also arranged a large number of charms, amulets, and talismans used by both primitive and modern man. In the Anatomy Room the history of anatomy is illustrated by means of drawings, paintings, and sculpture: there is a fine collection of bone and ivory mannikins used in the teaching of anatomy in the sixteenth and seventeenth centuries. Proceeding through a short picture gallery, the visitor enters the Hall of Statuary, containing statues and casts of the deities associated with medicine in ancient times. In addition, the hall and its gallery contain collections of surgical, scientific, and dental instruments, arranged to illustrate the evolution of each particular instrument. Special mention may be made of the collection of microscopes and that illustrating the development of the modern spectacles.

One of the most interesting collections in the Museum is found at the end of the Portrait Gallery, where the Jenner relics are arranged: there one can see the original manuscripts in which Jenner's views on vaccination are set forth, and also the instruments used by him in his work; a homely touch is provided by the presence of his favourite arm-chair. Passing from the Alchemy Room, a flight of stairs is descended to the ground floor; the main hall contains a varied collection of pictures and material illustrating the War in both its naval and military aspects. At the far end is found the Lister Collection, including a portion of the actual Lister Ward from the Old Infirmary in Glasgow, in which he developed the practice of antisepsis in surgery. Passing sections illustrating methods of torture, the plague, and a lying-in room of the sixteenth century, the visitor enters a large hall devoted to the history of pharmacy. Here will be found a sixteenth-century alchemist's laboratory, a London chemist's shop of the eighteenth

century, a barber-surgeon's shop, and Chinese and Turkish drug stores.

Two impressions remained with us when we left: the great boon to mankind the discovery of anæsthetics has been, after inspection of the pictures illustrating surgical operations in pre-anæsthetic days, and the persistence of a belief in charms through many centuries up to the present day, in spite of the increase in scientific knowledge.

In the course of his address at the reopening of the Museum, Sir Arthur Keith said that a museum should fulfil two functions: it should serve the needs of students, fostering research, and at the same time it has a duty to the public, that of direct education. One way to write a history is by the study of the writings of others which have been preserved to us; the other is by the examination of the objects of man's handiwork, many of which have been retrieved through excavations, when their situation throws light on the periods at which they were in use: thus the existence of stone, bronze, and iron ages was discovered by this means. History, then, can be written on the shelves of a museum. But a history of medicine is the most difficult of all to write, since the use of a primitive medicine-man's emblems of his art is only really understood when we have a knowledge of his beliefs. On these he bases a theory of medicine, which guides him in the practice thereof; in general, the spirit is the real person and illness is due to the attack of baneful spirits, so that his practice is directed to the driving out of these immaterial beings.

A museum can only fulfil its main function of encouraging research if it is itself a centre of research. It can be seen when a museum is successfully fulfilling this function, by the appearance of members of its staff at scientific meetings, by the publications issuing from it, and by the number of students who make use of it.

In the education of the public the curator of a museum should be an able 'case-dresser.' The average man has little time or inclination for a detailed study of the exhibits, so that he requires his history to be put before him in a few well-chosen and salient objects Since the best elementary treatises are usually written by the most learned men, it is probable also that the educational function of a museum will be directed equally well with research by the most learned of our curators.

Money is an essential item in the work of a museum, so that the thanks of all are due to those who contribute service to mankind by founding and maintaining it as a centre of research and education.

University and Educational Intelligence.

CAMBRIDGE.—Mr. L. H. Thomas, Isaac Newton student and Smith's prizeman, has been elected to a fellowship at Trinity College. Mr. H. M. Robertson (Leeds) has been elected to a research studentship in economics at Emmanuel College, and Mr. A. H Wilson to an honorary research studentship in mathematics. The Hon. Bertrand Russell, Trinity College, will lecture on "The Analysis of Matter" at Trinity College, giving the Tarner lectures on the philosophy of the sciences.

Dr. A. C. Haddon, Christ's College, has been appointed honorary keeper of the New Guinea collections in the Museum of Archæology and Ethnology. J. A. Ratcliffe, Sidney Sussex College, has been elected to the Stokes Studentship for research in physics at Pembroke College.

The Commissioners have offered to the University for discussion new statutes modifying the statutes with regard to various trust emoluments to bring them into line with the new statutes. They propose a new statute, throwing open scholarships and prizes to women on the same terms as to men, leaving the University power to exclude women from any one or more of the emoluments for which they have not hitherto been eligible.

EDINBURGH.—Prof. E. Shearer, in his inaugural address as professor of agriculture, spoke on "Agricultural Education and the Community." He stated that our system of agricultural education is based on lines which are sound and well adapted to the general circumstances of the country. Useful work has been accomplished in the past, but present efficiency and future progress are unduly handicapped by meagre financial provision. Nothing is more certain than that the agricultural future, amidst ever-increasing competition, will lie with those nations that take the fullest advantage of scientific knowledge.

ST. ANDREWS.—The Court has appointed Dr. J. D. McBeath Ross to the lectureship in physical chemistry in University College, Dundee, vacant by the resignation of Dr. O. R. Howell, appointed to a post in Manchester Muncipal Technical College. Mr. J. M. Hay has been appointed to the lectureship in mechanical engineering and machine design in University College, Dundee, vacant by the resignation of Dr. W. J. Walker, appointed to the chair of mechanical engineering in the University of Witwatersrand, Johannesburg, South Africa.

ON Wednesday, October 20, H.R.H. the Prince of Wales opened a new women's hostel, a teaching dairy, and farm buildings at the Cheshire School of Agriculture, Reaseheath. These buildings complete the equipment of the institution, and render possible centralisation of a comprehensive scheme of agricultural education, hitherto somewhat scattered. The school lies in the centre of a small estate, the mansion on which serves as a residential hostel for forty men students and as the headquarters of a scientific staff. There are two farms, the larger, 210 acres in area, being used for teaching and commercial ends, and the smaller, which extends to 50 acres, being devoted to experimental work A 6-acre holding within the estate has been equipped as a poultry department, and the original gardens have been extended and stocked to illustrate various phases of horticultural work. An extensive range of stabling has been adapted as chemical, botanical, and bacteriological laboratories. The dairy, now added to the buildings, has been built primarily for teaching purposes; it has been equipped with the ordinary apparatus of a good cheese-making farm, and also with sufficient examples of dairy machinery to demonstrate the possibilities of mechanical devices. The Women's Hostel is a pleasing structure which perpetuates the half-timbered style so characteristic of the county. There is accommodation for thirty students. A county institution, the school aims primarily at instruction suited to the needs of farmers' sons and daughters, and others taking up rural pursuits for a livelihood. Separate courses, all of three to six months' duration, are provided in agriculture, dairying, horticulture, and poultry-keeping. Though the end in view is severely practical, instruction is largely on the traditional lines of scientific institutions; for it is characteristic of the Cheshire farmer that he wants his son to be taught "something he cannot learn at home," rather than to be trained in manual operations. The school also maintains an extensive advisory service throughout the county.

Contemporary Birthdays.

October 24, 1854. Right Hon. Sir Horace C. Plunkett, K.C.V.O., F.R.S.

October 26, 1874. Prof. T. M. Lowry, C.B.E., F.R.S.

October 27, 1856. Prof. Ernest William Hobson, F.R.S.

October 28, 1868. Mr. Frederick William Lanchester, F.R.S.

October 29, 1868. Mr. Charles P. Eugène Schneider.

Sir HORACE PLUNKETT, sometime an Irish administrator, was born in Gloucestershire. He was educated at Eton and University College, Oxford. Soon after attaining his majority he worked at the development of a ranch in Montana, acquainting himself with all the details of American agricultural methods. Afterwards, Irish agriculture and industry engaged his whole-hearted energies for many years, with much practical issue. Chairman of the (then) Sub-Section of Agriculture at the British Association's Dublin meeting in 1908, Sir Horace gave a highly informative address, worthy of reference to-day, on "Science and the Problem of Rural Life."

Prof. LOWRY was born at Low Moor, Yorkshire. Educated at Kingswood School, Bath, he entered later the Central Technical College of the City and Guilds Institute, South Kensington. Here for seventeen years, from 1896, he held an assistantship to Prof. H. E. Armstrong, F.R.S. From 1912 until 1916 he was lecturer in chemistry at Guy's Hospital Medical School. In 1920 Prof. Lowry was appointed to the chair of physical chemistry in the University of Cambridge. Bakerian lecturer of the Royal Society in 1921 (in collaboration with Dr. P. C. Austin), he dealt with "Optical Rotatory Dispersion." On the same subject he discoursed in December 1925, before the Société de Chémie Physique, Paris, in exemplification of Biot's researches. Prof. Lowry is the author of two useful works, "Historical Introduction to Chemistry" (1915) and "Inorganic Chemistry" (1922).

Prof. HOBSON, Sadleiran professor of pure mathematics in the University of Cambridge, was born at Derby. Entering Christ's College, Cambridge, he graduated senior wrangler. The Royal Society awarded him a Royal medal in 1907 in respect of the fundamental character of his contributions to mathematics and mathematical physics, particularly with reference to the history and development of mathematics.

Mr. F. W. LANCHESTER, whose pioneer work and researches in aeronautics were recognised last year by the Royal Aeronautical Society in the award of its gold medal, and by his election as an honorary fellow, was educated privately and at the Royal College of Science, South Kensington. Early in his career he was technical adviser to the Birmingham Small Arms Company, and to the Daimler Company. From 1909 until 1920 he was a valued member of the Advisory Committee for Aeronautics.

Mr. C. P. EUGÈNE SCHNEIDER, ironmaster and metallurgist, owner, in family succession, of the famous Creusot Works in France, was nominated in 1917 president of the Iron and Steel Institute, and he held office for a year. It was a departure in procedure cordially and unanimously received. Distinguished specially in metallurgical research and practice, Mr. Schneider is also prominent as a scientific industrialist. In 1920–21 the Iron and Steel Institute published papers of his in its *Journal* on "An Investigation of various Forging Operations carried out under Hydraulic Presses."

Societies and Academies.

LONDON.

Society of Public Analysts, October 6.—A. Chaston **Chapman**: On the presence of compounds of arsenic in marine crustaceans and shellfish. Marine crustaceans and shellfish have been found to contain from 10 to 174 parts of arsenic (as As_2O_3) per million of the wet edible portions. Native oysters contained from 5 to 10 parts, and Portuguese oysters from 33 to 70 parts per million. In fresh-water fish, shellfish and crustaceans, the amounts of arsenic ranged from only about 0·4 to 1·5 parts per million. The arsenic in the marine animals is therefore derived from the sea water. Potted and canned crustacea and shellfish contained from 0·5 to 85 parts of arsenic per million. The arsenic in the urine of two experimental subjects was raised from the normal figure of about 1/200 grain per gallon to ½ grain in one case, and ¼ grain in the other, after a meal of lobster.—A. Chaston **Chapman** and H. **Linden**: On the presence of lead and other metallic impurities in marine crustaceans and shellfish. The following amounts of copper (parts per million of the dried edible portion) were found: lobster, 167; crab, 130; and whelks, 115. The amounts of lead ranged from 5 (whelk) to 25·6 (lobster). Native oysters contained from 12 to 400 parts and Portuguese oysters 10 to 307 parts of lead per million. Like the arsenic, these metallic impurities are probably derived from the sea water.—A. R. **Tankard** and D. J. T. **Bagnall**: The examination of fish for formaldehyde. Various kinds of fish gave a positive reaction in Schryvor's phenylhydrazine test, indicating the presence of 1 to 2 parts per million of formaldehyde. Since, however, trimethylamine (a common constituent of fish) can be readily oxidised to formaldehyde, a positive reaction does not necessarily indicate the presence of added formaldehyde. The reaction tends to be less marked when putrefaction of the fish has set in.—Karl **Sandved**: The potentiometric titration of tin with potassium bromate. The best results (error 0·5 per cent.) were obtained by oxidation of the stannous tin with antimony chloride or ferric chloride, and potentiometric titration of the reduction compound with potassium bromate. A method of determining tin in the presence of antimony has been devised, and the potentiometric titration of ferrous iron has been closely studied.—R. R. T. **Young**: The determination of nicotine in tobacco. Kellor's, Kissling's, and other methods have been critically examined. Accurate results are obtained by extracting the tobacco with a mixture of petroleum spirit, ether, and aqueous potash, shaking the ethereal extract with dilute (1 : 1) alcohol containing cochineal, adding excess of hydrochloric acid to the separated aqueous layer, and titrating with standard sodium hydroxide. Ammonia is best determined by distillation after precipitation of the nicotine with iodine, but little ammonia, if any, was present in the tobaccos examined.

PARIS.

Academy of Sciences, September 6.—Alfred **Rosenblatt**: The plane irrotational movements of incompressible viscous fluids.—H. **Pélabon**: Rectifying contacts. A detector consists essentially of the system metal-dielectric-metal. The thickness of the dielectric must be as small as possible and remain constant. Various practical means of satisfying these conditions are suggested.

September 13.—H. **Deslandres**: Remarks on the law of distribution in time of magnetic storms. The theory of corpuscular radiation appears to be

able to explain the greater part of solar phenomena.—Valère **Glivenko**: Surfaces of finite area.—Julius **Wolff**: A generalisation of a theorem of Schwartz.—**Gossot** and **Liouville**: The principles of interior ballistics.—V. N. **Ipatief** and B. A. **Mouromtsef**: The reduction of chromic combinations by hydrogen under pressure and at high temperatures.—F. **Taradoire**: The rapid oxidation of drying oils and antioxygens. With the exception of the nitroso derivatives of diphenylamine, none of the other organic antioxygen substances employed were sufficiently active to prevent the spontaneous inflammation caused by the oxidation of drying oils on cotton wool.—**Raymond-Hamet**: A supposed sympathicotropism of Uzara.—Methodi **Popoff**, Minco **Dobreff**, and George **Paspaleff**: The development of the eggs of the sea-urchin (*Strongylocentrotus lividus*) under the action of extracts of the pollen of the oak and of calla.

September 20.—Th. **Got**: A remarkable class of ruled surfaces.—A. **Myller**: Normal curvature and geodesic torsion.—George D. **Birkhoff**: The signification of the canonical equations of dynamics.—André **Meyer**: The catalytic rôle of mercury in the sulphonation of anthraquinone. To explain the catalytic influence of mercury on this sulphonation, Martinet and Roux have formulated an ingenious hypothesis. One deduction from this is that α-anthraquinone sulphonic acid should be transposed into the β-acid by simple heating with concentrated sulphuric acid. This the author is unable to confirm, the α-acid remaining unchanged under these conditions.—E. **Kohn-Abrest** and S. **Kawakibi**: Nitrates in animal and vegetable tissues. Details of a modification of Lunge's method of determining nitrates suitable for organic material.

SYDNEY.

Royal Society of New South Wales, September 1.—F. W. **Booker**: The internal structures of the Pentamerinae of N.S. Wales. Brachiopod material was examined by means of serial thin sections, from 1 to 1.5 mm. apart. A new sub-genus, Barrandina (Synonym *Pentamerus linguifera*, var. *Wilkinsoni*, Eth. Fils 1892), containing two new species, *B. Wilkinsoni* and *B. Minor*, is described. A structure new to science is noted in the cruralium of these two species. It is also present in *Sieberella galeata*, Dalman, and *Sieberella glabra*, Mitchell, but not in *Pentamerella* (*Barrandella*) *Molongensis*, Mitchell.—M. B. **Welch**: The wood structure of certain eucalypts belonging chiefly to the ash group. The woods of seven species of eucalyptus are described in detail. In common with other members of the genus, the woods are practically diffuse-porous, though growth rings are more prominent in certain of these species than in most. The vessels possess simple end perforation. Transition forms occur between the fibre-tracheids, making up the bulk of the woody tissue, and the typical tracheids. Wood parenchyma is usually not abundant and is chiefly vasicentric.

transplanting our laws, our customs, our institutions, our processes, among alien peoples and on alien soil, we should take heed lest we destroy much that is intrinsically valuable. We cannot legislate for every section of humanity as if it were cast in the same mould.

There are tremendous responsibilities implied in our trusteeship of the African native. Our duty to him and to the world does not end by making him a more efficient instrument for the development of the natural resources of his country. We have to safeguard him against the evils arising from a catastrophically sudden contact with our so-called modern civilisation. Our aim should not be to evolve Europeanised Africans, but to enable Africans to build up their own civilisation based upon all that is best in their culture and traditions.

The task confronting our administrators demands much patience, much tact, and a ripe understanding based upon knowledge born of intensive study of the peoples. We cannot afford to send out our administrators like "little children stumbling in the dark." They must be equipped for their task lest they destroy faster than they build. There is now a wealth of accumulated experience and knowledge at our command in our schools of anthropology. It is this which Mr. Ormsby-Gore wishes to enlist in the service of the British administration in tropical Africa.

"If we are to succeed in our duties towards these peoples as rulers or as missionaries, or as instruments for their advance or civilisation, we must study them objectively and base our policy on real understanding acquired not only from personal contact, but from scientific study of their mental and moral characteristics, of native law and customs, of native history, language and traditions. Native methods of agriculture, native arts and crafts, should be examined scientifically before any attempt is made to supersede what we find existing."

The above quotation is a prelude to a delightful chapter on the indigenous population. The rest of the report is dull in comparison. In the small compass of twelve pages are summarised the results of much reading and still more careful observation. In them is to be found more information most attractively presented of the West African natives, their traditional forms of government, their languages, their forms of religion, their special characteristics, than it is usual to find in several volumes. It is almost Wellsian in style. With zest the author repeats the description by a Mohammedan ruler in Northern Nigeria of an English court of law as a place where "two professional liars appear to prevent the judge from ascertaining the truth." If this is the usual conception held of our legal system by Mohammedans, it is obvious that any attempt to supersede theirs, where judicial and executive functions are combined, would lead to considerable friction.

While the East African tribes have so far no aptitude for trading, and consequently are at the mercy of Indian, Arab, and Syrian middlemen, the West Africans have in their midst a negro tribe, the Hausas, who carry on itinerant trading and have created trading centres throughout Nigeria and the Gold Coast. The Yorubas, another negro tribe, have solved the problem of town-dwelling in a way which should commend itself to our own city-dwellers. They are both farmers and townsmen. They live in great towns—Ibadan contains 250,000 people—and go out daily to cultivate their holdings, some so far as ten to twelve miles from the city. None would interfere with his neighbour's crops. They are as sacrosanct as the fruit of the apple trees planted by German municipalities along their main roads.

Just as in East Africa, in the mountain fastnesses, there are remnants of tribes like the Wachagga and the Bagishu scattered among the Bantu and the Nilotic races, so in West Africa there are remnants of the Bauchi tribe, a primitive pagan people - still, it is alleged, addicted to cannibalism—scattered among the virile and intelligent Moslem tribes of Northern Nigeria. The Bauchi have protected themselves against attack by building heavy stockades hedged with the poisonous euphorbia shrub and cactus, and the use of poisoned arrows. They live in isolated communities, each of which has its own dialect, and are not yet accustomed to wearing clothes. Of the Ashantis we are told that they are organised in a quasi-feudal system, and even their land system is strikingly parallel to that which obtained in Britain in medieval times. The king himself, the Omanhene, has not only a council of barons to advise him, and if they consider necessary, to dethrone him, but also his position is rendered more delicate by a council of women headed by the Queen-Mother, who, being elected to the office, exercises parental authority without necessarily having had the responsibility of giving birth to the king. She is almost invariably a political power to be reckoned with.

The existence of an English-speaking African population raises special problems both in their relations with government and with the vast mass of their fellow Africans in the interior. They have sprung up through long contact with European traders on the coast, and by the creation of settlements for freed slaves from the Americas. Unlike the French, who encourage it, we definitely dislike the assimilation of our culture, our outlook, and our social habits by people of a different race; the nearer they approximate to us in these respects the wider becomes the gulf between them and us. Mr. Ormsby-Gore states the problem, but he gives

no indication of a definite policy to be pursued, contenting himself with saying that the relations between the races must be based on mutual respect and understanding. It would be well if we faced the fact that the natives are rapidly becoming suspicious of the motives underlying the social exclusiveness of the English-speaking whites. It is notorious that many of the natives in Northern Rhodesia are forsaking British territory for work in the Belgian Congo, preferring the absence of racial discrimination among the Latin whites to the comparative freedom they enjoy under British rule. We cannot afford to be content with the expression of pious sentiments regarding mutual respect and understanding. We must have a definite policy, one that is intelligible and does not affront the intelligence of the better educated natives, who are capable of exercising considerable sway over their fellow-tribesmen: otherwise we shall create an ever-widening gulf between ourselves and the black races which can never be bridged.

British policy with regard to the administration of the native races has its parallel in the policy of the average captain of industry in a European industrialised state towards the workers in industry. Every material inducement is offered to enable the workers to produce more and to produce better in order that they may live fuller, more contented lives, yet one thing is lacking: neither rulers abroad nor rulers in industry at home are prepared to share the control which they monopolise; and in denying the peoples concerned a progressive share in the control of the machinery of government or of industry, they are wounding their self-esteem and progressively widening the breach between races and between classes.

So far in Africa, Great Britain has not determined to share the highest authority with members of the subject races. We are prepared to delegate authority; we are perpared to permit and even to bolster up a system of indirect rule under our supreme authority; we are not prepared to relinquish control for guidance. Whatever benefits we may have bestowed upon the Africans, therefore, will be regarded by them as being actuated by no higher motive than self-interest or as more subtle means devised for their exploitation. Every new road, every new railway, every new plant-product introduced, every new process, however necessary they may be if the potential resources of these vast territories are to be developed, increases the complexity of the African's life and sounds the death-knell of many of his institutions, habits, and customs. His needs increase and he has to work harder than ever. The transitory delight in the new gives way rapidly to an infinite regret for the loss of the old. Discontent is the parent of suspicion, and the suspicion can only be allayed by fitting him for the assumption of full responsibility.

Education is the only means by which the natives can be fitted to assume responsibility and adjust themselves deliberately to their special environment, and to adjust the environment itself to the changing conditions brought about by impact with the modern world. Mr. Ormsby-Gore has an abiding faith in the efficacy of education as an instrument of progress. He realises that in West Africa at least there is no possibility of creating an English colony. The personnel of the technical services, therefore, must be largely in the hands of the natives themselves, who look to the Europeans for guidance only in the initial stages of development. The chief needs of the country are education services which must supply well-trained natives for medical, sanitary, veterinary, agricultural, and other technical services. They will also have to meet the growing demand for native administrators. The basis of all education must be the primary school system, and it will be the greatest mistake to limit the provision of education to the favoured few. Mr. Ormsby-Gore is probably right in condemning a large number of the small bush schools which flourish throughout the territories, but it would seem to be a mistaken policy to close down any type of school catering for the native communities and selected by themselves for the satisfaction of their appetite for education, before the governments are in a position to satisfy the needs of the natives by the adequate provision of better schools. Our motives in suppressing the one without creating another to take its place would not be understood.

Mr. Ormsby-Gore's picture of the standard of teaching in the schools in West Africa makes somewhat depressing reading, and is certainly a reflection upon the capacity of the administration, the directors of education, and the missionaries. Where any system exists, education has been subordinated to the task of cramming African children for the Oxford and Cambridge junior and senior local examinations and the University of Durham pass degree. The majority of text-books in use in the various schools he considers to be unsuitable. Some of the elementary English reading books in use have been long obsolete in Great Britain. In respect of text-books and readers the schools in West Africa under British administration fall far short of those in use in the neighbouring French colony. Children had a parrot-like knowledge of the names of places in England, but no knowledge at all of the geography of West Africa. Many of the books used dealt with words and objects entirely outside the experience of the African children.

It is evident from the description of what purports to be an education system in West Africa, that education has been entrusted to people without any conception of

the true purpose of education or any ideas of modern educational methods. Much is hoped for from the newly created Prince of Wales College at Achimota in the Gold Coast Colony, but it is evident that profound changes will have to be made in the personnel of the advisory committees on education and the education staffs themselves if any effective progress is to be made. What is needed are directors of education and staffs who are professionally trained to be alive to the potentialities of education, to the paramount need for elasticity in the treatment of educational problems, to the importance of psychology as a factor in educational training, and to the need for continuous experiment and research in educational method. With ignorance at the helm, education degenerates into mere instruction, its aim is confined to fitting persons for predetermined tasks, and the wider aim is unfulfilled of fitting them to live fully and to accept the responsibilities of citizenship, the basis of which is ungrudging service to the community. Mr. Ormsby-Gore is disappointingly silent on this aspect of education.

Cotton and Food.

The Cotton-Growing Countries, Present and Potential: Production, Trade, Consumption. International Institute of Agriculture, Rome. Pp. xxxvi + 317. (London: P. S. King and Son, Ltd., 1926.) 12s. 6d. net.

STUDENTS of the cotton industry were placed under a lasting obligation to the author of "The World's Cotton Crops" when it was published in 1915, and a grasp of the subject thus became available to any reader. The details of cotton-growing interests collected in that book gave internal evidence of the labour required to make an effective compilation by single handed effort; the form of the book gave a reality and unity to the subject which a bald compilation must lack. It was too much to expect that Prof. Todd would be able to keep his book up-to-date, so that the action of the International Institute of Agriculture in producing the memoir now before us is doubly welcome, both as an authoritative statement of facts and as a supplementary volume to be shelved for reference beside "The World's Cotton Crops."

The present memoir amplifies an earlier publication on the same subject which the Institute issued in 1922. As its title indicates, the fact of a small production does not exclude a country from its pages, so that unexpected information can be derived from them; several acres of cotton grown successfully near Budapest in 1924 may be cited. It is not the function of such a compilation to balance critically the information derived from one country against that from another; this must be left to those who use the facts provided, in which they are assisted by a useful foreword. Such users will be well advised to bear this limitation of function in mind, for in many countries the full potentiality can never be made commercially effective, on account of such restrictions as are imposed by unevenly distributed rainfall, by the area available for irrigation, or by the irrigation available for the area.

The information given for eighty-one geographical localities, including the United States and Liberia, Egypt and Fiji, India and Barbados, is arranged to show so far as practicable the authorities quoted, data of area and crop, local geography and chronology of the crop, botanical and entomological information, together with merchanting particulars, including local manufactures.

Returning from the details which are the chief constituent of this volume, we may with advantage look more carefully at the interesting foreword. Amongst other things to which it directs attention is the stimulus given to cotton growing of late years by the high prices which resulted from short crops in the United States; this stimulus is very evident in some of the tables, where new countries continually appear from 1922 to 1925. It also directs attention to the probability of a continued fall in price from those stimulating levels, and to the consequent repetition of that vicious circling movement so familiar in cotton supply and demand. The foreword leaves the topic at this stage, for it is by such presentation and discussion of facts as this memoir provides that the radius of the vicious circle may be contracted. It is, nevertheless, quite possible that the ostensible circle is in reality part of a spiral, and that the whole cotton industry is entering upon a transition phase, from which it will emerge as a smaller and more highly specialised producer of high quality goods. The years during which short-time working has lately been practised may not be ephemeral, and the fact of such prolonged short time may not be a mere incidental consequence of post-War disturbances; it may be part of a coming shrinkage. While the significance of the artificial fibres as a cause which has begun to contribute to such shrinkage may be open to discussion, there can be little question that the supply of cotton will very soon be liable to direct competition through the rivalry of food crops.

The world's food demands were brought to the notice of the public by Sir Daniel Hall's recent address at the British Association, and there is an admitted probability that these demands will equate to the available known resources within a few generations; the situation will rectify itself, of course, by moving

in the same vicious circle of demand and supply as obtains with cotton, but at the cost of some inconvenience to the world, unless it is anticipated. Such anticipation is not merely a problem for the dim and distant future; indeed, Prof. E. M. East has ventured to date the impact to happen within the life of potential centenarians already born. But long before this date is reached there will be a shouldering-out movement, wherein the textile plant will have to get off the arable earth, unless it can show itself to be irreplaceable by synthetic or forest products.

Another phenomenon which may perhaps be symptomatic of the same process in the making is also mentioned in the foreword. The design of the cord tyre for motor-cars gave the durability of the best cotton an opportunity to assert itself, which the chances of accidental damage had obscured in the old fabric tyre; the tyre-maker's demand for Sakel cotton, still more for Sea Island, outran the supply available at a competitive price, and many tyres are now made to wear well enough with lower quality cotton. But those who combine some knowledge of cotton with an interest in the autocar will be well aware that one firm which persisted in using Sakel won itself enviable reputation. Again the solution seems to lie in specialisation towards producing more good cotton, even if less of ordinary cotton.

We notice that the foreword makes one frank statement of ignorance which it is refreshing to meet. "Quality, in cotton, is a very vague term, and cannot be conveniently or tersely expressed, except in terms of the market price." Though this statement may appear surprising, it is quite true, and the absence of any analytical comprehension of 'quality' has been such a drag on the possible usefulness of botanists and plant breeders to the industry as must have been experienced to be appreciated. The late Mr. J. W. McConnel realised this, and initiated research work on the subject some twelve years ago; a book which summarises our broad conclusions is now in course of preparation, while the fuller details are being patiently dissected out in various textile research institutions. It may be hoped, therefore, that when the next issue of this memoir appears, the editor will be in a position to excise the statement we have quoted, and to extend his useful analysis of the general position accordingly.

The text is commendably free from misprints ("*Neocosmospera vas infecta*" is noted on p. 11), which carries the presumption that the tabulated data are equally correct. Thus, for reasons already given, and for its citation of authorities, this volume should be within reach of all who are interested in cotton supplies, whether industrially or scientifically.

W. LAWRENCE BALLS.

Modern Aspects of Evolution.

Nomogenesis: or Evolution determined by Law. By Prof. Leo S. Berg. Translated from the Russian by J. N. Rostovtsow. Pp. xviii + 477. (London: Constable and Co., Ltd., 1926.) 28*s.* net.

THIS volume represents the mature thought of an accomplished ichthyologist and traveller who speaks from the point of view of a naturalist and field observer and marshals, in the first nine chapters, all the difficulties that have arisen through field observation in the original concept of Darwinism. The title "Nomogenesis" signifies "evolution determined by law" rather than by selection from the accidents of variation. In the opinion of the author and in the language of Prof. D'Arcy Thompson, who writes the introduction, "No place is left for Chance in the manifestation of new characters; the course of evolution is fixed and determined. The same laws are at work in the growth of the individual as operated with like results in former generations; and what we call 'recapitulation' means nothing more."

In the work before us, all the arguments against selection are cited from the works of a list of authors which fairly cover the whole field of literature from Darwin to the present time. A very fair statement is made of the arguments of prominent selectionists, like Poulton and Plate, of the new direction of the selection hypothesis in the work of mutationists, as well as of comparable results reached by palæontologists such as Abel, Dollo, and Osborn. But a large and more valuable part of the work and of the literature cited is that pertaining to field observations of naturalists working in every branch of zoology and botany.

The author's general attitude toward the selection theory is a reaction which, in the reviewer's opinion, carries him much too far in the opposite direction: in endeavouring to undermine the whole doctrine of the selection of chance variations, he undermines the broad selection principle as well, and thereby loses all touch with what may be called the larger concept of Darwin and of Wallace, namely, that evolution is constantly guided and directed by "the preservation of favored races in the struggle for life." Nor is any serious attempt made by the author to formulate the coefficients of living forces which are observed to combine in the formation of new sub-species and species. In this aspect the author is facing what we are all obliged to face—complete ignorance of the underlying causes of the origin of the new adaptations and new species which he sums up in the word 'nomogenesis.'

Prof. Berg is naturally strongest in his own field, namely, in his observations on the geographical

variations of the fresh-water fishes of Europe, among which he notes the following curious circumstance:

"As we move further south the number of species and varieties of fishes, as of other animals, increases. But, at the same time, it becomes evident that variations in genera very widely separated often exhibit a tendency to develop *in one direction*. Thus, in the South European and Caucasian species of Chondrostoma (of the Cyprinidæ), we observe a decrease in the number of the rays of the dorsal and anal fins as compared with what occurs in the North European and Russian representatives of that genus: in the North European *Chondrostoma nasus* the dorsal fin usually contains 9 branched rays, and the anal 10-11; in the numerous South European species of the same group there are generally 8-9 branched rays in the dorsal fin, while the number of those rays in the anal falls to 9. Such a decrease in the number of rays is still more pronounced in the South European and Caucasian species, which are grouped about *Chondrostoma toxostoma*: the number of rays in the dorsal and anal fins has in both cases decreased to 7."

Prof. Berg observes a similar diminution of fish rays in other genera of the carp family (Cyprinidae), namely, in bleaks, chubs, and roaches, which are also distinguished as one travels southward by a diminished number of scales, of fin rays, and of vertebræ, and by an abbreviation of the body. He extends this comparison very widely with similar observations by Günther, Jordan, and other ichthyologists, and concludes (p. 268) that "it is highly improbable, and indeed quite incredible, that in all the species named, belonging to separate genera, variations, which have led to the same results in all the species, should have arisen *by chance*."

In Chap. x., "The Formation of New Species," the author extends his comparison to the gudgeon (*Gobio gobio*), and gives his final opinion as follows:

"*In the origination of new geographical forms* (species, sub-species, nationes) *a vast number of individuals inhabiting a certain geographical area are simultaneously involved in the production of new characters*. . . . The trend towards the development of scales on the throat, united with a combination of other characters, is something *primary, occurring in accordance with some law throughout the entire area of distribution of the southern gudgeon*."

A novel, but we believe thoroughly sound, application of the same directive principle in evolution to new verbal forms in languages is illustrated by Russian and French examples, with the following conclusion by the author:

"In my opinion, the above-mentioned variations of language are determined by modifications in the organs of speech, *i.e.* possess an anatomical basis. These phenomena, consequently, enter into the domain of the naturalist: they are fully homologous to the new formations to which the various forms of organisms have been subject in time (geologically) and in space (geographically)."

Although the reviewer is unable to agree with many of the points of view of the author and to accept the complete antithesis presented (p. 406) between Darwin's conceptions and his own, this volume is welcomed as a thoughtful and, in large part, original contribution to the newer modern aspect of the evolution theory.

HENRY FAIRFIELD OSBORN.

Mind and Matter.

The "Margery" Case. By E. J. Dingwall. *Proceedings of the Society for Psychical Research.* Vol. 36, Part 98. June 1926. Pp. 79-170. (London: Francis Edwards, 1926.) 6*s*. net.

ONE of the best arguments for the utility of a Society for Psychical Research is furnished by a case of apparently well-authenticated telekinesis and 'materialisation' such as that of the medium known in the United States as 'Margery,' the wife of a highly qualified Boston surgeon.

The test was undertaken by the Society's research officer, Mr. E. J. Dingwall, and its course and result are closely analogous to the case of the 'Goligher Circle,' investigated after the death of Dr. W. J. Crawford. In both cases the investigator was prejudiced in favour of the authenticity of the phenomena and their 'supernormal' character, but was gradually forced to the opposite conclusion by the consistent failure of every attempt to render the phenomena evidential.

As in the case of Crawford's experiments, the proceedings are controlled by an 'operator,' purporting in this case to be the medium's deceased brother Walter, whose direct voice, apparently independent of the sitters, is heard in the room. The voice prophesies or promises the physical phenomenon, and then, under test conditions, it often happens as stated. But when pressed by suggestions which are distasteful to him, Walter either makes promises which are never fulfilled, or turns the thing into a joke with a series of droll witticisms, at which he is both skilled and highly amusing.

Control was made difficult from the beginning by the stipulation that the medium's husband should have free access to the sittings and should control one of the medium's hands. But Mr. Dingwall thought it best to let the phenomena develop along their own lines in the first instance and to tighten up the control later. He was rewarded by some very remarkable manifestations, including the ringing of an enclosed bell constructed by the *Scientific American* Committee. This was done in a red light, but was preceded by an 'incubation' period of darkness.

The record of the sittings shows a steady development which appeared to justify the waiting attitude adopted by the investigator. In the course of the ninth sitting (January 9, 1925) a self-luminous cardboard was introduced, and what appeared to be a mass of teleplasm was thrown upon it and underwent certain changes of shape as promised by Walter. One, two, three, four, or five fingers of all shapes were made to grow out from the mass, some slowly, some quickly; then a short coarse thumb, and finally one long projection with a hook on it, in all twelve inches long. Meanwhile Walter kept up almost continual conversation mixed with his characteristic laugh, all heard in between the medium's obvious snores.

A suggestion made by Mr. Dingwall to employ a gauze cage in order to prevent manipulation by the medium was refused, but as a compensation Walter promised to show a materialised head upon the medium's shoulder, and eventually to show the appearance and disappearance of the teleplastic substance from the body of the medium. From what he said it was clear that the extrusion of the substance would resemble a normal birth, as indeed it has been alleged in the case of other mediums. Walter stipulated that a flat piece of wood should be provided projecting in front of the medium's chair in order to support the substance on its emergence. Mr. Dingwall remarks that this proviso is inconsistent with the supposed vitality of the substance. At the twenty-fifth sitting some excellent photographs were taken, and in the course of intermittent illuminations with red light an object was seen on the table resembling a very aged hand. Walter said, "This mass is really blood, the white corpuscles. When it goes back it strikes the heat and dissolves" Mr. Dingwall obtained permission to raise the object from the table. It resembled in shape a hand, but appeared to be a light skinny bag weighing two or three ounces. The medium turned in her chair and the object was pulled out of his hand, crumpling up in the process.

The attempts to show the growth and disappearance of the substance had no evidential value, since a few glimpses of the substance, separated by dark intervals, were only allowed to show successive stages

Summing up his impressions, Mr. Dingwall says: "The one fact which stands out in favour of the hypothesis of genuineness is undoubtedly the personality and position of Margery and her husband, and the improbability of their engaging in persistent trickery." On the other hand, he considers it possible that a surgeon of rationalistic tendencies might experiment on the gullibility of a presumably expert investigator with the view of its eventual exposure.

The interest of this case lies in the fact that it constitutes, in Mr. Dingwall's opinion, the most advanced example of alleged telekinesis and teleplastics ever investigated by the Society. It is quite arguable that any phenomenon the occurrence of which depends upon the whim of a disembodied entity whose behaviour escapes the application of all human standards is *ipso facto* outside the pale of science; and it is a matter of history that the progress of science has coincided with the elimination of such factors. On this planet, at all events, the controlling mind is the embodied mind of man, and to admit any other to a position of superiority, or even equality, involves the abdication of science.

It is all the more important that alleged phenomena of a 'supernormal' character should be subjected to sympathetic, critical, and competent investigation, and of such investigation Mr. Dingwall's report is a good example.

The Hon. Everard Feilding appends a well-written review of the adverse Hoagland Report on the same medium published in the *Atlantic Monthly* on behalf of a committee of Harvard graduates. He does not regard this highly controversial matter as by any means finally settled. E. E. F. D'A.

Our Bookshelf.

Sarajevo: a Study in the Origins of the Great War. By Dr. R. W. Seton-Watson. Pp. 303. (London: Hutchinson and Co., Ltd., n.d.) 18s. net.

This important book appears at a very opportune moment. A vigorous and characteristically thorough movement has been going on for some time in Germany, to shift the responsibility for the War from German shoulders, and land it on those of the allies, and in the first place of Russia. Quite recently, the movement has taken hold of a large section of the historians of the United States under the lead of Prof. Barnes, who has been lecturing with great acceptance in Berlin this summer on these lines. They call themselves the 'Revisionist' School, and Prof. Barnes's book is now expected in Great Britain, if indeed it has not already arrived. Now, just before we get it, Dr. Seton-Watson gives us in this compact and well-documented volume an authoritative account of the whole thing from the most important point of view, that is, the relations between the Southern Slavs centred in Serbia and the Austrian Government under Francis Joseph. This was the point of ignition, and the crime of Sarajevo was the spark.

Dr. Seton-Watson has made a life study of the whole Slav question, and his account is obviously impartial and as exhaustive as the published documents permit. These are unusually numerous and full, as the new Succession States have naturally published everything they could. The result is astounding but unquestionable. The assault on Serbia was deliberately engineered with determination, unexampled duplicity, and a complete recklessness of the consequences, by the war

party in Vienna, and above all by the Chancellor Berchtold, who, having secured a free hand from Germany, managed gradually, and in the end by a falsehood, to win over the old Emperor to the declaration of war.

The only satisfaction one can derive from the terrible story is that those have paid most heavily who sinned worst. The old Austrian system which produced such things has been completely swept away—the best and greatest clearance of the War. F. S. MARVIN.

The Natural History of Wicken Fen. Edited by Prof. J. Stanley Gardiner. Part 3. Pp. 173-266. (Cambridge: Bowes and Bowes, 1926.) 5s. net.

THE acquisition of Wicken Fen by the National Trust has afforded Prof. Stanley Gardiner and his colleagues an opportunity of carrying out a type of natural history investigation which British zoologists have been inclined to neglect, although it promises valuable results. In the British Isles, collecting has tended to diffuseness: the entomologist flits from one area to another where good collections are likely to be made; other local lists owe their existence to the chance presence of enthusiasts, but seldom is a single limited area worked to the bone as regards all its content. Part 3 of the "Natural History of Wicken Fen" continues the results of the intensive study of natural groups, ranging from Oligochæta and Mollusca to several insect orders, and including a flora list and a historical note on changes in the fen during the last forty years, all valuable contributions.

The biological aspect is notably prominent in the papers by Prof. Balfour-Browne, Miss Pickford, and Mr. Hutchinson, and a perfect foundation is being laid for an ecological study which will trace the fluctuations of the animal groups in relation to each other and to the vegetational and soil changes from season to season and from year to year. Zoology has lagged far behind botany in ecological study, but we trust that before this series is completed, the editor may be able to arrange a symposium which will make up some of the leeway. J. R.

Naturforscher und Erfinder: Biographische Miniaturen. Von Prof. Dr. Ludwig Darmstaedter. Pp. vii+182+16 Tafeln. (Bielefeld und Leipzig: Velhagen und Klasing, 1926.) n.p.

THIS charming book consists of thumb-nail sketches of the lives of famous men of science, and is well illustrated with portraits and with facsimiles of autograph letters. Physicians, physicists, chemists, and others all find a place, and the true internationalism of science is reflected in the catholic nature of Prof. Darmstaedter's gallery. Biographical details have a perennial interest, and in the present instance many of them are new, or at least not generally known. One of the most interesting sections deals with the men who were responsible for "the error of phlogiston and its overthrow," namely, Stahl, Black, Marggraf, Priestley, Scheele, and Lavoisier, though microscopists will derive equal enjoyment from the sketches of Leeuwenhoek, Redi, and Ehrenberg, and physicists from the sympathetic insight into the minds of Gilbert, Guericke, von Kleist, Galvani, Volta, and Ohm. Prof. Darmstaedter says that the compilation of this book has brightened his life during the last two years, and he may be assured that the wish he expresses—that his readers may get as much enjoyment from it as he has done—will be fulfilled. If we ourselves may express a wish, it is that he may live long and give us more books of the same kind.

The Whalers of Akutan: an Account of Modern Whaling in the Aleutian Islands. By Knut B. Birkeland. Pp. vi+171+16 plates. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1926.) 14s. net.

MODERN whaling with explosive harpoons has spread to all parts of the world, generally through Norwegian enterprise. This book describes vividly the life and methods in a whaling station in Akutan in the Aleutian Islands, where blue whales and sperms were the chief catch. It dwells not only on the adventure and incidents of the life, but also contains a great deal of information about the commercial side of the industry, the preparation of the oil, the utilisation of the débris for fertiliser and whale meat as human food. Since the author, at nearly sixty years of age, was new to whaling when called upon to manage the station, he describes many minor matters that an experienced whaler would be likely to pass by as unworthy of mention. This adds to the interest of the book; but unfortunately he had little opportunity to see much of the Aleutian Islands beyond the station, and has relatively little of value to say about the natives, and nothing about the geography and natural history of these little-known islands.

Methoden der angewandten Geophysik. Von Dr. Richard Ambronn. (Wissenschaftliche Forschungsberichte, Naturwissenschaftliche Reihe, Band 15.) Pp. xii+258. (Dresden und Leipzig: Theodor Steinkopff, 1926.) 15 gold marks.

As the title indicates, this book is largely influenced by the economic aspect of geophysics. Prominence is given to the discovery of ores and salt deposits by means of the Eotvos torsion balance, and by seismological and magnetic methods. Most of the book deals, however, with the purely scientific parts of the subject. It contains a bibliography of about 1700 references, but unfortunately there are signs that they have not all been verified, and the author seldom gives much information himself, referring the reader instead to original sources, with little indication of what is to be found there. H. J.

Description du ciel. Par André-Danjon. (Bibliothèque générale illustrée, 2.) Pp. 80+59 planches. (Paris: F. Rieder et Cie, 1926.) 15 francs.

THIS pleasantly written and well-printed booklet gives in eighty pages a brief but wide survey of present-day astronomy. It can be recommended to English readers of the French language who desire acquaintance with modern views and problems in astronomy, rather than a knowledge of the detailed facts. The fifty-nine plates, each occupying a page, are reproductions, good on the whole, of photographs of observatories and telescopes, the sun and moon, the planets, comets, stellar spectra, the Milky Way, clusters, and nebulæ.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Recurrence of Magnetic Storms.

CE journal a publié le 4 Septembre dernier une lettre du Dr. Chree intitulée : " The Recurrence of Magnetic Storms." Le Dr. Chree présente un examen critique de plusieurs communications que j'ai faites récemment à l'Académie des Sciences de Paris (voir *Comptes rendus* **182**, 1926, p. 296, 669, 733, 1301, et **183**, 1926, p. 153), et qui annoncent la répétition des orages magnétiques à des intervalles égaux à iT/6 ; i étant un nombre entier et T la durée moyenne de rotation synodique des taches solaires.

Or les travaux antérieurs de Chree sur la succession de ces orages (*Phil Trans*, 1912, A, vol 112, p. 78, et 1913, vol 213, p. 245) font bien ressortir leur tendance à revenir à des intervalles qui sont des multiples de la période T, mais non d'une période plus petite. Aussi le Dr. Chree, sans condamner absolument mes résultats, émet des doutes sur leur validité

Je suis conduit à présenter quelques remarques sur les recherches de Chree et les miennes Je montrerai brièvement que les méthodes employées par les deux auteurs sont très différentes, et que les résultats obtenus pouvent ne pas être exactement les mêmes

I Le Dr. Chree, dans sa note du 4 Septembre, rappelle les bases principales et les conclusions de son étude déjà ancienne des perturbations magnétiques Il s'appuie sur le nombre, appelé caractère magnétique, 0 (calme) ou 1 (modérément troublé) ou 2 (fortement troublé), qui est adopté chaque jour dans les observatoires magnétiques pour représenter les variations de l'aiguille aimantée pendant les 24 heures. Dans chaque mois d'une longue période de 11 années, il choisit les cinq jours les plus troublés ; ce qui fait en tout 600 jours troublés, et il prend la moyenne de leurs caractères magnétiques, moyenne qui, dans une première série de 11 années, a été 1·51 Il considère les 3 jours qui précèdent et les 35 jours qui suivent chacun des 600 jours troublés, et il prend encore la moyenne de leurs caractères magnétiques. Le rapprochement de ces 39 moyennes conduit à plusieurs propriétés intéressantes, et, en particulier, aux résultats ci-dessus résumés

D'autre part, l'Observatoire de Meudon que je dirige, et qui est consacré spécialement à l'étude du soleil, enregistre depuis 1922 la déclinaison magnétique sur un papier sensible qui noircit sans développement et est placé dans la salle même de notre grand spectrohéliographe L'observateur du soleil peut, en soulevant un simple voile, avoir sous les yeux la courbe magnétique des 48 dernières heures, et il est prévenu par une sonnerie, lorsque la perturbation est forte. Le papier se déroule avec une faible vitesse (40^{mm} en 24 heures) et est relevé seulement toutes les semaines. L'appareil est surtout avertisseur, et il enregistre toutes les variations un peu notables, en assurant leur comparaison très facile

Or, dans les premiers mois de 1926, à Meudon où les aurores boréales sont rares, nous avons observé quatre fois ce curieux phénomène, accompagné d'un bel orage magnétique, les 26 Janvier, 23 Février, 5 et 9 Mars. J'ai noté que les deux derniers orages étaient séparés par un intervalle très voisin de T/6, et que, en ajoutant les orages plus faibles des 13, 18, et 23 Janvier, que les 7 orages ont entre eux des différences qui sont des multiples de T/6. Puis, en remontant à l'année 1925, et en examinant les mois de Mars à Août 1926, je trouve encore des orages qui ont entre eux les mêmes différences, et d'autres orages reliés aux précédents d'une manière simple. Finalement les conclusions sont les suivantes : Plusieurs orages, qui sont en général les plus forts, ont entre eux des intervalles qui sont des multiples de T/6 ; d'autres orages, en général moins forts, occupent à peu près le milieu des intervalles précédents, les différences étant des multiples de T/12. Enfin, au milieu des intervalles de la 2^{me} série, on distingue des perturbations plus faibles, qui correspondent aux multiples de T/24 De Janvier 1925 à Août 1926, toutes les perturbations un peu notables sont comprises dans ces trois séries.

Størmer a mis récemment hors de doute que les aurores et les orages magnétiques sont dus à un rayonnement corpusculaire émané du soleil et formé le plus souvent de particules négatives. Les points de forte émission corpusculaire, qui, dans le soleil, sont de véritables volcans, ont donc une distribution régulière ; ils occupent des méridiens dont les différences en longitude sont des multiples de 60°, 30°, et 15° Comme cette division spéciale est celle des corps à symétrie circulaire qui se refroidissent, les faits précédents conduisent à admettre, tous les onze ans, des brisures régulières dans trois couches solaires, qui, placées sous la surface, rejettent au dehors par intermittences leur matière fortement ionisée ou radioactive. Ils conduisent aussi à une explication simple des variations undécennales du soleil (voir les mémoires originaux).

En fait les orages magnétiques sont rapprochés et comparés tout autrement que dans le travail antérieur de Chree J'ai noté non la durée de l'orage, comme l'ont fait la plupart des auteurs, mais l'heure de sa pointe caractéristique, de sa pointe maxima, ou, ce qui revient au même, la longitude correspondante du centre du soleil. Les orages les plus frappants sont les orages S de Maunder, à commencement brusque qui sont en général les plus forts ; et j'ai vérifié la loi d'abord sur les orages S de 1925-1926, puis de 1882 1883, qui sont les uns et les autres un peu avant un maximum de taches Le tableau suivant permet de juger l'accord des orages S de 1882-1883 avec la loi posée. Les longitudes sont celles de Maunder et se rapportent à la première pointe de l'orage

PERTURBATIONS MAGNÉTIQUES

Date et particularités	Longitude du centre du soleil	Différence avec 93°.	Différence avec 51·2
1882 Avril 16·98 G. S.	93°	0	..
,, 20·15 G. S	51·2		0
Juin 15·13 M. S.	30·0	+62·1	
Août 4·05 A. S	82	.	−30·8
Sept 12·12 A. S	293·9		242·7

Je suis conduit à présenter quelques remarques sur les recherches de Chree et les miennes. Je montrerai brièvement que les méthodes employées par les deux auteurs sont très différentes, et que les résultats obtenus peuvent ne pas être exactement les mêmes

I. Le Dr. Chree, dans sa note du 4 Septembre, rappelle les bases principales et les conclusions de son étude déjà ancienne des perturbations magnétiques Il s'appuie sur le nombre, appelé caractère magnétique, 0 (calme) ou 1 (modérément troublé) ou 2 (fortement troublé), qui est adopté chaque jour dans les observatoires magnétiques pour représenter les variations de l'aiguille aimantée pendant les 24 heures Dans chaque mois d'une longue période de 11 années, il choisit les cinq jours les plus troublés ; ce qui fait en tout 660 jours troublés ; et il prend la moyenne de leurs caractères magnétiques, moyenne qui, dans une première série de 11 années, a été 1·51. Puis il considère les 3 jours qui précèdent et les 35 jours qui suivent chacun des 660 jours troublés, et il prend encore la moyenne de leurs caractères magnétiques Le rapprochement de ces 39 moyennes conduit à plusieurs propriétés intéressantes, et, en particulier, aux résultats ci-dessus résumés.

D'autre part, l'Observatoire de Meudon que je dirige, et qui est consacré spécialement à l'étude du soleil, enregistre depuis 1922 la déclinaison magnétique sur un papier sensible qui noircit sans développement et est placé dans la salle même de notre grand spectrohéliographe L'observateur du soleil peut, en soulevant un simple voile, avoir sous les yeux la courbe magnétique des 48 dernières heures, et il est prévenu par une sonnerie, lorsque la perturbation est forte. Le papier se déroule avec une faible vitesse (40^{mm} en 24 heures) et est relevé seulement toutes les semaines. L'appareil est surtout avertisseur, et il enregistre toutes les variations un peu notables, en assurant leur comparaison très facile

Or, dans les premiers mois de 1926, à Meudon où les aurores boréales sont rares, nous avons observé quatre fois ce curieux phénomène, accompagné d'un bel orage magnétique, les 26 Janvier, 23 Février, 5 et 9 Mars. J'ai noté que les deux derniers orages étaient séparés par un intervalle très voisin de T/6, et que, en ajoutant les orages plus faibles des 13, 18, et 23 Janvier, que les 7 orages ont entre eux des différences qui sont des multiples de T/6. Puis, en remontant à l'année 1925, et en examinant les mois de Mars à Août 1926, je trouve encore des orages qui ont entre eux les mêmes différences, et d'autres orages reliés aux précédents d'une manière simple. Finalement les conclusions sont les suivantes : Plusieurs orages, qui sont en général les plus forts, ont entre eux des intervalles qui sont des multiples de T/6, d'autres orages, en général moins forts, occupent à peu près le milieu des intervalles précédents, les différences étant des multiples de T/12. Enfin, au milieu des intervalles de la $2^{ème}$ série, on distingue des perturbations plus faibles, qui correspondent aux multiples de T/24. De Janvier 1925 à Août 1926, toutes les perturbations un peu notables sont comprises dans ces trois séries.

Størmer a mis récemment hors de doute que les aurores et les orages magnétiques sont dus à un rayonnement corpusculaire émané du soleil et formé le plus souvent de particules négatives Les points de forte émission corpusculaire, qui, dans le soleil, sont de véritables volcans, ont donc une distribution régulière, ils occupent des méridiens dont les différences en longitude sont des multiples de 60°, 30°, et 15°. Comme cette division spéciale est celle des corps à symétrie circulaire qui se refroidissent, les faits précédents conduisent à admettre, tous les onze ans, des brisures régulières dans trois couches solaires, qui, placées sous la surface, rejettent au dehors par intermittences leur matière fortement ionisée ou radioactive Ils conduisent aussi à une explication simple des variations undécennales du soleil (voir les mémoires originaux).

En fait les orages magnétiques sont rapprochés et comparés tout autrement que dans le travail antérieur de Chree J'ai noté non la durée de l'orage, comme l'ont fait la plupart des auteurs, mais l'heure de sa pointe caractéristique, de sa pointe maxima, ou, ce qui revient au même, la longitude correspondante du centre du soleil Les orages les plus frappants sont les orages S de Maunder, à commencement brusque, qui sont en général les plus forts ; et j'ai vérifié la loi d'abord sur les orages S de 1925-1926, puis de 1882-1883, qui sont les uns et les autres un peu avant un maximum de taches. Le tableau suivant permet de juger l'accord des orages S de 1882–1883 avec la loi posée Les longitudes sont celles de Maunder et se rapportent à la première pointe de l'orage

PERTURBATIONS MAGNÉTIQUES

1883 Fév. 1·75 A. . .	213·9	−120·7	..

On distingue les deux séries à intervalles de 60° et de 30°. A noter que la deuxième série n'occupe pas

exactement les intervalles de la première ; les orages nous arrivent avec un certain retard, ce qui peut tenir à la vitesse plus faible des particules (voir le mémoire original).

Les orages ordinaires non S de 1925–1926, plus nombreux que les orages S, rentrent aussi dans la loi précédente ; ils sont représentés par leur pointe la plus élevée, la variation diurne de l'aiguille étant défalquée. Parfois on hésite pour décider si un orage est S ou non S, ou hésite entre deux longitudes ; mais le cas est rare et il arrive que les deux longitudes peuvent se rattacher à la loi qui est seulement approchée.

Enfin, fait curieux, les petites perturbations (entre 10′ et 2′ d'écart en déclinaison) qui se détachent nettement sur une courbe calme ou peu agitée, satisfont aussi à la loi posée ; et, dans les tableaux publiés, ces petites perturbations sont les plus nombreuses (voir le mémoire original).

Par contre je n'ai pas considéré les parties, d'étendue souvent grande en longitude, où l'agitation est continue, après un fort orage ou en dehors d'un orage. Les pointes sont alors petites, nombreuses et très rapprochées, sans offrir de maximum bien net. L'émission correspondante du soleil n'est plus limitée, comme dans les orages S, à une région étroite de l'astre avec des particules plus ou moins rapides ; elle s'étend sur les côtés en longitude, étant en même temps plus faible. Ce mode particulier d'émission sera l'objet d'une étude spéciale.

En résumé, tous les maxima bien nets, grands ou petits, des courbes ont la distribution régulière qui est annoncée ; mais, et il faut insister sur ce point, il y a des lacunes dans leur succession, l'émission solaire étant intermittente, comme l'émission de nos volcans.

Après ces explications, on comprend pourquoi les maxima iT/6, spécialement examinés par le Dr Chree, n'apparaissent pas dans ses calculs ; les moyennes adoptées ont l'inconvénient de masquer les inégalités périodiques dont l'intensité est très variable Seule la période T émerge ; ce qui indique qu'elle est la plus fréquente et qu'elle est attachée à des orages forts ; et ce résultat est certes fort important. D'autre part le caractère magnétique sur lequel s'appuie le Dr. Chree, représente incomplètement l'état des choses, et a été déjà vivement critiqué. La division rigide en tranches de 24 heures, qui convient certes pour l'étude de la variation diurne, est beaucoup moins indiquée pour les orages proprement dits. Pour faire ressortir les périodes T/6 et T/12, il faudrait prendre dans chaque mois non pas 5, mais 14 jours. Enfin mon étude porte seulement sur 18 mois et celle de Dr. Chree sur les onze années d'une période solaire.

Que le Dr. Chree veuille bien étudier séparément, comme je l'ai fait, chaque perturbation, puis la comparer directement aux autres, et son opinion sera modifiée.

II Il reste ensuite à reconnaître dans le soleil les points d'émission corpusculaire dont la distribution régulière est annoncée par notre aiguille aimantée. On a d'abord pensé aux taches, puis aux facules, et je me suis rallié à cette dernière opinion. Depuis longtemps j'ai l'idée que les points actifs du soleil correspondent surtout aux parties de la facule qui présentent la raie D_3 de l'hélium noire, que la facule soit avec tache ou sans tache. La proportion de gaz helium y est plus grande et donc aussi la proportion de corps radioactifs. L'Observatoire de Meudon s'organise pour enregistrer d'une manière aussi continue que possible ces portions spéciales des facules, et d'Azambuja, astronome de Meudon, a commencé la recherche depuis plusieurs mois.

Le mois dernier, l'astronome anglais A. A. Buss m'a signalé une note publiée par lui en 1915 dans *The Observatory* et intitulée : "A possible Systematic Distribution of Solar Activity Areas in Longitude." Sur 57 taches relevées de 1912 à 1914 dans une phase de minimum, Buss en note 10 dont les différences en longitude sont très voisines de 60° ou de multiples de 60° ; et il suggère que cette régularité pourra se retrouver dans les orages magnétiques. L'intérêt du fait annoncé est manifeste ; et on peut s'étonner que l'auteur n'ait pas poussé plus loin cette première étude. Les 10 taches signalées n'étaient pas toutes parmi les plus fortes ; il faudra rechercher si les autres taches de 1912–1914 ont entre elles des différences qui soient des multiples de 30° et de 15°. Il faudra aussi étendre la recherche aux facules avec taches ou sans taches et aux perturbations magnétiques d'une période solaire tout entière.

III. Le rayonnement corpusculaire du soleil a été jusqu'ici plutôt négligé ; or il a une très grande importance et s'annonce comme étant la cause première de la plupart des grandes variations que subissent le soleil et ses dépendances dans la période undécennale. Le phénomène toujours mystérieux des champs magnétiques intenses, reconnus au Mont Wilson sur plusieurs points de l'astre, est dû peut-être à ce rayonnement. Une propriété remarquable des particules électrisées est ici à rappeler : lorsque ces particules ont traversé une certaine quantité de matière, elles ont une trajectoire hélicoïdale (Wilson, Rutherford). Si les hélices ont des rotations de même sens sur une portion un peu notable de la surface, il en résulte un champ magnétique, à composantes horizontale et verticale, très semblable à ceux du soleil. On peut aussi, avec ce rayonnement corpusculaire négatif et positif, expliquer en grande partie les facules, les taches avec leurs deux polarités, les protubérances et filaments : et on s'accorde déjà pour lui attribuer les formes caractéristiques de la couronne solaire.

Science and Psychical Research.

NICKNAMES are seldom exhilarating or welcome, especially when intended to be contemptuous, so the question raised on p. 553 (NATURE, October 16), whether Prof. Richet can rightly be bracketed with Crookes and Lodge as a 'spiritist,' seems a barren one, but it may be used as a peg for some general remarks.

None of the three would like the term ; all would prefer to be regarded as explorers or gropers in a tangled region off the obvious track, but only one of the three would resent the term as definitely erroneous.

I suppose it is generally admitted that there are facts requiring explanation If the facts are all explicable in terms of human duplicity, the only branch of science to which they can be of the smallest interest will be anthropology or abnormal psychology or psychiatry. But if any of the facts are what we may call for brevity 'real,' they are bound to be sooner or later of importance—even of great importance—not only to psychology but to physiology also, and perhaps to humanity at large. All three of the above-mentioned protagonists have gradually come to believe that that is so, in opposition to many of their colleagues who are still labouring under the delusion of undiluted fraud.

May I assume for the moment that some of the unpalatable or undigested facts are real, in the sense

that when understood they will lead to an extension of natural knowledge. We now require a working hypothesis wherewith to tackle them. The particular hypothesis employed as a tentative clue is comparatively of small importance; and if any onlookers are unwise enough to elevate such vague notions to the rank of a theory, they can scarcely be aware of the high status required of a scientific theory. A working hypothesis is an elastic thing, or rather a living and growing thing; parts can be shed, parts may become consolidated, while other parts may shoot out new growths and bud amazingly, but all are variable; and various hypotheses may be favoured at different times and by different people.

Of the hypotheses so far tried to account for strange happenings, one group of scientific men ejaculate 'fraud'; another set try what they can do with 'ectoplasm'; while a small group, in sympathy with these last, try to go further, and postulate unrecognised intelligences; so this last group may be represented as murmuring 'spirit.' But none of these hypotheses is an explanation: indeed, only the first class imagine that they have an explanation, though if they press it with care and patience they will find if often does not work. Let us give the other two a moment's chance.

By ectoplasm, Richet and his group mean a mass of protoplasmic material, emanating under exceptional conditions from the human body, and endowed with singular and unexpected properties; no more astonishing in themselves than the properties exhibited by an egg, or indeed any other form of living tissue, but unusual in location and also unusual in the apparently temporary character of the result. Like muscle, ectoplasm is controlled by intelligence and can exert force, but unlike muscle it extrudes itself beyond the normal periphery of the familiar organism. Like a placenta or an egg or a pupa, it exhibits a formative power, being able to manipulate itself or other substances into organised forms; but, unlike the forms to which we have grown accustomed, these are singularly evanescent. Nevertheless, while they last they act in an intelligent way, and are as subservient to control as, let us say, a dog. Such are among the facts testified to by Richet, Schrenck-Notzing, Morselli, and other continental investigators.

If we grant all or any of this, merely for the sake of the discussion—for facts are not established by citation of authority—the question arises, What is the control? Is it the unconscious mind of the person from whom the substance emanates—naturally the first and easiest idea—or does it represent the intervention and activity of some intelligence not obviously and in perceptible form present? The three men mentioned above, though sometimes bracketed together, might take different views. I venture to say that their views, whatever they are, must at the present stage be so crude as to be scientifically almost negligible. The facts alone are important; it is those that, granted their genuineness, need far more investigation. In that opinion they all agree. Time enough for a theory when we know more.

In fairness, however, let me go on to excuse, and in some sort justify by an analogy, the third kind of working hypothesis here briefly labelled spirit. Consider the reaction of a race of secluded but intelligent aborigines to whom there comes a rumour, from one or two of their number, about things quite inconceivable and absurd—X-rays, let us say, or telephones, or radio telegraphy. At first utterly sceptical, they may denounce and expel the heretic; but if, nevertheless, the rumour is persisted in by successive generations, and supported by some whose observations are generally treated with respect, some working hypothesis becomes necessary. Delusion is the simplest notion; the idea of corporeal emanations and vibrations is more troublesome, but may be made to look impressive and materialistic; while the hypothesis of the existence of a hitherto unsuspected race of white men, to whose activity the phenomena are due, would probably be stigmatised as a degrading superstition. Whatever it is, it is certainly not a theory of X-rays or of telegraphy; and yet the suggested clue that these incredible things are the work of unknown intelligent operators has, in this case, an element of something that would ultimately lead to an explanation. It may be sneered at as superstitious, but cannot rationally be stigmatised as false.

So also the hypothesis popularly associated with the term 'spirit,' though it is not a theory of either apparitions or telepathy or telekinesis, yet in so far as it contains any element of truth—that is the crux—it may be the beginning of what will ultimately constitute a new branch of science. It may be only the first rung of a ladder; yet if we follow our leaders and begin to climb, who knows what unearthly region may be ultimately scaled! Science is young: the human race may reasonably be expected to continue on this planet for several million years; so it would be rather dull, as well as unlikely, if man's outlook on the universe, and his realm of natural knowledge, should always conform to the orthodoxy of A.D. 1926.

OLIVER LODGE.

The Naming of Wild Hybrid Swarms.

ONE of the most important developments of botanical research in New Zealand of recent years, since it concerns not only taxonomy but also the question of evolution, is that of the study of wild hybrids. Evidence has rapidly accumulated as to the prevalence of polymorphic swarms of wild hybrids in several sections of the flora. Whereas (*Trans. N.Z. Inst.*, **44**, 1912, 30) Cockayne stated, "Hardly anything is known as to the occurrence of wild hybrids in New Zealand," he was able later (*New Phytol.*, **22**, 1923, 124) to list 130 certain or extremely probable groups of interspecific hybrids. The number has since been considerably augmented, and now stands well above 200. The following table is illuminating, taking only the monocotyledons and dicotyledons.

Classes of Genera.	Number of Genera.	Number possessing Hybrids.	Percentage.
Genera with 2-5 species	125	42	34
Genera with 6-10 species	33	17	52
Genera with 11-20 species	15	13	87
Genera with over 20 species	16	16	100

All genera containing 14 or more species are known to show hybridism. Remembering that many species are so isolated that hybridism is difficult or impossible, that species in close proximity may bloom at different seasons, and that many groups have not been critically examined in the field, but the vague term 'variation' has been used to explain polymorphy, these figures speak for themselves

Now this wealth of wild hybrids raises many important questions, not the least of which, as a necessary preliminary to further progress, is the matter of suitable nomenclature. The formular treatment allowed by the "International Rules of Botanical Nomenclature" is too cumbrous for general and field

studies. Nor do the "Rules" have in view the existence of the highly polymorphic hybrid swarms—in no few cases hundreds or probably thousands of distinct individuals—that are now known to exist. In the absence of any recognised method of procedure suited to our needs as field ecologists, we have been forced to draw up our own rules. Elsewhere we are publishing a more detailed statement of our case, but it seems well to place the essence of the matter before the wider audience available in the columns of NATURE.

For the whole diverse group arising from the crossing of two species we construct a name formed by the combination, suitably abbreviated, and with the ending appropriately modified, of the specific names of the parents. Thus to the great group *Hebe elliptica* × *salicifolia* we give the name × *Hebe ellipsala*, and so for *Hebe Astoni* × *laevis* the name × *Hebe laevastoni*, preferring euphony to strict adherence to alphabetical order. Where one of the names is quite short it may be used entire, *e.g.* *Melicope tersimplex* = *M. simplex* × *ternata*. This idea is derived from names given to horticultural hybrids, *e.g.* × *Iris monspur* = *I. Monnieri* × *spuria*. Where a specific name has been given to a smaller group within the swarm, as has often happened, especially for forms about midway between the parents, we may adopt this name for the minor group. Thus *Melicope Mantellii* is the name we propose for that small group of hybrids "intermediate" between *M. simplex* and *M. ternata*.

To us it seems most inappropriate to widen the conception of such names to include the whole group, as not only have we no warrant for doing so, but also confusion would inevitably result. Moreover, our method provides for the placing of forms still undiscovered, or those certain to arise later. A hybrid swarm is a totally different biological group from that of a species. In the latter case there can be a "type", in the former a "type" is impossible. Further, species deal with definite, static groups, but hybrid swarms with indefinite dynamic groups, for the hybrids of to-day are being replaced before our eyes by other forms, yet for these the group name will serve. The name *Nothofagus Blairii* is that of an extremely small group of the vast swarm *N. cliffortioides* × *fusca* (× *N. cliffusca*), but were the name *N. Blairii* used for the whole swarm its original conception would vanish, for it would include forms having no characters in common with *N. Blairii*, as originally described, and possessing characters not known previously in the genus, *e.g.* almost circular leaves with blistered surfaces.

The procedure outlined above seems to us adequate, of easy application, and helpful in revealing the parentage and history of the hybrids, whereas an arbitrary name reveals little or nothing. To one versed in the names of New Zealand plants, × *Aristotelia fruserrata* at once tells the group is *Aristotelia fruticosa* × *serrata*, whereas to apply the name × *A. Colensoi* to the group not simply tells nothing, but also actually misleads, insomuch as the 'species' *Aristotelia Colensoi* was based on a non-flowering specimen taken from a shrub some seventy years ago that is almost certain to have died some time back, and could not now be matched by any living plant.

Another matter to be considered is the citation of authors' names for hybrids, this not being fully provided for in the "Rules." Thus, if for any reason we still maintain Cheeseman's name *Ranunculus Matthewsii*—it was based on two specimens taken most likely from one individual—for a very limited portion of the large polymorphic group *R. Buchanani* × *Lyallii* we should cite it as × *Ranunculus Matthewsii* (Cheesem.) Ckn. et Allan as hyb., but by the "Rules" we need not use that name at all in moving the group it represents into a group of such a different status as a hybrid swarm.

The "Rules" demand diagnoses in Latin for hybrids as for species. This is all very well for small groups made up of fairly uniform individuals, and many such diagnoses occur in systematic literature. Obviously, however, with the groups we are considering, *e.g.* × *Myrtus bullobcordata* with its hundreds of distinct forms, diagnoses of reasonable length must be vague in the extreme, and we think that this requirement should be abandoned. This, of course, does not gainsay that detailed analysis of the individuals composing the groups is imperative.

Since the whole matter is of not merely local interest, but also applies to all floras and is particularly important from the point of view of definite names for the use of students of evolution, and since some commonsense uniformity of treatment is highly desirable, we bring the subject forward in the hope of arousing discussion, so that perhaps some such procedure as we have indicated may be adopted, and suitable rules drawn up for insertion at a future revision of the "Rules."

Early Egypt and the Caucasus.

WE are grateful to Sir Flinders Petrie for constituting himself his own reporter (NATURE, Oct. 9, p. 514) in the matter of his reply to our papers at Oxford, for we had at the meeting no opportunity to cover the ground on to which he transferred the argument. On that occasion, we kept studiously to the examination of the prehistoric and the geological evidences for the Caucasian-Solutrean argument. The difficulties we indicated (1) cultural, (2) distributional, (3) geological, were left unanswered. If Sir Flinders Petrie prefers to argue on historical ground we have here, too, certain comments to make.

The essential question is stated to be a conflict between (*a*) a 'received view,' whereby the Fayum lake gradually rose by the rise of the Nile level up to '205 or 220' feet above present lake, and (*b*) a 'new view,' whereby a high lake in the early human period was gradually dried down to the present size. In regard to this summary of the position the following comments may be apposite.

The view which is labelled 'received' was formulated in the late 'eighties; the chief contributors to the subject being Hanbury Brown, Scott Moncrieff, Cope Whitehouse, and Sir Flinders Petrie himself (as a result of his excavations of Biahmu and Arsinoe). This was long before the Fayum depression had been geologically investigated. The evidence for two lakes was undreamt of, and none of the palaeontological or stratigraphical work required as a sound basis for what is primarily a geological theory was attempted, nor had these gentlemen the specialised training to do so. It was not until 1905 that H. J. L. Beadnell published the official geological memoir on the Fayum. As is usual in these official surveys, the Pleistocene received relatively little investigation, but the fact was noticed that the upper limit of the lacustrine beds occurred at 223 feet (O.D. 23 m.), and the view was expressed that this gives evidence for "a great fresh-water lake in Pleistocene and prehistoric times."

The chief authors of the 'received view' do not appear to be in agreement between themselves.

Sir Hanbury Brown writes: "There is nothing to support the theory that there has been any great change in the Nile levels since the waters first found their way into the Fayum," and he believed that the old high-level lake was controlled and artificially kept at 222 feet in XII. Dynasty times. Sir Flinders Petrie, on the other hand, believes that instead of the prehistoric lake being at a more or less constant high level, it was gradually rising, reaching a height of about 205 feet (O.D. 17 m.) in XII. Dynasty times, attaining its full maximum of 220 feet (O.D. 22 m.) in Ptolemaic times.

With regard to the 'new view' (*b*), may we point out that we found abundant evidence for the existence of two lakes, the older corresponding to the 220-foot level; the newer never exceeding a maximum of 205 feet, which was attained in prehistoric times. From this point a steady fall appears to have taken place; the Fayum industry is closely linked to its 190-foot stage and lower, thus limiting the waters of the historic period to something below this level. We should like to add, what is not clear from Sir Flinders Petrie's statement of our case, that we consider, so far as the evidence is available, that both lakes were connected with the Nile, but the nature of this connexion cannot be definitely stated until detailed investigation has been undertaken along the Lahun-Hawara channel.

Our answers to Sir Flinders Petrie's six reasons in support of his view are briefly as follows:

(1) There is no evidence as to the depth of the inlet channel. As regards the question of siltage, geologists with knowledge of modern rivers under similar natural conditions regard blockage as highly probable, and Hanbury Brown himself considered that the growth of rushes in the channel "would check the inflow, and, while preventing the rise of the lake, would favour silt deposit."

(2) Completely ignores the probability of climatic change in Quaternary times, to which the other oases bear witness.

(3) The interpretation of the name "Soknopae Nesos" is not sufficient evidence to counteract hard geological facts.

(4) Schweinfurth notes especially the abundance of ruins around the edge of the basin, and it seems probable, from topographical considerations, that the nature of the underlying ground controlled the choice of site, rather than the relation to the lake level. The partially consolidated lake deposits would give but poor foundations for the massive ancient stone buildings. It should also be noted that dynastic flints were found at levels which would have been submerged at that time according to view (*a*).

(5) Of the four stone structures regarded by Sir Flinders Petrie as quays, three lie at Qasr-el-Sagha; these are known to him by photographs only. The fourth is the termination to the long paved road leading south from Dimê Temple; evidence points to this being not earlier than the first century A.D. The three structures at Qasr-el-Sagha show rough slabs of stone capping outstanding ridges of old lacustrine beds. This accounts for their approximately uniform height. The loosely consolidated material upon which they are based would not serve as foundation for a 'quay.' We are supported in our view of them by several archæologists, who came over at our request to see them, and are emphatic that such structures could not serve as quays. Further, one of these would, on Sir Flinders Petrie's rising levels, have been an island.

(6) The value of Herodotus as a witness can be judged from the fact that his estimate of the circumference of the lake was at least 87 miles too big, supposing the water to have stood at the 220-foot level in his time.

G. CATON-THOMPSON.
E. W. GARDNER.

Bedford College, London.

The Occurrence of Helium and Neon in Vacuum Tubes.

A SHORT time ago we published (*Proc. Roy. Soc.*, A, **109**, 186, 1925) an account of some attempts to confirm the observations by Collie, Patterson, and Masson (*ibid.* **91**, 30, 1915) of the occurrence of helium and neon in vacuum tubes. In view of the fact that we were able to obtain small quantities of these rare gases by passing the discharge through oxygen at low pressures when a magnesium or aluminium anticathode coated with nitride was used, no trace being found in the absence of the nitride, we attributed their formation to the disintegration of the nitrogen atom. Success depended on the use of an induction coil provided with a hammer break rather than a mercury break, an observation which agrees with those made by the previous authors.

We have now carried out some further experiments which would seem to confirm our original results. In the first place, both helium and neon have been obtained by passing the discharge between a concave aluminium mirror as cathode and a magnesium anode through a mixture of oxygen and nitrogen under reduced pressure. No trace of the rare gases was formed if the discharge were passed in the opposite direction; and since in this series of experiments the two types of discharge were used alternatively, the same mixture of oxygen and nitrogen was used, and the apparatus was not changed in any way, this would obviate any possible criticism that the rare gases had their origin in an air leak.

In the second place, the rare gases are produced when the condensed discharge is passed between aluminium wire electrodes through mixtures of oxygen and nitrogen, no result being obtained in the absence of the condenser. In these experiments the character of the discharge was found to be of great importance, as the production of the rare gases depended on the length of the auxiliary spark-gap, the capacity of the condenser, and the pressure of the gases. An increase in the gas pressure necessitated an increase in the length of the spark-gap. Considerable trouble was at first met with, owing to the fouling of the mercury in the exhaust pump by ozone and active nitrogen, and this difficulty was surmounted by interposing a vessel containing boiling mercury.

In the third place, the aluminium of the electrodes was replaced by tungsten; and in view of Boomer's observation that active helium is readily absorbed by this metal (*Proc. Roy. Soc.*, A, **109**, 198, 1925), we confined ourselves to the examination of the electrode splash. Little or no splashing occurred until the pressure of the nitrogen-oxygen mixture was reduced so far that the discharge tube phosphoresced strongly. After the discharge had been passed for sixty hours the electrode splash was heated, and helium and neon were obtained. In these experiments a 14-inch spark coil was used and supplied either with alternating current (110 volts, 50 cycles) or with direct current, using a mercury break. A condenser and auxiliary spark-gap were used in both cases.

Lastly, we have obtained a successful result by passing a condensed discharge between two tungsten electrodes about 1·5 inches apart in mixtures of oxygen

and nitrogen at atmospheric pressure. Before use the electrodes were strongly heated in a vacuum to remove all occluded gases. After passing the discharge for sixty hours, the electrodes were strongly heated and, after removing a small trace of hydrogen, pure helium was obtained. This result is one of very few in which helium has been obtained without the presence of neon, and may be accepted as a final disproof of any contamination by air. Moreover, no rare gas was obtained with the uncondensed discharge in the same apparatus.

These more recent results would seem to establish the reality of the formation of helium and neon in vacuum tubes, and completely to confirm the original observations by Collie, Patterson, and Masson. As regards the origin of these gases, we believe that they arise from the disintegration of the nitrogen atom. Attention may be directed to the fact that hydrogen is always to be found in the residual gases along with the helium and neon, although the greatest possible care was taken to remove it from the electrodes before each experiment. At the same time it may be pointed out that in spite of all precautions it is impossible to secure the total absence of oxides of carbon. Whilst it seems very improbable that our last recorded observation at atmospheric pressure can be attributed to the disintegration of carbon, it may be mentioned that Bell and Bassett (*Science*, 56, 512, 1922) noted the presence of helium lines in the spectrum of the negative tongue of the Sperry searchlight and suggest that this gas is produced by the disintegration of the carbon atom.

The Canadian School of Prehistory in France.

THE Canadian School of Prehistoric Research in France was started in Ottawa, Canada, in May 1925, when twelve fellows of the Royal Society of Canada were elected on a committee for the object in question. The first year's work in France under the auspices of "Les Beaux-Arts de France" in Paris, Ministry of Public Instruction, Department of Historical Monuments, etc., has just closed its labours, and the School can now be stated to have been fairly well launched and started, having gathered a rather extensive and interesting lot of materials for study and distribution to various academic and scientific centres throughout the Dominion.

The site, or *gisement*, granted by the Beaux-Arts to Canada is situated in the Dordogne district, at Combe-Capelle, near Monferrand, up the beautiful valley of the Couze river, Commune of St. Avit-Sénieur. Amongst the many problems in prehistory to be solved, there occur a number at this locality, as well as in other not distant *gisements*, including La Micoque and other Moustierian sites of the Vézère valley.

Combe Capelle was expected to yield some information desired, and the result of the work of the Canadian School at this site, in June, July, and August, has revealed a certain amount of excellent material—especially at the base of the section examined—bearing upon some of those problems. No sensational discoveries were made in this virgin piece of excavation, but a large amount of worked-stone implements of a very primitive sort were found in four distinct layers or beds at Combe-Capelle.

Two nearly complete skeletons of a fairly large rodent (Marmota), besides isolated and fragmentary bones and teeth of bison, equus, rhinoceros (?), were added to the collections of flint or stone implements made on the spot. The work was undertaken as a careful and methodical piece of investigation under the auspices of the Beaux-Arts in order to obtain certain definite results. Very curiously and roughly shaped implements were found in all of the four layers traversed, being especially abundant in the oldest two beds. Types not hitherto much heeded, on close examination, proved to be either new or unrecorded implements made by Moustierian man as revealed in the Combe-Capelle station, exhibiting much cleverness and skill, as well as resourcefulness in the result of his industrial achievements in stone.

The type of human beings living in this very early stage of man's civilisation utilised even the simplest, rudest, or most common type of flint-flake, obtained by one or more well-directed blows given by his right hand or left hand, holding a *percuteur* or hammer, and from this flake wrought a number of fascinating shapes of instruments for his everyday use, whether it were for hunting, skinning animals, cleaning hides, building canoes, or for domestic purposes.

This ancient citizen of the Couze valley, like Moustierian man of other parts of France, of the Channel Islands, and of Great Britain, made a number of racloirs (scrapers), tranchets, blades, knives, saws, and other tools of rough, yet of intelligent workmanship. All the implements found reveal, as of to-day, two types of men: one, careful and industrious, taking an intelligent interest in his work; the other, careless perhaps and heedless of the advantage of turning out a well-made tool, satisfied with a comparatively inferior article to meet his tastes in all likelihood. There were good, fine, and well-made implements discovered at Combe-Capelle, of materials carefully chosen, carefully wrought, which any one, even a twentieth-century man, might be proud to be able to produce. Time, evidently, was not of very much consideration, and amongst the best, or carefully made tools, some must have taken quite a long time to make.

Careful study of the various types discovered at Combe-Capelle by members of the Canadian School in France remains to be made, and it is hoped that excellent results will be achieved, besides the procuring of specimens to illustrate the various epochs in the history of human civilisation, for which France is specially noted:

The Chellean Period (Chelles in Seine and Marne); the Acheulean (Somme valley): Moustierian (Vézère valley), Aurignacian (southern France and at Cro-Magnon in Les Eyzies), Magdalenian (La Madeleine, of the Vézère valley); the Azilian (Mas-d'Azil, of southern France), and the Tardenoisian (Tardenois-en-Fer)—all French stations marking the advancement and progress of humanity throughout the ages of man in Quaternary times, in the last chapter of the history of life on this planet.

Liveing's Fire-Damp Indicator.

THE author of a note on p. 497 of NATURE of October 2, while giving credit to E. H. Liveing as the originator of the method of detecting and measuring fire-damp by means of an electrically heated platinum wire, wrote: "The apparatus in skilful hands would certainly measure fire-damp, but its value lay rather in its promise than in its practical utility." I desire to protest against this disparaging statement. I helped Mr. Liveing to make his original magneto-electrical machine, for this was before the days of the Faure battery or the Clowes hydrogen lamp. While

all sorts of physical laboratory methods for comparing the temperatures of the two platinum helices, for example, Wheatstone bridge, etc., were considered. Liveing elected to adopt the more simple photometric device of a sliding white angle block placed between the two sources of light. When the two sides appeared equally bright the position of the block read against a scale indicated the proportion of fire-damp. This was an operation which a fireman could perform quite as quickly and easily as the usual one with a 'cap.'

Not long after the development of this instrument, I went at the instance of Mr. Fletcher, of Bolton, to investigate fire-damp in his own and in some neighbouring fiery pits. Its practical utility was such that, at any place selected, about a quarter of a minute was sufficient to turn the handle, slide the block, and read the proportion from ½ per cent., the lower limit, up to about 2 per cent. While I was in Bolton there was a minor explosion of fire damp in a neighbouring pit, and Mr. Fletcher and I went there immediately. On reaching the place where the gas had fired the safety lamp filled with flame. On collecting gas from the roof I found it to be practically pure fire-damp, for, like hydrogen, it quenched the wire exposed to it in consequence of its greater mobility. If instead of writing "practical utility" the author had used the expression "general adoption," he would have been right. At this time the really practical man had much influence. He suspected instruments which he did not understand, and he did not want to have fire-damp found even in minute quantities where none could be detected by the usual means, and where therefore no danger existed.

C. V. BOYS.

IN my note I had no intention of disparaging the very ingenious invention of Mr. E. H. Liveing; on the contrary, I wished, while commenting on a new application of the same principle to recall the fact that the credit of utilising the increased glow of a heated wire over which a methane-air mixture is drawn, as a measure of the methane present, is due to Mr. Liveing. Like Prof. Boys, I tested the apparatus both near working faces and in the return airways of mines which gave off fire-damp. Although I cannot claim to approach Prof. Boys's unique experience in photometric work, I had had several years' practice in comparing the illuminating power of lights—and especially of lights of different tints—and I found it possible to make concordant readings with the instrument. But my companions—men of great mining experience—did not agree with my readings, or with each other's. The impression formed by me was that the indicator was not adopted because the mine-managers thought (rightly or wrongly) the instrument allowed too much margin to the 'personal equation.'

THE WRITER OF THE NOTE.

The Imaginary Roots of Equations.

IN discussing the stability of an oscillating system, it is often necessary to know whether the period-equation has any root the real part of which is positive. We proceed to show how to find out the number of such roots. Let the equation $f(z)=0$ be of degree n and let $f(iy)=u+iv$ where u and v are real. If v is of higher degree than u put $f_1(y)=-v$, $f_2(y)=u$, otherwise put $f_1(y)=u$, $f_2(y)=v$. Go through the operation of finding the G.C.M. of f_1 and f_2 with the difference that the sign of each remainder is changed before it is recorded or used as a dividend (just as in getting Sturm's Functions), and let the remainders (with changed signs) be $f_3(y), \ldots f_m(y)$. Let the number of changes of sign in the sequence $f_1, \ldots f_m$ be χ when $y=\infty$ and χ' when $y=-\infty$. Then the number of roots of $f(z)$ having their real parts positive, less the number having their real parts negative, is $\chi'-\chi$. If now there are r real roots of the common divisor $f_m(y)$ of f_1 and f_2, then $f(z)$ has $(\chi'-\chi+n-r)/2$ roots with the real part positive, $(\chi-\chi'+n-r)/2$ with the real part negative, and r purely imaginary roots.

For proof we divide f_1 and f_2 by $f_m(y)$ and $f(z)$ by the corresponding factor $f_m(-iz)$, and then find the increase in argument of $f(z)/f_m(-iz)$ on going round the positive half plane by considering its passages through $n\pi$ in the first case or $\pi/2+n\pi$ in the second. The number for the infinite semicircle is the degree of $f(z)/f_m(-iz)$, and that for the axis of y is found by reasoning very similar to that used for Sturm's Functions to be $\chi'-\chi$.

Spatial and Time Relations in Dreams.

THE letter with regard to so-called 'mind-pictures,' printed on page 372 in NATURE of September 11, has greatly interested me because such non-volitional pictures have been very familiar to me from my childhood up. I used frequently to amuse myself by observing them, especially when in bed, just before I went to sleep, but I can bring them on by closing my eyes at almost any time. They are non-volitional in the sense that I do not knowingly control their content. So far as my consciousness is concerned, I am simply in the position of an observer. The pictures are of moving events and include landscapes with persons and animals, buildings, trees, vehicles, etc. I am totally ignorant at any one moment with regard to what may appear on the scene at the next, and the whole thing is as interesting and amusing as if I were observing an actual scene. The fact that I do not amuse myself with these pictures in my adult age as I used to do as a child, I attribute to the fact that they are mentally tiring. Their production must involve some expenditure of energy in the brain in a way of which I am ignorant.

St. Louis, Mo., September 30

The Influence of General Electron Displacement on the Reactivity of Conjugated Systems in the Molecules of Carbon Compounds.

IN the September issue of the *Journal of the Chemical Society*, Baker and Ingold state that the nitration of benzoic esters is being investigated at Leeds. A similar study is in progress in these laboratories, and preliminary results show, for example, that the proportion of the *m*-nitrobenzoic acid derivative obtained on nitration rises in the series $Ph.CO_2 \leftarrow CR_3$ ($R =$ alkyl), $Ph.CO_2.CH_3$, $Ph.CO_2 \rightarrow CH_2 \rightarrow C_6H_4NO_2$. This is in accordance with the writer's theoretical views (*Chemistry and Industry*, 1925, 44, 118, 563; Allan, Oxford, Robinson, and Smith, *J. Chem. Soc.*, **129**, 401, 1926; Ing and Robinson, *ibid.*, 1655), and it is anticipated that the nitration of benzoic esters (and of substituted benzamides) will afford a convenient auxiliary method for the estimation of the electron affinities of various groups. The arrows show the assumed direction of displacement of electrons, methyl benzoate being the standard of reference.

The *Discovery* Expedition.

By Dr. STANLEY KEMP, Director of Research

August 18, 1926.

THE R.R.S. *Discovery* left Falmouth on October 5, 1925, and, after touching at Las Palmas and Ascension Island, arrived at Cape Town on December 20. On this passage apparatus and nets were tested, and certain defects which were found were made good. Later passages, until our return to Cape Town in June of the present year, are shown in the accompanying track-chart (Fig. 1).

We left Cape Town on January 17, delivered mails and stores at Tristan d'Acunha on January 30, and sailed for South Georgia on February 1. During the first few days very heavy weather was experienced and we were driven far out of our course by gales of almost hurricane force from the west and south-east. On the passage five deep-water stations were taken. We sighted our first iceberg on February 16, and arrived at Grytviken, in Cumberland Bay, on February 20. For about two months from this date we were engaged in observations on the whaling grounds, sailing for the Falkland Islands on April 17 and arriving in Port Stanley on April 25. A short cruise was made to Falkland Sound (northern end), where whales had been reported, and on May 20 we left on the return passage, laying a course to the north-east in order to pass the reported position of two shoals. On the passage nine full stations were taken and large plankton nets were towed at intervening points. Strong westerly winds and high seas prevented us from making as many observations as we had hoped. We reached Cape Town on June 29.

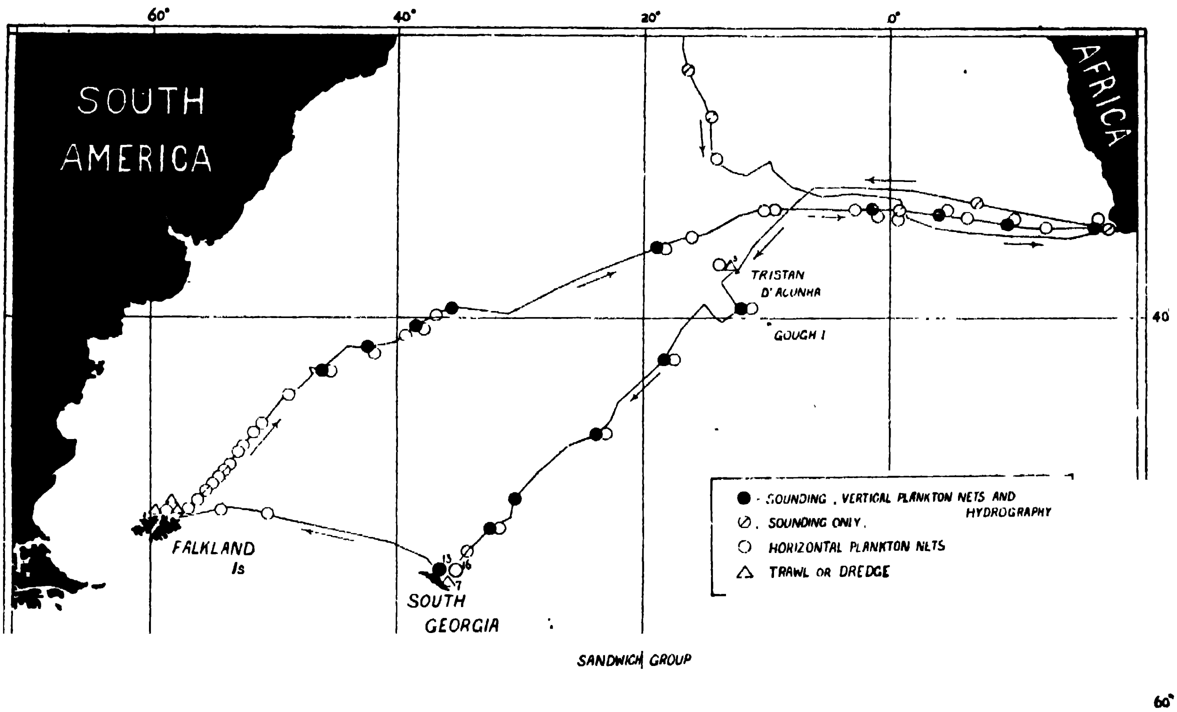

FIG. 1.—Track-chart of the R.R.S. *Discovery*, November 1925 June 1926.

An account of the *Discovery* expedition and its objects has already been published in this journal (vol. 115, 1925, p. 950), and our principal aim during the recent cruise was to carry out a biological and hydrographic survey of the South Georgian whaling grounds. In this we were largely frustrated by the bad weather which prevailed. Data of considerable interest were, however, obtained and experience acquired which will be of great value in our next attempt.

During the 1925–1926 season the whaling grounds at South Georgia were situated on the shelf on the north-east side of the island in soundings of 200 to 250 metres. In this area, at the time of our visit, Euphausian Crustacea were plentiful and *Euphausia superba*, which in our experience forms the only food of fin and blue whales, was often extremely abundant. *E. superba* is a comparatively large species, too active to be caught in vertical nets; to obtain adequate samples it is necessary to use nets towed horizontally. We have not yet sufficient material for a study of the life-history of this species. On the whaling grounds we obtained a few very early post-larval forms, while the great majority were in stages just short of sexual maturity. An Amphipod of the genus Euthemisto occurs in prodigious numbers in the same area and appears to feed almost exclusively on young Euphausians.

As regards hydrographic conditions on the whaling grounds, the most striking feature was the existence of a cold middle layer, with temperatures of about 0° C. at a depth of some 150 metres. This layer was

found to within about ten miles of the shore and, as shown by observations taken on our passage from Tristan d'Acunha, extends seaward to 50° 26′ S. The salinity increased regularly from about 33·7 per thousand at the surface to 34·3 per thousand at the bottom. As might be expected, at the end of the season Diatoms were almost absent on the whaling grounds, but a dense patch of *Thalassothrix longissima* was found in 51° 55′ S. and another of *Rhizosolenia polydactyla* between South Georgia and the Falkland Islands. Phosphates showed very high values in the whaling area, the readings, expressed in mgm. per m.^{3}, varying from 102 to 108 at the surface to 183 at the bottom. Hydrogen-ion concentration varied from 8·26 at the surface to 7·96 in the lower layers.

During a short cruise to the northern end of Falkland Sound, quantities of *Grimothea gregaria* were taken. This decapod Crustacean, which is the pelagic post-larval stage of the rock-lobster, *Munida gregaria*, no doubt forms the food of the rorqual whales which periodically visit the islands.

Large midwater nets have been hauled on numerous occasions, more particularly on the passage from the Falklands to the Cape, yielding collections which should add greatly to our knowledge of the plankton of this region. Among the more interesting forms are great numbers of Diphyids, including a species with scarlet zooids, several pelagic Nemertines one 13 cm. in length—Decapods with luminous organs belonging to the genera Sergestes, Systellaspis, Hoplophorus, and Stylopandalus, the Pteropod Schizobrachium, Thaumatolampas, and other peculiar Cephalopods, and, among the fish, Chiasmodon, Cynomacrurus, and *Stylophthalmus paradoxus*.

The Continuous Plankton Recorder has been employed on numerous occasions and has given successful records on runs which exceed 1300 miles in total length. Mr. A. C. Hardy, to whom the invention of this instrument is due, contributes an account of the apparatus and of the results so far obtained (see App. II.).

The 40-feet otter trawl was used on a few occasions in shallow water at South Georgia and off the Falkland Islands. The bottom fauna is very rich and varied, and, particularly in the former locality, quantities of Nototheniiform fish were taken. Among large collections of invertebrates special mention may perhaps be made of the ten-legged Pycnogonid *Decolopoda antarctica*, of which six individuals were obtained. Dredgings off Tristan d'Acunha resulted in large hauls of Alcyonaria and Antipatharia, and it was found that some colonies of the latter were being invaded by a small brilliantly luminous Actinian, apparently allied to the genus Girardia.

Between the equator and Ascension Island, over a distance of some 600 miles, vast quantities of Pyrosoma were seen every night at the surface, giving a most wonderful display of luminescence, and, at a later date, not far from Cape Town, a colony of another species of this Tunicate was caught which must have been fully 8 ft. in length when intact. Patches of discoloration in the water were on one occasion found to be due to the alga Trichodesmium, on others to swarms of Salpa, in which numbers of semi-parasitic Copepods of the genus Sapphirina were obtained.

During the course of the work, 48 deep-sea soundings have been taken and an examination made in the vicinity of a reported shoal lying to the north-east of the Falkland Islands. Latterly, tests have been made with a modified form of the Nansen tube, designed to bring up cores of ooze enclosed in glass tubes. With this apparatus a core of red clay 47 cm. in length, and one of Globigerina ooze 30 cm. in length, have been secured. It is anticipated that still better results will be obtained in the future. At two points between Tristan d'Acunha and South Georgia, in 46° 35′ S. and 50° 26′ S., the bottom was found to consist of a pure radiolarian ooze, a deposit apparently hitherto reported only from the Pacific. The deep-water echo-sounding apparatus unfortunately developed defects which rendered it unserviceable, but repairs have been put in hand and it is hoped that good results will be obtained with it during the latter half of the voyage.

While at South Georgia, the coasts of which are very poorly charted, as much survey work as possible was undertaken by Lieut.-Comm. J. M. Chaplin. He made a special visit in a sailing vessel to Undine Harbour in order to fix positions at the north-west end of the island.

To shoot and haul large nets and to carry out all the operations necessary for modern oceanographic research in a barque-rigged vessel such as the *Discovery* has naturally proved to be a formidable undertaking. The results we have obtained are due in no small measure to the interest and enthusiasm shown by Commander J. R. Stenhouse, who has invariably done his utmost to render the work successful.

A second ship belonging to the expedition, the R.S.S. *William Scoresby*, has recently arrived in Cape Town. She is of the whale-catcher type, and has been designed especially for whale-marking and trawling. According to the provisional programme which has been drawn up, both vessels will be employed on the south-west coast of Africa until the middle of October, the *Discovery* in plankton investigations on the whaling grounds off Saldanha Bay and the *William Scoresby* in whale-marking. Towards the end of October the passage to South Georgia will be made, the *Discovery* taking a southerly route and skirting the pack-ice. At the end of the year the two vessels will co-operate in a survey of the South Georgia whaling grounds, the *Discovery* afterwards proceeding to the South Shetlands, while the *William Scoresby* undertakes trawling in the vicinity of the Falkland Islands. The Marine Station at Grytviken, South Georgia, will be open throughout the season. I append an account of the work at Grytviken.

APPENDIX I.

WORK OF THE MARINE STATION AT GRYTVIKEN.

By N. A. MACKINTOSH.

The Marine Station was established chiefly for investigations on whales brought to the whaling station, and work has now been in progress since February 1925.

The main problems with which the whale work is concerned fall under the following headings: (1) the specific and subspecific identity of southern whales in comparison with their northern representatives; (2) the investigation of various problems connected with the reproduction, growth, and general breeding habits

of whales; and (3) the interrelations of breeding, migration, nourishment, age, adolescence, etc. Data have been obtained from 738 whales examined at South Georgia.

The routine work included under the first heading consists in the collection, by a series of measurements, of statistical records of the bodily proportions of a large number of whales and notes on a variety of external characters taken with the view of determining what characters are constant and to what extent variation may occur. In this way a large body of material has been collected for subsequent analysis. Attention has been paid to such parasites as occur, since the study of the species of external and internal parasites might be found to have a bearing on the distribution of species or communities of whales.

In regard to breeding and the subjects with which it is related, it should be pointed out that whaling at South Georgia is carried on almost exclusively during the southern summer. The indications point to the winter as the period of maximum pairing and calving, and the material so far obtained cannot therefore be regarded as complete until observations have been made which extend over the whole year. In order that these observations can be made, work is now being started in South Africa at Saldanha Bay, where whaling is carried on during the southern winter. In the meantime, some provisional conclusions can be drawn from the results obtained at South Georgia.

The type of information required relates to such problems as the time occupied by the different stages in the reproductive cycle, and the seasons at which they take place, the time required to reach sexual and full maturity, etc., and to the general reproductive potentiality of the stock of whalebone whales in southern waters. A certain amount of evidence has been obtained on a number of these points, and some indication can be given of the lines on which the investigations are developing. A study of the monthly increment in the average length of fœtal fin whales at South Georgia corroborates the theory that both pairing and parturition occur most frequently during the winter months, while the diversity of lengths of the fœtuses taken at any one time shows that the pairing and consequently the calving seasons are relatively extensive. There is evidence that parturition occurs when the fœtus has reached a length of about 6·0 metres, and the monthly average fœtal lengths suggest that this length would in general be reached about the middle of the southern winter. It does not in any case seem possible that the period of gestation can be much more or much less than a year. With regard to the frequency of the recurrence of pregnancy, the most that can be said at present is that whales probably do not become pregnant every year.

The study of the ovaries has revealed no sign of œstrus occurring between October and May, which is in keeping with the supposition that impregnation mostly takes place during the southern winter. The testes also appear to be in a quiescent condition. The inspection of the ovaries of whales taken in South African waters should be of special value in defining the pairing season more exactly.

An important point to be considered is the proportion of sexually immature whales which are killed. In the case of fin whales, about 26 per cent. are estimated to be immature, while in the case of blue whales, the ratio is so high as 58 per cent., a fact to which attention must be paid in considering the effect of the whaling industry on the general stock of whales.

A point of special interest arises from a study of the numbers of blue whales taken at different sizes. There are indications that the majority of these whales approximate to one of three different lengths, two of which represent a stage of growth at which the animal is still sexually immature. This suggests that young blue whales are inclined to visit South Georgian waters at two successive stages in their development towards maturity, living elsewhere between the stages until they grow to the next size. If they make regular annual migrations, the suggestion at once arises that the difference between the first and second sizes represents a year's growth. Then, assuming that the young are born in the warmer waters during winter and travel towards South Georgia during their first spring, it would follow that sexual maturity is reached just three years after birth. This, however, is a point which will need confirmation from a larger body of material, and it is noteworthy that no indications of the same nature have been detected in the fin whale statistics.

In regard to the estimation of the age of whales, there is some indication that the number of corpora lutea, including the traces of very old ones left in the ovaries, may be to some extent correlated with the age of the whale. The evidence is arrived at from a comparison of the length of the whale with the number of corpora lutea, and partly from the fact that blue whales, which appear to be taken in general at an earlier age than fin whales, usually have fewer old corpora lutea in the ovaries.

Several other points of interest have arisen, amongst which are the observation of a curious structure, found only in some immature female fin whales, which consists of a fleshy band bridging the entrance to the vagina, and the finding of a 24-mm. fin whale fœtus. Twin fœtuses have been found on two occasions.

Other work done at the Marine Station includes the chemical analysis of water-samples collected by the *Discovery* and investigations on elephant seals and on the bird life of the island. With the help of a motor-boat, with which the station is now provided, observations have been begun on the rich fauna of Cumberland Bay.

Appendix II.

A New Method of Plankton Research.

By A. C. Hardy.

Hitherto our knowledge of the density and distribution of the plankton has been gained from samples taken at a number of stations within the area concerned. When, as on long cruises, the stations have to be twenty, fifty, or even a hundred or more miles apart, it may be doubted whether such samples are giving a true idea of the planktonic content of the water traversed: at one point one may strike a swarm of Copepods, or between two others miss an important zone of Diatoms. For a long time I have felt the need of an instrument which, by giving a continuous record

mile by mile to scale, would enable one to study and compare the uniformity or irregularity of planktonic life in different areas, to measure the size, varying internal density, and frequency of patches, and to indicate more exactly than can be done with comparable tow-nettings whether any correlation exists between different species.

Whilst on the *Discovery* expedition I have been experimenting with such an instrument, which I am calling the Continuous Plankton Recorder. Numerous little defects and difficulties have had to be overcome; but now that, taken together, more than 1300 miles of plankton have been recorded, it may be of interest to publish a brief description of the instrument and a note of some of the results obtained by its use. It is a development of the simple Plankton Indicator which I used in the North Sea (*Min. of Agric. and Fisheries Fishery Investigations* II, vol. 8, No. 7, 1926), but in place of the silk netting discs, which had to be reloaded for each sample, I have substituted a long continuously moving roll operated by a propeller turned by the water through which it is towed. Like the Indicator, it is used at full speed without stopping the ship.

Fig. 2 is a diagram of the instrument. It has a hollow cylindrical body tapered at each end, is weighted in front and furnished with planes P and P′, a vertical fin V with adjustable rudder R, and buoyancy chamber Q, so that when it is towed at the point T it 'flies' like a paravane in a horizontal position in the water at the required depth. I am greatly indebted to H.M.S. *Vernon*, Portsmouth, which carried out stability tests up to a speed of 16 knots and fitted the present planes and fin in place of those of my own design which proved unsatisfactory.

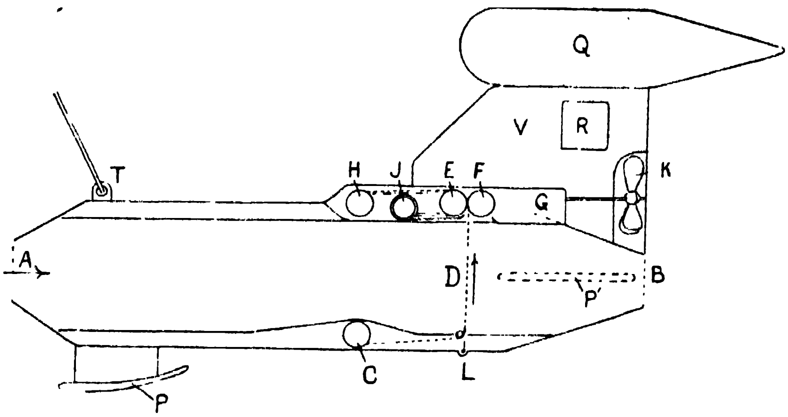

FIG. 2. Diagrammatic section of the continuous plankton recorder.

As the apparatus is towed, water enters through the circular opening A, passes through the cylinder and out at B. A length of silk netting, 9 inches wide and with 60 meshes to the inch, is arranged to wind off the braked roller C across the stream of water at D, where, supported behind by a gridwork of fine rollers, it catches the organisms in the water, then between the driving rollers E and F, which are of soft rubber but with hard ends gripping the edges of the silk, and so on to the storage roller H. The openings A and B, of 4 inches diameter, are smaller than that of D and approximately equal to the filtration area of the netting; a steady flow of water is thus assured, which by its pressure causes the organisms to adhere to the silk. The rollers E and F are driven through the gear-box G by the propeller K, and the storage roller H from E by a chain and friction drive, which prevents acceleration in winding due to its increasing diameter. At J, in a box, is a roll immersed in 5 per cent. formalin; this winds in with the catching roll between E and F, so preserving and separating the layers of organisms on the storage roller H. The instrument is hinged at L and made to open so that the rollers C, J, and H can be quickly taken out and replaced by others. It will be noted that the opening A is not masked by any towing bridle and cuts the water cleanly. The drawings of the instrument were prepared by Mr. M. T. Denne of

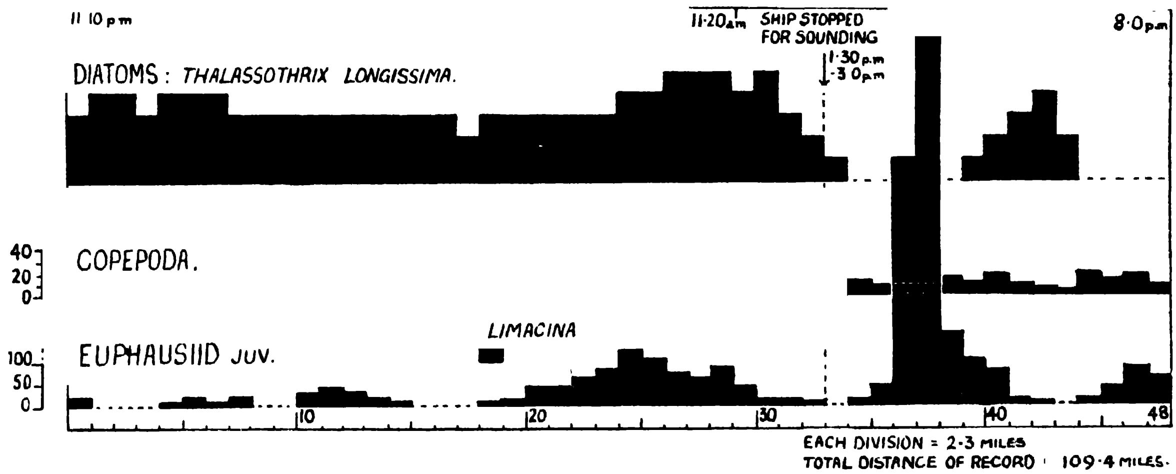

FIG. 3.—Graphic representation of continuous plankton record approaching South Georgia February 18-19, 1926.

310 Regent Street, W., to whom I am indebted for a number of valuable suggestions.

Each silk-catching roll is ruled with transverse numbered lines at 6-inch intervals. Rolls up to 75 sections in length may be used. The blades of the propeller are adjustable so that each section may represent an equal distance of one or more miles as required; the distance actually travelled by the instrument is measured by the ship's log.

At the end of the record the completed roll is unwound across a glass stage with mirror below and examined section by section with a microscope; occasionally an organism may have been removed from the netting for identification. As detailed an analysis is made as may be desired or time permits, from an exact quantitative estimation of all the species to a rough estimation of the general density in different places. The specimens are sometimes damaged in the process of winding, but in nearly all cases they can be identified; in areas where the plankton is well known determination is conspicuously easy. The instrument is not intended for collecting purposes, and, having different functions, is a supplement to, rather than a substitute for, the plankton net.

Fig. 3 shows one of the records obtained; it indicates the distribution of the Diatom *Thalassothrix longissima*, the Pteropod Limacina, the Copepoda, and young Euphausians on a run of 109·4 miles, each section representing approximately 2·3 miles. In the twenty-two records so far made there is evidence of a marked variation in the density and regularity of the plankton in different oceanic regions, and various methods of comparison may be adopted. Discontinuity is expected more in coastal waters, but in mid-ocean sharply defined patches of small Salps, *S. democratica* and *S. longicauda*, Pteropods of the genus Limacina, young Ianthina, Ostracods, Copepods such as *Candacia ethiopica* and *Calanus robustior*, and young Euphausians have been demonstrated. On the other hand, Diphyids and Chætognaths, where they occur, have tended to be constant in numbers. On one occasion, by their occurrence in patches on the roll together, a relation was suspected between small Salps and the Copepod *Sapphirina angusta*; this was afterwards confirmed by living material, the latter being found to enter the former and feed upon the food collected on the endostyle.

Operations with the instrument were temporarily suspended owing to a mechanical defect; this has, however, been remedied, and I hope in the coming season that many more results may be obtained.

City and Guilds (Engineering) College.

THE Duke of York, on October 21, opened the extension of the City and Guilds (Engineering) College at South Kensington, which has been provided by the munificence of the Goldsmiths' Company at a capital cost for building of 87,000*l*. Soon after the Royal Charter was granted in 1907 to the Imperial College of Science and Technology, of which the City and Guilds College forms the engineering department, it was decided that a large extension was necessary to provide adequate equipment for engineering education and research. A site was granted for the purpose by the Commissioners of the 1851 Exhibition to the north of the old college in Exhibition Road, and Prof. Dalby, the Dean of the College, drew up a scheme for three new laboratories: (1) hydraulics, (2) structural engineering, motive power engineering and strength of materials, and (3) railway engineering. Building was commenced in 1911 and completed in 1914, the architect being Sir Aston Webb. The laboratories, one of which is top-lighted, cover an area of 32,900 square feet. Apart from the cost of the building, defrayed by the Goldsmiths' Company, Mr. Hawksley contributed 4000*l*. towards the equipment of the hydraulics laboratory, the governing body of the Imperial College expended 20,000*l*. on equipment, and the Clothworkers' Company has provided 4000*l*. per annum for a number of years towards the cost of research. During the War, the buildings were occupied by the Government for war purposes, the structural laboratories, in particular, being used by the Admiralty as research laboratories.

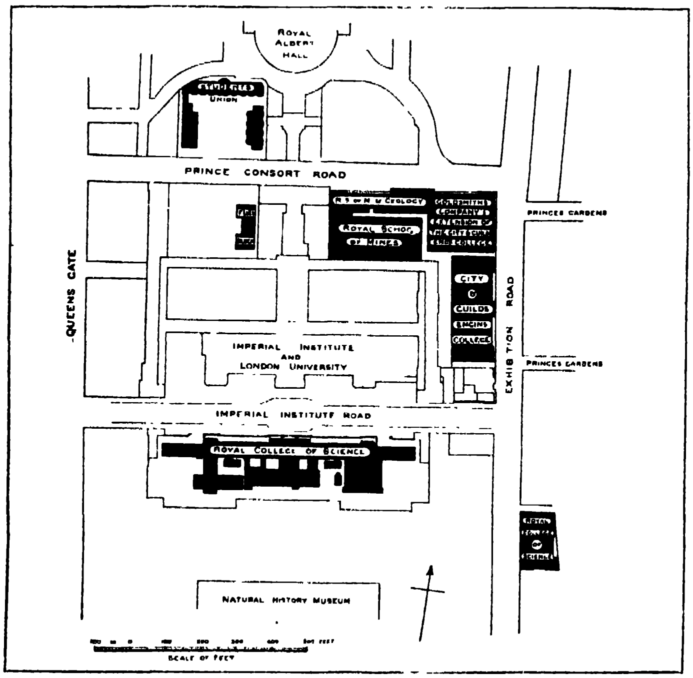

FIG. 1.—General plan of the associated buildings which have been erected on the site of the 1851 Exhibition. The areas coloured black indicate the buildings of the Imperial College of Science and Technology

The main building of the extension is in the shape of a letter **L**, the short arm facing Exhibition Road and the long arm Prince Consort Road, the space in the angle being filled by the top-lighted laboratory. The façades are pleasing and well-designed, and the building forms a worthy addition to the great group of educational and public buildings for which South Kensington is famous. Equipment has been provided

for the laboratories on a generous scale with the double object of training engineering students and providing for research. With the old building the new extension forms a complete unit providing undergraduate training in all branches of engineering for 500 students, post-graduate instruction for between 50 and 100 students, and opportunities for research.

In the unavoidable absence of Lord Buckmaster, the chairman of the governing body of the Imperial College, the guests were received by Mr. Herbert Wright, the chairman of the Executive Committee. Sir Dugald Clerk, as Prime Warden of the Goldsmiths' Company, delivered the building to Mr. Wright, representing the governing body of the Imperial College, and to Mr. Walter T. Prideaux, representing the delegacy of the City and Guilds (Engineering) College. The Duke of York, in declaring the building open, made a graceful reference to the interest which his grandfather, the late King Edward VII., had always shown in technical education. The late King, then Prince of Wales, laid the foundation column of the original City and Guilds College building in 1881 and became president of the City and Guilds Institute. Three years later he opened the buildings, declaring that the college represented one of the most cherished objects his lamented father (the Prince Consort) had in view. Finally, in 1909, towards the end of his reign, King Edward laid the foundation stone of the new Royal School of Mines, adjoining the engineering extension and also forming part of the Imperial College. Throughout his life his interest in technical education, inspired by the example of his father, was sustained and enthusiastic, and he took an active part in establishing many of the institutions at South Kensington which were rendered possible by the success of the 1851 Exhibition.

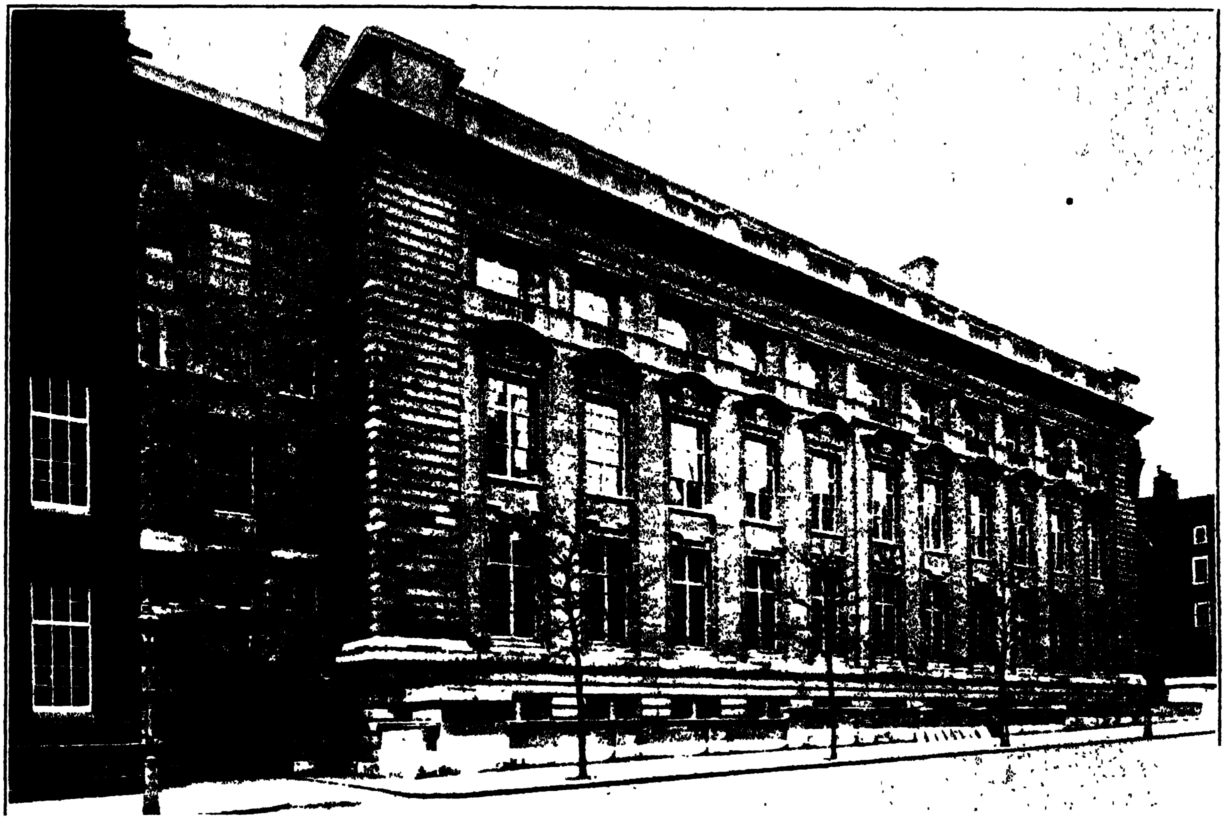

FIG. 2. The front, facing Exhibition Road, of the Goldsmiths' Company's Engineering Extension of the City and Guilds (Engineering) College.

The completion of this great undertaking, which places London in the leading position it should occupy in engineering education and research, provides an appropriate occasion for expressing appreciation of the work of the City Guilds in the promotion of technical education. Their munificence was enlisted in the earliest days of the movement and has not been restricted to London. Mr. C. T. Millis, the historian of technical education, states that the total grants of the City companies to the City and Guilds Institute amounted to the end of 1924 to 1,122,994*l.*, the Goldsmiths' Company heading the list with total grants of 204,523*l.*, followed by the Clothworkers', the Fishmongers' and the Mercers' Companies. Adding contributions to other institutions, including the Universities of Leeds and Sheffield, and the East London College, he estimates that the total amount expended by the companies must have exceeded 2,000,000*l.*

Naturally, the original schemes for promoting technical education were somewhat nebulous and have suffered modification in course of time. For example, the college at South Kensington, now dedicated to the training of engineers, was originally intended for the training of teachers in diverse crafts and industries. With the lapse of time also, the Government

and other public authorities have accepted an increasing responsibility for the maintenance of technical institutions; and the companies, relatively impoverished by the War and confronted by many other urgent calls for financial assistance, have shown a tendency to restrict their educational expenditure. One of the unfortunate results of this economy has been the recent closing of the Finsbury Technical College.

There is a desire also on the part of some of the companies to restrict their interest in technical education to the crafts represented by the respective companies; thus, the Clothworkers' Company has subsidised the textile department of the University of Leeds by a capital sum of 220,000*l*. and an annual grant of 4000*l*.; the Drapers' Company has devoted 20,000*l*. to scholarships for the textile industries; and the Leathersellers' Company have expended more than 20,000*l*. for a building for the Leather Tanning College.

In the early days of the technical education movement, a strong feeling was expressed by Huxley and others that part of the wealth of the city companies could be used to great advantage for the assistance of technical education. The educational deficiencies of the British workman were the first object of solicitude, and the provision of purely craft training still retains an important place in schemes of technical education. Developments in engineering, in the use of electricity, and in many other industries based on science, brought a demand for more specialised training, a demand which, in respect of civil, mechanical and electrical engineering, has been admirably met by the City and Guilds (Engineering) College.

The College has been loyally served by many distinguished professors and instructors and has rigorously maintained a high efficiency in all its work. No college can be trusted more implicitly to ensure proper standards of education and training in the award of degrees and diplomas. The College has sent out a large number of well-trained engineers to all parts of the world, and the Duke of York was well advised that he may expect to meet many City and Guilds men during his forthcoming Imperial tour. It will afford great satisfaction to all friends of engineering education that the College, thanks mainly to the generosity of the Goldsmiths' Company, has acquired this important addition to its equipment.

Obituary.

MR. G. W. LAMPLUGH, F.R.S.

BY the death of George William Lamplugh on October 9, British geology has lost one of its ablest exponents. Born at Driffield on April 8, 1859, he was educated at private schools, but spent the latter part of his boyhood at Bridlington, where the absorbing interest of the Yorkshire coast stimulated his natural bent for geology. Here arose a question, the answer to which was to determine the course of his future life. He had actually embarked upon a commercial career with geological work as a recreation. On one hand lay lucrative posts with the possibility of affluence; on the other, scientific research with a small competence. He considered the matter with characteristic deliberation; the possibility of affluence appealed to him not at all; he decided in favour of a life of research as soon as he was satisfied that the competence, if small, would suffice for his modest needs. In 1892 he joined the staff of the Geological Survey.

Lamplugh's first paper was published in the *Geological Magazine* in 1878 when he was nineteen years of age. In this and several papers which followed in the next few years, he described the sequence of beds which constitute the glacial drift of the Yorkshire coast, and the occurrence of marine shells, more or less fragmentary, in them. He noted also the drawn-out remains of a pond deposit crowded with the fresh-water shell *Limnæa peregra*, which occurred as lenticles in the boulder clay. At that time marine shells in the glacial drift were held by many to betoken submergence. Lamplugh then, as always, formed his own conclusions. Of the Bridlington Crag he writes that it is "probable that its great thickness and amassed appearance may have been due to the accumulating power of a huge mass of ice, which, grounding (and not, as with the smaller bergs, merely grating) on a soft bottom, would slowly continue its forward course for some distance . . . and might push before it a constantly increasing mass of sand and shells"; and again: "the movement of ice at one time on a soft sea-bottom and, at another, over the silty bed of a pond, has produced precisely similar effects." More than thirty years later I was with him and shared his excitement on seeing the process of transportation he had pictured, actually in operation in Spitsbergen.

The more important part of Lamplugh's work in those early years lay, however, in his study of the Speeton series and of his comparison of it with the Tealby series of Lincolnshire. He approached the subject from a thoroughly scientific point of view, bringing to bear an intimate knowledge of the fossils, acquired apparently and not taught, as well as detailed field-work. One of the results was to show "that in Lincolnshire, as in Yorkshire, the various species of belemnites present in the rocks afford the most natural and convenient means for classifying the strata; but that the well-defined zones which they form do not always coincide with the lithological divisions." This work attracted the attention of Prof. Alexis Pavlow, of the University of Moscow, and led to a joint paper on the correlation of the Upper Jurassic and Lower Cretaceous horizons of Speeton with their equivalents in Russia and other parts of Europe.

In 1892, as a member of the staff of the Geological Survey, Lamplugh commenced official duties which were to occupy nearly all the remainder of his life. He was entrusted soon after his appointment with the geological surveying of the Isle of Man. Except for a few weeks, during which I accompanied him for the purpose of initiating him in survey methods, he accomplished this great work single-handed. The range of problems which confronted him was prodigious, including as it did the sequence and structures of the older palæozoic rocks, the mapping of the newer palæozoic rocks and of the Trias, the great suite of igneous rocks, both contemporaneous and intrusive, an extraordinary development of glacial deposits, and lastly, mining developments that had once been of much importance. Some of

these lay outside the scope of his previous experience, but on all he brought to bear a judgment founded on the deliberate and exhaustive consideration of a problem from every point of view that was characteristic of him. Incidentally, I am reminded that we disagreed on the interpretation of the small tract we mapped together. I thought that certain structures in the volcanic rocks of Scarlet Point might be attributed to the turmoil of the eruption. He took the view that they were due to subsequent overthrusting. Which was right I do not know. The Isle of Man occupied him for five years. His memoir upon it, with its wealth of records and of original observations, takes rank as a classic in modern geology.

In 1901 Lamplugh was placed, as a district geologist, in charge of the Irish branch of the Geological Survey. He remained in Dublin until that branch was transferred to an Irish Department in 1905, and during his stay took part in the mapping of the country round Dublin, Belfast, Cork, and Limerick, turning his experience of glacial phenomena to great advantage. On his return to England he served as district geologist for the Midland district and afterwards for North Wales. Administrative duties took up much of his time, but he contributed to and edited several memoirs. Later on he was engaged in surveying part of the Wealden area and became concerned with the borings which were then being made to prove the extent of the Kent coal-field. The records of the boreholes were obtainable only under much difficulty, and many of them until they were interpreted by him were unintelligible. They revealed developments of the Secondary strata that differed from any known exposures, and when accompanied by the palæontological observations made by his colleague Dr. Kitchin, threw a new light on the Secondary geology of southern England. In 1903, with the late J. F. Walker, he wrote "On a Fossiliferous Band at the top of the Lower Greensand near Leighton Buzzard." The conclusions formed were not accepted by palæontologists, on the ground that the fossils were characteristic of a higher stratigraphical horizon and could not be in place. The beds, it was argued, must have been inverted, presumably by glacial agency. Lamplugh's last paper, in the *Quarterly Journal of the Geological Society*, in 1922, was devoted to a detailed account of all the sections in which the band had been recognised. He showed that the sequence originally described by himself and Walker has invariably held good in every successive exposure and over a large area. He did not regard the palæontological evidence as conclusive, and considered the suggestion of inversion to be untenable.

It was Lamplugh's desire to continue his work on the Lower Cretaceous rocks after his retirement from the Geological Survey in 1920, but it was not long before failing health rendered it impossible. In 1914 Lamplugh had been appointed assistant director for England and Wales. He held the post until his retirement. Never could there have been a more loyal colleague than he was to me.

Lamplugh loved travelling, but always with the view of increasing his geological experience. In 1884 he visited the Eastern and Central States of North America, Vancouver, and Alaska, and went southwards to the Mexican border and as far as New Orleans. In 1893 he saw the Grand Cañon of the Colorado, and in 1897 attended a British Association excursion to Vancouver. In 1905 he made a systematic examination of the gorge of the Zambezi, below the falls. "It is difficult to believe," he writes, "that the fissure into which the river is so suddenly precipitated has been formed gradually by the action of the river itself, and not by some great convulsion during which the very crust of the earth was rent." He was able, nevertheless, to find conclusive proof that the gorge was due to the erosive action of water as the river gnawed its way back into the heart of the continent, a view that had been put forward by Molyneux. In 1910 he attended the International Geological Congress at Stockholm and took part in an excursion to Spitsbergen. There, under the leadership of Baron De Geer, we were shown not only a magnificent development of Tertiary, Secondary, and Upper Palæozoic rocks, but also shelly drift in the process of manufacture. His last trip was to Australia, for the meeting of the British Association in 1914.

Lamplugh received several honours, but, if I may say so without breach of confidence, declined some through a somewhat over-sensitive modesty. In 1891 he was awarded by the Geological Society a half of the Lyell fund in recognition of his work on the Yorkshire coast, and in 1901 he received the Bigsby medal as an acknowledgment of the value of his researches on the Speeton series. In 1925 he was awarded the Wollaston medal, the highest honour in the bestowal of the society. He became a fellow of the Geological Society in 1890, served several times on the council, partly as vice-president, and was president in 1918–20. He was elected to the Royal Society in 1905, and served on the council in 1914–16. He was for a time secretary of Section C of the British Association, and was president of the section in 1906. He was past-president of the Yorkshire Naturalists' Union, of the Hull Geological Society, and of the Hertfordshire Natural History Society, and an honorary member of several other societies.

Lamplugh's work was characterised by thoroughness of observation and by his habit of devoting prolonged consideration to a subject before forming conclusions. Though an original thinker, he never advanced a view that he was not able to support by sound evidence. He was a wide reader, mainly of a class of literature that makes no appeal to the multitude, and had acquired a critical judgment of style. In his own writing he took infinite pains to express his exact meaning, and expected this of others. As a colleague he was loyal; as a friend, lovable. A. STRAHAN.

DR. PAUL KAMMERER.

THE family Kammerer is of Saxon descent. The ancestors migrated first to Transylvania, and from there to Lower Austria and Vienna. Here Paul Kammerer's father erected a manufactory for scientific instruments. Paul Kammerer was born on August 18, 1880, studied at the University of Vienna in 1899–1904, took the degree of doctor in philosophy on June 23, 1904, and got the *venia legendi* for experimental morphology at the philosophical faculty of this same University. Having been a member of the staff

of the Biologische Versuchsanstalt since its beginning (1902), he was given the post of state-adjoint when thi: institution was taken over by the Viennese Academy o Sciences, and remained in this post from 1914 until 1923 He then applied for his pension, and undertook lecturing tours to many European states, and twice to Nortl America. Last year he was called to Moscow, where he was appointed to a chair in the State University and was entrusted with the erection of a laboratory for the biological department of the Moscow Academy However, in a moment of mental depression, he deemed himself not able to undertake this task and shot himself on the Hochschneeberg, near Vienna, on September 23.

Kammerer's work will without doubt secure him a lasting place in the memory of biologists, even if some points in his papers require further elucidation and are still open to criticism. His scientific investigations were mostly published in the *Archiv. für Entwicklungsmechanik*. They apply to experimental modification of animal form, colour, and function, to their behaviour in subsequent generations, to regeneration and age, symbiosis, and the crossing of species. Kammerer's first studies were in pœcilogony or the modifiability of gestation in the same species For his discoveries of this phenomenon in *Salamandra atra* and *S. maculosa* he was awarded the Sömmering medal for the year 1909 by the Senckenbergische Naturforschende Gesellschaft in Frankfort-on-Maine. The president of this society, Prof. A. Knoblauch, had himself undertaken the task of repeating some of these experiments (*Zool. Garten*, 45, n. 11, 12, 1904). Kammerer later extended his studies on pœcilogony to Hyla, Alytes (1906), Proteus (1912), and Lacerta (1910, 1925). Summarising the results, we may say that external factors, especially temperature and moisture, may modify the reproductive process in amphibians and reptiles in such a manner as to shift it in the direction taken by other species living in localities with a corresponding climate.

For many years Kammerer was occupied with the adaptation of amphibians, reptiles, and other animals to the colour of the background. He showed that *Salamandra maculosa* is capable of changing its colour after metamorphosis according to the colour of light reaching its eyes (1913), and that this slow morphological colour-change evolves from the quick physiological colour-change in the larvæ (1922). These results, often doubted, have been confirmed from different quarters (see Przibram a. Dembowski, 1922 ; *A. f. Entwm.* 50, 108 ; Biedermann in *Ergebnisse der Biologie*, 1, 1925 ; MacBride, *Proc. Zool. Soc. London*, 3, 983, 1925). Succeeding several times in raising Proteus, Kammerer had the opportunity, in his experiments on pœcilogony and colour-change, to test the dependence of the eye on light, a question to which he was able to give a positive answer (1912). He also proved the restoration of the power of vision (*Pflüger's Archiv.*, 1913). The possibility that these specimens with enlarged eyes may have been mutations was later discarded even by the originator of this explanation, Jacques Loeb, in his last book, " The Organism as a Whole " (1916), as highly improbable.

Kammerer exhibited his most remarkable specimens to the Linnean Society of London, and in Cambridge, during the year 1923. The honour he was shown during his visit to England was one of his most pleasant recollections. Even if Kammerer's proof of the inheritance of acquired characteristics may be held to require confirmation, it is not too much to say that no one else has made greater advance towards the solution of this fundamental question, and that his numerous papers include several very important contributions to biological science. Results confirmatory of his views have been obtained by Dürkhen (1924) and Heslop Harrison (1925), who worked entirely independently of Kammerer, and on totally different animals. Kammerer's last paper on the origin of the island-races of Lacerta in the Adriatic (1926) is one of the finest contributions to the theory of evolution which has appeared since Darwin.

PROF. ALEXANDER GUTBIER, Rector of the University of Jena, died suddenly on October 4 at the age of fifty years. We learn from the *Chemiker Zeitung* that Prof. Gutbier was a native of Leipzig. He became professor of chemistry at the Technische Hochschule at Stuttgart in 1912, and ten years later he succeeded Prof. Knorr at Jena, where he built up an efficient modern chemical institute, in which numerous valuable researches in analytical and colloid chemistry were carried out. His own publications dealt chiefly with investigations of tellurium, selenium, and the noble metals, with atomic weight determinations, and with colloidal metals and protective colloids. He also published several works on practical chemistry.

WE regret to announce the following deaths :

His Honour Sir John Bucknill, Puisne Judge of the Patna High Court, formerly editor of the *Journal of the South African Ornithologists' Union* and author of works on the birds of Surrey and of Cyprus, on October 5, aged fifty-three years.

Prof. J. D. F. Gilchrist, professor of zoology in the University of Cape Town, and president in 1922 of the South African Association for the Advancement of Science, aged sixty years.

Mr. George Lewis, who devoted the greater part of his life to the study of the Coleoptera, and particularly the Histeridæ, visiting China, Japan, Ceylon, and Algiers, on September 5, aged eighty-seven years.

M. Edouard Naville, fellow of King's College, London, and a foreign associate of the Institute of France, listinguished for his archæological work in Egypt, on October 17, aged eighty-two years.

Mr. Washington A. Roebling, engineer and builder of the Brooklyn Bridge, on July 21, aged eighty-nine ars.

Mr. Oberlin Smith, an authority on the pressing and stamping of metals, and a past president of the American Institute of Mechanical Engineers, on July 8, aged eighty-six years.

Mr. Charles Turner, for many years principal of the Manchester School of Pharmacy, who made many contributions to our knowledge of the freshwater algæ, on September 10, aged sixty-two years.

News and Views.

THE address given by the Secretary of State for the Dominions and Colonies at the fourth session of the Imperial Conference is a further revelation of the growing popularity of scientific research as a theme for statesmen's utterances and an indication of their lost faith in ephemeral economic theories. The greater part of Mr. Amery's discourse was devoted to a survey of the problems of Empire development which await investigation and the steps which must be taken towards their solution. He announced that a very small committee has been appointed to consider what existing research organisations can do for the improvement of the production, transportation, and storage of Empire food-stuffs and raw materials required for manufacturers, what further support is necessary to make their work more effective, and what additional institutions are required He reminded the Empire premiers that the standard of work of the agricultural departments of the Colonies and of the agricultural staffs of various private companies is no credit to the Empire, and that there is need for greater support for such institutions as the Imperial College of Tropical Agriculture at Trinidad and the Amani Institute in Tanganyika, to act as training centres for agricultural staffs and as an inspiration to all agricultural departments in the tropics. Out of the fund at the disposal of the Empire Marketing Board, further support has been given to assist the work of the Low Temperature Research Station at Cambridge, probably a grant will be made to the Fruit Research Station at East Malling, and the Imperial Bureau of Entomology has been allocated a contribution to enable it to set up a special laboratory for the breeding of beneficial parasites and their distribution as required to all parts of the Empire Mr Amery expressed his belief that incalculable results will follow the expenditure of money derived from a fund which can be freely allocated to the vital needs of research on Empire problems

MR AMERY might have reminded the Empire delegates that the British Empire is on its defence in the matter of scientific research Great Britain has assumed the responsibility for the development of the illimitable potential resources of a large part of the world's surface It possesses some of the finest scientific investigators in the world, but hitherto our statesmen have not performed the essential function of catalysts in bringing the knowledge of the latter to bear upon the problems of the former. Several other colonial powers, notably France, Belgium, and Holland, have given more scope and encouragement to the work of their scientific researchers than Great Britain, and a former colonial power, Germany, in the comparatively few years in which it was interested in colonial development, built up a corps of research workers in every field of scientific endeavour and a chain of scientific institutions which still commands the respect of the world. Mr Amery's speech, it is hoped, will imbue the Empire premiers and other representatives with the same enthusiasm and appreciation for the need to apply science to the problems facing them as he and his able Under-Secretary, Mr. Ormsby-Gore, already possess. Elsewhere in this issue of NATURE appears the first of two articles referring to Mr. Ormsby-Gore's recently published report on West Africa, a report which can be commended to the Empire delegates for their most careful study. Therein is set forth in some detail the avoidable waste which occurs in this part of the British Empire in connexion with the production, storage, and transport of the products of the tropics, the avoidable waste of human endeavour and human life, the toll taken by insect pests on human beings, domestic stock and plants, the non-utilisation of natural resources, and the tremendous expansion of trade which would result if these problems were investigated by competent scientific workers

BOTH Mr. Amery and Mr Ormsby-Gore emphasise the need for co-ordination and dissemination of the knowledge accumulated by scientific investigators, to the end that science shall be applied generally throughout the Empire to the common problems of development But neither of them realises, apparently, that the present machinery of administration is inadequate to this all-important task. Last year the Prime Minister raised great hopes by the announcement of the creation of a body charged with the responsibility of initiating research into imperial problems. These hopes have not been realised The new body, the Civil Research Committee, was modelled on the Imperial Defence Committee · its deliberations are characterised by the utmost secrecy : even its findings and its reports on subjects of general interest are not made available to the public, and it has been overloaded with irrelevant problems No scientific man was appointed to the Committee; its work has been farmed out to *ad hoc* sub-committees possessing no powers and commanding no funds It bears no resemblance to the body suggested by Mr. Baldwin, and later by Lord Balfour during the House of Lords debate on the Report of the East Africa Commission the Report which gave such prominence to the need for scientific research in Empire development. Perhaps Mr. Garvin's demand in the *Observer* of October 24 for "a Great General Staff for . . . the systematic accumulation and arrangement of knowledge—a greater Domesday Book showing clearly what works, enterprises, and scientific institutions are required to make the most of the resources of the Empire in every part," may have the desired effect. Mr. Garvin might have added that it is imperative that this general staff should be composed mainly of those who have been trained in the methods of science, appreciate the aims of science, and understand its language.

IN his inaugural address to the Institution of Electrical Engineers, delivered on October 21, Dr. W H. Eccles presented a review of the present-day position of electrical industry in Great Britain, both in relation to its development and to the state of the industry in other countries. The conclusions he drew are in some respects unfavourable to British practice and he suggested certain necessary lines of

advance. Dealing first with electric supply, Dr. Eccles finds for the five countries, the United States, Canada, Germany, France, and Great Britain, taking only the larger undertakings which had collectively an output of 2000 million units or more in 1925, that the output in units per kilowatt of plant installed varied from 4500 for Canada to 2110 for Great Britain and 1820 for France. The low efficiency of the British undertakings is attributed to the smallness of the machines and stations and the rigid separation of the undertakings. The chief cause of the slow development in Great Britain appears to be the neglect of the principle of intercommunication. With a few large generating stations between which there is thorough intercommunication, each in turn can take the peak of the other's load. The size of each station need not then be so great and the efficiency of the whole undertaking is enhanced. In Germany there are four great zones the power of which varies from 400,000 kilowatts to 1,500,000 kilowatts, and these zones are now being connected into one national system Similarly in France, the United States and Italy, but in Britain the largest plant capacity is that of the London Power Company, which is about 250,000 kilowatts. The use of electricity on railways was discussed, and it was pointed out that the electrification of main lines may not lower the cost of working; its chief advantage will lie in providing national intercommunication networks and in extending electrical facilities into areas which could not otherwise be made suitable for modern factories.

It is satisfactory to note the growth in the use of electricity in the chemical and metallurgical industries pointed out by Dr. Eccles. There is a marked rise in the production of aluminium. In the case of sodium, we imported from Norway 41,800*l*. worth and exported 14,000*l* worth in 1924; in 1925 the figures are 17,000*l* for import and 28,000*l*. for export. Increases are also taking place in the production of ammonium sulphate and magnesium. Electricity in agriculture is backward in Britain. In Germany, 90 per cent. of the farms have an electric supply; in America there are 700,000 farms using electricity, but in Britain only 400 farms, *i e* 0·8 per cent., are supplied with electricity. One of the brightest points in the address refers to the export of submarine cable for telegraphy and telephony. The new type of cable loaded with permalloy (American) or mumetal (English) has rendered possible the transmission across the Atlantic of 2500 letters a minute. Of the 12,000 miles of this cable which has been ordered, all but one length is from British manufacturers. The positions of the telephone, telegraph and radio manufacture and services also come under review, and two appendices give details of the imports and exports of electrical apparatus and machinery for 1912, 1913, 1923, 1924 and 1925. The third appendix gives the export figures for the United States, Great Britain, and Germany for 1913, 1924 and 1925.

Perhaps the most significant fact brought forward by Dr. Eccles in his address was that referring to research and invention. Dr. Eccles has obtained statistics of the patents granted in America, Germany, and Great Britain, the three principal electrical countries. The native inventors were in the case of America 89·2 per cent. of the whole number; in Germany 77 per cent.; and in Britain, 57 per cent. Of the electrical patents in America, 13·5 per cent. are of foreign origin, and in Germany the figure is 26 per cent.; in Britain 59 per cent. are foreign. This means that "in this intellectual side of industry we have a big adverse trade balance, for which, doubtless, we pay a correspondingly large annual tribute in money." Dr. Eccles insists again upon the folly of starving technical education and research, which must both be considerably extended, unless we are to "pay other nations to do the necessary brain work for us."

On Monday last, October 25, a commercial high-speed radio telegraph service, utilising the principles of short-wave beam transmission and reception, was opened between Great Britain and Canada. This event followed the satisfactory completion of a preliminary seven days' test conducted by the General Post Office, during which the average speed of signalling was 600 letters per minute simultaneously in each direction. In England the transmitting station is situated near Bodmin and the receiving station near Bridgwater, while the corresponding stations in Canada are in the neighbourhood of Montreal. The stations at each end of this communication channel are similar in design, and they utilise a straight row of vertical aerials located in front of a similar row of wires forming the reflector, the resulting radiation is thus concentrated in the form of a beam directed towards the receiver. The wave-length employed is in the neighbourhood of 100 metres, and while the transmitting power is only 20 kilowatts, the effect of the reflectors at each end is to give a very much greater received signal strength than is obtainable with the usual type of aerial arrangement. Among the advantages possessed by this beam system for long-distance radio communication are the comparatively low capital cost of erection, economy of maintenance, freedom from atmospheric interference, and the possibility of very high signalling speeds. The combination of these advantages should result in the handling of a large volume of traffic at a cheap rate. The service now opened is the first of four similar beam circuits which will link Great Britain directly with Canada, South Africa, India and Australia. The completion of these 'point-to-point' services will, together with the high-power 'world-wide' station already in operation at Rugby, place Great Britain in the forefront of commercial radio practice.

The news that Messrs. Brunner, Mond and Co., Ltd, Nobel Industries, Ltd., the British Dyestuffs Corporation, Ltd, and the United Alkali Co., Ltd. are about to fuse their interests and form a huge chemical combination on the lines of the German Dye Trust, was not entirely unexpected, owing to recent activity in the shares of some of these companies. Rumour had mated Brunner, Mond and Co. with the

Dyestuffs Corporation, but the adhesion of the other two companies to the alliance was not anticipated. Only in July last, Lord Ashfield told his shareholders that it was more than probable that the Corporation would co-operate, and possibly consolidate, with other large chemical undertakings. On October 22 the directors of the four companies announced in the Press the proposed formation of a new company to acquire their shares and to develop their businesses and resources on broad Imperial lines. Nobel Industries already controls thirty companies largely, but not exclusively, engaged in the manufacture of explosives; and Brunner, Mond and Co. has a controlling interest in such important undertakings as Synthetic Ammonia and Nitrates, Ltd., and the Castner-Kellner Alkali Co., Ltd. The aggregate authorised capital of the associating companies is 47,500,000*l*., and their issued share capital is 38,225,714*l*. On October 22 the market value of the ordinary and deferred shares (24,918,753*l*.) was more than 40,000,000*l*.

SIR ALFRED MOND will be chairman of the new holding company, and Sir Harry McGowan, chairman of Nobel Industries, will be its president and vice-chairman. In a statement issued to the Press, Sir Alfred Mond emphasised the national and Imperial aspect of the combination. The existence of similar organisations on the Continent and in the United States has compelled the British manufacturers to combine their forces and present a united front to the rest of the world. The identity of the individual companies is not to be destroyed, but the board of the new company will act as a supervisory and connecting link between them, in finance and in policy. Modern mergers are not made to create monopolies or to inflate prices, but to achieve economy in effort and costs, and to provide insurance against market fluctuations. A combination such as that now contemplated will be able to finance, develop and explore many new potentialities in chemical industry, and so keep Great Britain in the front rank both as regards national safety and the supply of chemical products to a vast number of industries that depend upon chemistry. Few will disagree with Sir Alfred's remarks, although he did not mention certain disadvantages that sometimes result from the concentration of money and power in the hands of small groups.

ON October 22 a destructive earthquake occurred in the district of Alexandropol (or Leninakan) in Armenia. Three hundred persons were killed and twelve villages were badly damaged, but as communications in many places are interrupted, the full extent of the disaster is as yet unknown. Alexandropol is one of the most active earthquake-centres in the territory between the Black Sea and the Caspian, though it is surpassed in the frequency and severity of its earthquakes by two other centres, near Tiflis and Chemakha. On the same day three earthquakes were felt in California, only one of which was strong enough to cause slight damage. The interest of the shocks is due to their possible connexion with the San Andreas rift and the earthquake of 1906. Their centre was evidently some distance, perhaps a hundred miles, to the south of San Francisco.

SHORTLY after the announcement of the recent discovery of a skull of Pithecanthropus type at Trinil in Java (see NATURE, October 2, p. 491) private information from Washington made it appear likely that its importance had been overrated, and that the skull would not provide the data relating to the facial portion which anthropologists especially desired. Later news had not confirmed the first announcement that the skull was complete. It now appears that the find is not a skull but a cast in spongy stone of volcanic origin. Its appearance indicates that volcanic ash settled round the skull and, in time, the bone disappeared. The cast shows the frontal bone, the right and two-thirds of the left parietal bones, the upper part of the right and a little of the left temporal bones, and the supra-orbital ridge. It must be noted that the cast was not obtained *in situ* but from natives by whom it had been unearthed, so that the geological conditions of its discovery must remain in doubt. It is not easy to understand how a cast made in such circumstances, which normally would give the internal and not the external form, could show the characteristic supra-orbital ridge; but for the re-solution of this and other questions, the arrival of photographs must be awaited.

THE problem of peopling Australia is discussed by Mr. J. de V. Loder in an article in the October issue of the *Empire Review*. He quotes the late Lord Leverhulme's advocacy of black labour in tropical Australia as an opinion based solely on economic grounds, without consideration of the deeper sociological issues involved It is not merely the desirability of excluding cheap labour that would undercut the whites, but the danger of introducing social, political, and religious ideals unacceptable to white civilisation, that are the real arguments in favour of the 'white Australia' policy. The suitability of the tropics for permanent white settlement by an increasing population has not been proved, and cannot be proved except by experiment. Modern science has done much to solve the problem, but there still remains a doubt as to the possibility of racial acclimatisation on a large scale. Mr Loder thinks that the policy of keeping Australia for the white races is a justifiable gamble, and sees possibilities for white settlement in the hot dry regions of the north which are suited for sheep-ranching. In the hot wet regions he is less hopeful, and unfortunately for Australia these are the really productive and valuable parts of tropical Australia. In any event, there is little hope of attracting emigrants to such lands until the more temperate parts of Australia are filled.

ON October 9, H.R.H. the Duke of York opened the new X-ray Department in the Royal Infirmary of Edinburgh, which has just been completed at a cost of 52,000*l*. The new Department, which is about 160 feet long by 60 feet wide, contains a sunk basement and two floors. The basement contains a large motor generator supplying alternating current to the whole

of the Department, together with X-ray transformers, main control boards, and a workshop. Thus there is no moving machinery with its attendant rumble on the ground floor where all the X-ray rooms are situated (radiographic, screening and treatment) The deep therapy (250,000 volts) and superficial therapy sets are valve rectified. There are also a lecture and demonstrating hall, dark rooms, waiting and examination rooms, together with private rooms for the staff. On the upper floor, accommodation is provided for electrical and massage treatment, remedial exercises, radium treatment, and artificial sunlight treatment. Some features of the new building are designed with the view of furnishing the fullest protection for the operators against constant exposure to the X-rays. The walls are constructed of concrete slabs containing barium sulphate These afford protection equivalent to 5 mm of lead, as measured by the National Physical Laboratory, which has also inspected the completed Department. From the point of view of the X-ray Protection Committee's recommendations, the new Department is almost ideal, and it should prove a worthy model for future X ray departments The University has instituted a diploma, D R Edin, for which a candidate will take a suitable course in physics at the University and carry out practical work in the infirmary, the course extending over about a year.

At the thirtieth annual meeting and annual foray of the British Mycological Society, held at Hereford on Sept. 27-Oct 2, Dr. G. H Pethybridge, president, gave an address on "Mycology and Plant Pathology." The British Mycological Society to some extent may be looked upon as an expansion and continuation of the activities of the Woolhope Naturalists' Field Club, which originated fungus forays more than half a century ago. The fungus flora of Britain is now fairly well worked out, and more attention might be paid to the ecology and bionomics of fungi. Tracing the development of plant pathology in Britain, we find that at one time mycology was regarded as of little or no importance in relation to the causation of plant diseases; fungi occurring in connexion with disease were regarded as the *result* of such disease, not the cause of it. Disease in plants is the consequence of disharmony between the plant and its environment. A parasite, if present, is part of the environment considered in its widest sense, and it must not be forgotten that both host and parasite are to some extent variable or unstable and that the fluctuating factors of the environment may influence the parasite as well as the host. However, the parasite—most frequently a fungus—is often the most important factor in disease production. Plant pathology in Great Britain is of comparatively recent growth. The possibility of the introduction of the Colorado beetle occasioned the passing of the first Act of Parliament dealing with the protection of crops, it was extended and amplified as the Destructive Insects and Pests Act in 1907 on account of the spread of the American gooseberry mildew. A small *ad hoc* inspectorate was then inaugurated by the Board of Agriculture. The greatest stimulus to the development of plant pathology has followed from the provision by the State of greatly increased funds through the Development and Roads Improvement Funds Acts 1909 and 1910, and afterwards through the Corn Production Acts (Repeal) Act of 1921.

An appointment to a Beit Memorial Fellowship, of the annual value of 1000*l.* and tenable for five years, is to be made for whole-time research in tropical medicine; allowances will be given for travelling and laboratory expenses. Applicants must be of European descent and of degree standing in a university of the British Empire approved by the Trustees of the fund, and must state their proposed subject of research. Forms of application, obtainable from the honorary secretary of the fund, Sir James K. Fowler, at 35 Clarges Street, London, W.1, are to be returned on or by February 1 next. This fellowship is a noteworthy addition to the opportunities for research now available, and there is no doubt that it will lead to important contributions to our knowledge of health and disease in the tropics.

The seventeenth annual Exhibition of Electrical, Optical and other Physical Apparatus arranged by the Physical and the Optical Societies will be held at the Imperial College of Science and Technology on January 4-6 It has been decided again to include, in addition to the well-established Trade Section, a Research and Experimental Section similar to that successfully initiated in last January The groups in this section comprise (*a*) Exhibits illustrating the results of recent physical research and improvements in laboratory practice, (*b*) effective lecture experiments, (*c*) repetitions of famous historical experiments Offers of exhibits should be addressed to the Secretary of the Physical Society at the Imperial College of Science and Technology, South Kensington, S.W 7, not later than November 10

The People's League of Health, 12 Stratford Place, Oxford Street, London, W 1, has arranged two interesting series of lectures to be delivered during November and December at the rooms of the Medical Society of London, 11 Chandos Street, Cavendish Square, W 1. One series, on November 1, 8, 15, 22, 29, December 6, 13, and 20, deals with the mind in normal and abnormal subjects, and the lecturers are Dr E Mapother, Dr. E. D. Macnamara, Dr. N. Hobhouse, Dr H. Crichton-Miller, Sir Maurice Craig, Sir Robert Armstrong-Jones, Dr. W A. Potts, and Dr. A. F. Tredgold. The other series, on November 3, 10, 17, 24, December 1, 8, and 15, is on various aspects of diet and foods, and the lecturers are Dr. H Campbell, Prof. Leonard Hill, Prof. Winifred Cullis, Prof. W. E. Dixon, Dr. J. Lewis Rosedale, Prof. Hugh MacLean, and Dr. R. Ll. J. Llewellyn. The lecture hour is 6 P.M.

A licence under Section 20 of the Companies (Consolidation) Act, 1908, has now been issued by the Board of Trade to the Research Association of British Paint, Colour, and Varnish Manufacturers, which has been approved by the Department as complying with the conditions laid down in the Government scheme

for the encouragement of industrial research. The Secretary of this Association is Mr. J. B. Graham, 8 St Martin's Place, London, W.C.2.

IN the short notice of "Phototopography" by Mr. A. L. Higgins which appeared in NATURE of June 26, p. 889, it was stated that ground photographs had been used for surveys in Canada but not in other parts of the British Empire. The Surveyor-General of India points out that experiments with the photo-theodolite were carried out in India more than twenty-five years ago, and the method was utilised on the Mount Everest expedition. The ground photographs which are being taken this year in Kashmir will be utilised in conjunction with plane-table surveys. They will only cover a small area of the country. It was not the reviewer's intention to suggest that ground photo-surveying had not been tested in India or elsewhere, but that it had not been adopted for ordinary topographic surveys outside Canada.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A lecturer in physics at the Royal Dental Hospital of London, School of Dental Surgery—The Dean of the School, Leicester Square, W.C.2 (November 1). A head of the department of Leather Trades of the Port Elizabeth Technical College, South Africa—G. H. Penney and Co., 23 Lime Street, E.C.3 (November 8). A head of the mechanical engineering department of the L.C.C. School of Engineering and Navigation, Poplar—The Education Officer, T.1.a., County Hall, Westminster Bridge, S.E.1 (November 8). A chemist for tobacco work under the Egyptian Government—The Chief Inspecting Engineer, Egyptian Government, 41 Tothill Street, S.W.1 (November 12). An assistant lecturer (man) on education at King's College—The Secretary, King's College, Strand, W.C.2 (November 26). A professor of archæology in the University of Edinburgh—The Secretary, University, Edinburgh (December 31). An assistant chief entomologist, an entomologist and a mycologist under the Egyptian Ministry of Agriculture—The Under-Secretary of State for Agriculture, Ministry of Agriculture, Cairo (January 1). An expert in pisciculture under the Egyptian Government—The Royal Egyptian Legation, 7 Charles Street, Berkeley Square, W.1. A lecturer in physics and electrical engineering at the Handsworth Technical School—The Principal, Handsworth Technical School, Goldshill Road, Handsworth, Birmingham. A head of the mining department of the Barnsley Technical and Mining School—The Principal, Harvey Institute, Barnsley. A technical officer in the air-worthiness department, Royal Aircraft Establishment, South Farnborough—The Chief Superintendent, R.A.E., South Farnborough, Hants, quoting A. 130).

Our Astronomical Column.

RELATIVITY AND THE DAYTON MILLER EXPERIMENTS.—The issue of the *Nineteenth Century* for October contains an article on this subject by Prof. H. Wildon Carr. The article is largely of a philosophical character and emphasises the great change that relativity has brought about in our outlook on the phenomena of the universe. Interesting parallels are drawn with the Copernican revolution, and with the birth of philosophy in ancient Greece. There is also an explanation of the theory in non-technical language. Incidentally, Prof. Carr gives 5000 miles per minute as the earth's orbital speed: it should be 1110.

Referring to the system of dynamics accepted by Newton, Prof. Carr says "It is now rejected as untrue in theory and useless in practice." This statement, however, needs qualification. The tables of the sun, moon, and planets that are still in use are based on pure Newtonian principles, save for an empirical increase in the motion of certain perihelia (adopted long before Einstein explained its cause) and an empirical term in the moon's motion (quite unconnected with Einstein). The most ardent relativist would not desire to supersede these tables, since the changes in them that would result from Einstein's law are absolutely inappreciable with our present means of observation.

The close of the paper deals with Dr. Dayton Miller's repetition of the Michelson-Morley experiment, but it describes him as still adhering to the theory of an ether-drag, which diminishes with increasing altitude. Dr. Miller made it fairly clear in his lecture at the Royal Institution some months ago that he no longer holds this view. He now considers that observations at all altitudes (including the original Michelson-Morley experiment) indicate an apparent change in the velocity of light depending on the sidereal time of observation. The change is only a small fraction of the orbital speed of the earth; it was suggested that the Lorentz-Fitzgerald contraction damps down the observable effect, but does not conceal it entirely. This tends to weaken the argument drawn by Prof. Carr for the non-existence of the ether, from the difficulties which he rightly puts forward as regards an ether-drag.

SOLAR ACTIVITY DURING 1925.—An account of solar observations made at the Astrophysical Observatory of Catania is published by G. A. Favaro in "L' attività del sole nell' anno 1925," in continuation of the series commenced in 1919. Observations for sunspots were made on 332 days in the year 1925, for faculæ 290 days, for prominences 104 days, and for the measurement of the height of the chromosphere on 140 days. Tables are given of the mean frequency of sunspots, faculæ, and prominences. Drawings also illustrate the chief disturbances of the year, the dates selected for sunspots being February 14, May 5, November 26, and December 27; those for prominences being February 24, June 17 and 18. The highest prominence recorded during 1925 occurred on February 24 with a maximum height of 211″, or about 153,000 km. The mean height of the chromosphere measured in the C line of hydrogen was 10″·9 or about 8000 km., the monthly means of the measures ranging from 10″·5 to 11″·7.

It is of interest to show in tabular form the rise of solar activity since the last spot minimum in 1923 as indicated by various observations.

Observation.	Place.	Year. 1923.	1924.	1925
Daily sunspot frequency (groups and single spots)	Catania	0·7	1·8	3·6
Wolfer's "Spot Numbers"	Zurich	5·8	16·7	41·6
Daily spot areas [1]	Greenwich	55	270	829
Days without spots	Greenwich	171	97	19

Research Items.

INDIAN ORIGINS.—An ingenious if highly speculative note by Mr. H. Bruce Hannah in the *Journal and Proceedings of the Asiatic Society of Bengal*, N.S., Vol. 21, No. 1, deals with the question of the approximate period of the Mahābhārata war and the ethnological affinities of the participants in it. According to the legend the war was fought between the Kūrūs and their cousins the Pāndavas. The concrete historical protagonists appear to have been the Kūrūs (Dasyūs and their followers) and the Pāncha-Janāh. The Pāncha-Janāh consisted of the Pūrūs or Pauravas, Yādūs or Yādavas, Tūrvaśas, Ānūs, and Drūhyūs—all mentioned in the Rig Veda. They were probably four communities of western Asia, namely, the Philistines, the Amorites of Yādai in Nāharin, broken Hittites, and a Phallus-worshipping people called "The People of the Pillar," of Heliopolis, in Deltaic Khem, who had been driven out by Rameses III. about 1156 B.C. These were the people responsible for the introduction into India of the divine names afterwards transmuted into Indra, Mitra, etc. They settled in the Punjab, where they found aborigines and a dominant race of dark white, or perhaps semi-mongoloid, stock. These latter were the representatives of a widely diffused ancient central Asiatic people known to the rosy-blond Aryanians as Dahyūs or Tokhs, and descendants of the Kūśa or "wolf-folk." They were not, however, uncivilised, and they dwelt in cities. Possibly the culture discovered at Mohenjo-Daro and Harappa and the civilisation of Susa discovered by de Morgan are vestiges of this civilisation. As a result of the struggle between the Dasyūs and the Pāncha-Janāh about 1000 B.C. in the Mahābhārata war, the Dasyūs or Kūrūs established themselves and acquired some of the culture of the Aryan Kshatriyās, evolving what has come to be known as Brāhmanism and caste. Further, it is suggested that about 4000 B.C. Dahyūs from central Asia penetrated to south India and, combining with the aborigines, founded the Dravidian race.

NEW AND LITTLE-KNOWN INSECTICIDES.—In the August issue of the *Annals of Applied Biology* (vol 13, No. 3) Messrs. F. Tattersfield, C. T. Gimingham, and H. M. Morris have a fourth contribution dealing with studies on insecticides. In the present instance they are more especially concerned with the insecticidal properties of plant materials, in the form of alcoholic extracts. Perhaps the most interesting plants with insecticidal properties are certain kinds used by natives of tropical countries as fish poisons. The roots and stems of White Haiari and the stems of Black Haiari (both species of Lonchocarpus from British Guiana), the roots of *Tephrosia toxicaria* and the leaves of *T. vogelii*, when tested as stomach poisons, all exert both a repellent and toxic action to caterpillars. The most toxic substance obtained from the Haiaris is shown to be identical with tubatoxin, the crystalline poison found in *Derris elliptica*. In the same journal Messrs. C. T. Gimingham, A. M. Massee, and F. Tattersfield discuss the toxicity of 3 : 5-dinitro-*o*-cresol and its sodium salt to the eggs of certain species of insects. The figures obtained show that these compounds have a very high toxicity to insect eggs. The 3 : 5-dinitro-*o*-cresol at concentrations ranging from 0·5 per cent. to 0·15 per cent. killed 80-82 per cent. of the eggs of the hop-damson aphis and did not injure the trees upon which the trials were carried out. These two compounds exercised a marked cleansing effect upon the bark, and it is evident, if further trials substantiate the results obtained, that such compounds afford considerable promise as winter sprays upon various fruit-trees.

LITERATURE OF SALMON FISHERIES.—In a paper recently prepared by Mr. W. J. M. Menzies (*Fisheries, Scotland, Salmon Fish.*, 1925, II. (Edinburgh and London: H.M. Stationery Office, 3*s*. 6*d*. net)) is given a general index to the reports and papers issued by the Fishery Board for Scotland on the subject of salmon fisheries for the years 1882-1924 inclusive. This has been arranged to contain an authors' index, a subject index, and a district index in which can be found all the published information about any particular district, river, or loch. Arranged as it is in these three divisions, the work should prove of great value

FOREST IN RELATION TO HUMUS.—Dr. W. H. Pearsall has recently reviewed (*Journ. of Ecology*, vol. 14, No 2, August 1926) a number of publications upon the Finnish forests; a comprehensive publication of similar nature upon the Swedish conifer forests and their relation to the different types of humus, by Henrik Hesselman (*Meddelanden från Statens Skogsforsöksanstalt*, Häfte 22, No 5), has also appeared. Different types of humus covering are distinguished, and attention is directed to the importance of the agencies preventing undue accumulation of leaf debris in the permanent forest The mobility of the nitrogen in the products of decay, during the changes undergone by vegetable remains in the humus layer, is suggested as a very important factor in forest ecology, as also the content of the humus in acid and basic buffering substances The Swedish study covers some 330 pages, with a 40-page abstract in German.

VALUES OF SCOTS AND CORSICAN PINES.—A recent number of the Oxford Forestry Memoirs (No. 6, by W. E. Hiley), entitled "The Financial Return from the Cultivation of Scots and Corsican Pine," should prove of value to those interested in afforestation work in Great Britain By means of financial calculations the author endeavours to show, using for convenience the general term *range of probability*, the financial advantages to be attained by planting either Scots pine or Corsican pine on suitable soils of different quality. Mr Hiley bases his conclusions on the possibility that higher prices may rule in the future than those at present obtainable for these timbers. It may be premised that Corsican pine costs more to raise in the initial stages than the Scots, and its timber is at present priced lower. "The result of this investigation," says the author, "shows that on first quality plantations, if the costs of the two species are the same, except that Corsican pine costs 1*l*. per acre more to plant than Scots pine, then the financial yield from the two species will be equal if the prices obtained for Corsican pine timber are 59 per cent. of those obtained for Scots pine timber of the same size. On Quality II. sites, too, the price of Corsican pine timber would have to be about 60 per cent. of that of Scots pine to yield the same financial return. If the prices for Corsican are more than 60 per cent. of those for Scots the advantage is with the former, and if they are three-quarters, the advantages in favour of Corsican pine are very great." As a result of his study of this important matter the author considers that only under the most favourable set of conditions—cheap land, planting and cost of maintenance combined with high quality growth and a rise of prices of 1½ per cent.

per annum—could Scots pine yield five per cent. compound interest on money invested in it, and under similar conditions four per cent. on second quality soil. The possibility, of doubtful practical feasibility on large areas, of so ameliorating pine soils that they would grow more profitable conifers, for example, larch, or Douglas fir, is also considered.

UNITED STATES RIVER SURVEYS.—In recent years the United States Geological Survey has published a number of monographs on various river systems from the point of view of water supply. The same department has now issued, as Water-Supply Paper 558, a preliminary index to all existing river surveys in the United States accompanied by a map showing the drainage areas. Twelve major drainage areas are recognised as the basis of the classification adopted both by the Geological Survey and the Weather Bureau. The index is by States and rivers, with references to the drainage areas indicated on the map. Maps produced by all Government departments and various States and private bodies are included. The list, which is to be revised from time to time, forms a useful guide to the cartographic resources of the United States.

TERTIARY MARLS IN NORTH CAROLINA.—Mr. L. B. Kellum undertook the task of clearing up certain doubtful relations in the Tertiary section of North Carolina represented by the Castle Hayne and Trent Marls, through a systematic study of their faunas. The result, as set forth in the *U.S. Geological Survey Professional Paper* 143, has been to show that the Castle Mayne Marl has its strongest affinity with the Jackson horizon of the Eocene, and that the Trent Marl is of approximately the same age as the Miocene 'Silex Beds' of the Tampa of Florida. The palæontological portion occupies the greater part of the paper. The Castle Hayne fauna comprises 305 species, of which 214 are Bryozoa, and these last have been described elsewhere by F. Canu and R. S. Bassler (*U.S. Nat. Mus. Bull.* 106) The Trent Marls yielded only 26 species of Mollusca. Tables of the local distribution of all these are given with systematic descriptions, especial attention being devoted to the new species and varieties. Eleven exceedingly good plates and a useful index complete this important paper.

MAGNETIC MOMENTS OF ALKALI METAL ATOMS — In the *Physical Review* for September, J. B. Taylor describes a modification of the apparatus of Gerlach and Stern with which he has carried out determinations of the magnetic moments of sodium and potassium atoms. The metals were evaporated into the apparatus at 345° C. and 245° C. respectively, and the images formed by the deposition of the atomic rays on cool glass strips were rendered visible by immersing the strips in hydrochloric acid gas, whereupon films of opaque chloride were formed. Both metals were found to possess an atomic moment of one Bohr magneton, within the limits of experimental error, which were about ten per cent.

ELECTROMETERS.—The new list of electrometers and photo-electric cells issued by the Cambridge Instrument Co., Ltd., contains complete descriptions of the instruments and outlines of the theory of their action. The table of sensitivity data of electrometers given in the list will prove of special value to research workers. Taking the instruments under normal working conditions, the sensitivities of those using microscopes magnifying 8 to 12 times with eyepiece scales of 0·1 mm. are for the tilted gold leaf 100, the string 30, and the Lindemann 40 divisions per volt; for the Dolezalek quadrant 1000 mm. and the Compton quadrant 12,000 mm. per volt on a scale a metre away. These values may be varied considerably by changing the volts on plates or needle or the diameter of the suspending fibre, with corresponding changes in the time required to obtain a reading of the instrument. The photo-electric cells are of the pattern used at the Clarendon Laboratory, Oxford.

SURVEYING INSTRUMENTS —A new catalogue (No. 541), issued by Messrs. C. F. Casella and Co., Ltd., contains a description and price list of the very large number of instruments which this well-known firm is prepared to supply. There is scarcely an instrument required by the surveyor, engineer, navigator, or draughtsman which cannot be found in the catalogue. The firm invites special attention to its new Double Reading Micrometer Theodolite. This instrument is so arranged that all four micrometers and the bubble can be read without moving from the front of the instrument. Much time is saved by this device. Another new instrument to be noted is the Casella Precise Tilting Level. The spirit-level is entirely enclosed in the instrument, and is fitted with a prism, which brings the two ends of the bubble into view in the field of the telescope. By means of a slow-motion tilting screw under the telescope, the two ends of the bubble can be brought into vertical alignment, and the telescope is then level. The adjustment of the bubble is made by moving the prism longitudinally, by means of a slow-motion screw. This enables a very fine adjustment to be obtained. Messrs. Casella are willing to let out certain survey instruments on hire.

NITROGEN IN IRON-CHROMIUM ALLOYS.—In a paper on "The Effect of Nitrogen on Chromium, and some Iron-Chromium Alloys," read at the Stockholm meeting of the Iron and Steel Institute by Mr. Frank Adcock, it is shown that when chromium is melted in an atmosphere containing nitrogen, the gas is rapidly absorbed and alloys containing up to 3·9 per cent. of nitrogen are readily obtained. Hence the melting-point of the pure metal cannot be ascertained when the melt is exposed to such an atmosphere. Pure iron, on the other hand, absorbs the gas slowly, and even when nitrogen is passed for thirty minutes over the surface of molten iron, 0·02 per cent. only is retained. Iron-chromium alloys both in the liquid and solid states take up nitrogen at high temperatures; the quantity of nitrogen in the alloy increasing with the chromium content. In alloys containing about 12 per cent. of chromium, nitrogen gives rise to a martensitic type of structure closely resembling that usually associated with iron-carbon alloys. The hardness of these alloys can be considerably modified by heat treatment, and ranges from about 115 Brinell in the annealed state to 315 Brinell when quenched. Most of the alloys containing nitrogen in the range 20 to 60 per cent. chromium present a two-phase structure under the microscope. Although one of these constituents invariably develops a structure of the sorbitic or pearlitic type on suitable heat treatment, these changes are not accompanied by any great variation in hardness. This pearlitic or lamellar type of structure is absent from the corresponding pure iron-chromium alloys, and is thus not due to carbon. It would thus appear that the presence of nitrogen in iron-chromium alloys can give rise to structures closely resembling those generally attributed to carbon in ordinary steel. Micrographs of stainless iron often reveal a martensitic type of structure which has been difficult to explain. This work on the effect of nitrogen may reveal the cause of this structure.

The Skin Constrictor (Psychogalvanic) Reflex.[1]

By Prof. R. J. S. McDowall and Dr. H. M. Wells.

The term 'psychogalvanic reflex' has been given to the fall in the electrical resistance of the skin which occurs during mental effort or emotion. It is probable that the fall in resistance in not the sole change which occurs, but from the work of Thouliss it is evident that it is by far the greatest change concerned. Various explanations have been sought for by individuals whose interests lay in special directions and who were not fully acquainted with the literature of the subject or with the physiology of the factors concerned.

It will be shown below that the fall in resistance can readily be explained as being the result of constriction of the blood vessels of the skin. In the past, this conception has been ignored because of the fact first noted by Veraguth, that the reflex was not abolished by the cutting off of the blood to the part concerned. Since, however, it has become realised, largely as the result of the investigations of Krogh, that the peripheral vessels are independent of the blood pressure, such negative evidence carries no weight.

The Influence of the Circulation on the Resistance of the Skin.

In the past too little attention has been paid to this aspect of the problem. In 1924, however, Aveling, McDowall and Wells carried out a series of experiments on chloralosed or decerebrate animals in which it was found that all procedures calculated to bring about vaso-constriction in the skin, *e.g.* hæmorrhage, adrenaline and cold, caused a fall in the electrical resistance; while conditions producing vaso-dilatation, *e.g.* obstruction of the venous return, caused a rise. They found that the fall could be brought about by sensory stimulation in a decerebrate animal, thus showing the elementary nature of the reflex, and suggested that the term 'skin constrictor' reflex should be substituted. It should be stated that conclusive evidence was obtained that the change in electrical resistance was not brought about by activity of the sweat glands. This sweat hypothesis was shown to be based on ignorance of the pharmacological action of pilocarpine and atropine. It was actually shown that pilocarpine, in the sweating stage when the blood-vessels are dilated, caused a rise in resistance, although it may be preceded by a fall in the pallor stage. In this point the results of Waller were confirmed. In final condemnation of the sweat theory, it may be stated that Golla records an example of neurotic hyperidrosis in which the sweat literally dripped from the patient who gave a normal reflex. It is inconceivable that such activity would not interfere with the reflex were it due to increased glandular activity.

The work has now been further extended by Wells, who has shown in a very simple series of experiments, the details of which will be given in a forthcoming paper, that any alteration of the circulation through the skin of the hand causes a considerable change in electrical resistance, greatly in excess of that occurring in the reflex. For example, if the carbon dioxide which normally keeps up the tone of the vasomotor centre be reduced by over-ventilation, a procedure producing an obvious pallor of the skin, the fall in resistance may amount to 20-30 per cent. of the original resistance. On the other hand, if the peripheral vessels be dilated by preventing the normal venous return by compression of the arm with a sphygmomanometer cuff at a pressure of 50 to 60 mm., there is a marked rise in resistance.

It is, however, important to note that all such experiments can only be carried out if conditions, as indicated below, are such that vaso-constriction can show itself; while it is not until the subject is thoroughly accustomed to the procedure of the experiment that the effect of psychical states can be got rid of.

The Influence of the Circulation on the Reflex.

It has long been known that in cold weather it may be very difficult to obtain the skin constrictor reflex; indeed, it is a routine procedure amongst psychologists to wash the hands in warm water in such circumstances. It is evident that if the cold causes the skin vessels to be constricted, no further constriction may be expected. Mere compression of the skin vessels by the electrodes may prevent the reflex from showing itself. There is little doubt that this accounts for the fact that it is most readily obtained from the palms of the hands and the soles of the feet, since the superficial blood-vessels in these regions are protected by a greatly thickened stratum corneum. This may readily be observed by pressing the finger on the palm and back of the hand and comparing the pressure necessary to cause an evanescent pallor. There seems little doubt that the failure to obtain a rise in resistance in blushing is due to the fact that the vessels in the face are exposed, since Wells has shown that hyperæmia of the hand, produced by plunging the hand alternately into hot and cold water, gives a marked result.

In the usual method of obtaining the reflex there is added to the pressure of the electrodes the cold due to evaporation of the saline by which they are kept moist, while the skin becomes sodden. All these factors may interfere with the appearance of the reflex.

Similarly, the reflex is abolished by drugs which cause marked dilatation and paralysis of the skin vessels, such as large doses of alcohol and atropine.

It is important also to remark that many observers who have been unable to explain the fact have noted that there is great difficulty in obtaining the reflex in patients suffering from arterial disease such as arteriosclerosis.

Evidence of Vaso-constriction during the Reflex.

It is stated by Krogh that if the ear of an unanæsthetised rabbit is observed, the occurrence of the slightest unusual sound causes the blood vessels in that region to become constricted, while Carrier, working in the same laboratory, has recorded closure of the skin capillaries of man during a thunderstorm which caused much apprehension in the subject. Hemingway in this laboratory, using Lombard's method, has found that there is commonly a closure of the capillaries of the skin during conditions which produce the reflex. The constriction is, however, limited to certain capillaries, while others remain permanently open. To be certain of these changes it is necessary to observe a given area of skin for several days in order to be thoroughly familiar with the normal state of the region; and due precautions must be taken to prevent the capillaries being affected from other causes during the observations.

[1] Summary of a paper by the author, before Section I (Physiology) of the British Association, delivered at Oxford on August 5. (From the Department of Physiology, King's College, University of London.)

It would be expected from the foregoing that if the reflex is caused by vaso-constriction, there ought to be a diminution in the volume of the limb as shown by the plethysmograph. This has been thoroughly investigated by Golla, and in a Croonian lecture he states that he not only found that there was a constriction of the limb, but also that the time relations and the degree of constriction corresponded to the change in electrical resistance. We have fully confirmed these results, which may readily be demonstrated by the 'rubber glove' method.

On searching the literature the extremely interesting fact has come to light that this was the first experiment of its kind ever done by Mosso, the inventor of the plethysmograph. Mosso records that so important did he consider the experiment that he visited Ludwig in Leipzig to demonstrate it. So impressed was the 'father of physiology' by the reduction in the volume of the limb of the subject, Prof. Paglianni, that he wrote in German on the tracing "Enter the lion."

Mosso goes on to relate how the volume of the limb changed in a subject passing from 'seen' to 'unseen' Greek translation, and remarks that in such emotional constriction we have the explanation of the common saying "Cold hands and a warm heart"

Since the blood flow through the skin influences an individual's temperature sensations, a number of common sayings such as "the blood running cold," "the pallor of fright," "eat till you grow cold," may be considered to have been placed on a definite physiological basis.

Taken together with the experiments on animals, it appears clear that the reflex is a very elementary one which may be brought about without co-operation of the higher centres, as the result of sensory stimulation. It should therefore be known as the *skin constrictor reflex* and may be considered as part of the mechanism by which the animal normally adapts itself to the anticipation of muscular exercise and defence. In man it occurs not only on sensory stimulation, *e.g.* of a pin-prick, but also in anticipation of the stimulus. Here we may look upon a threatening movement as a conditioned stimulus which has developed as an effect of experience. The fact that many of the emotional stimuli affecting civilised man may bring about a reflex so closely associated with sensory stimulation physiologically and apparently teleologically, suggests that in responding to such stimuli the individual is, in a sense, defending or preparing to defend himself. The problem appears to offer an excellent line of psychological investigation.

Fuel Research

AT the postponed annual general meeting of the Institution of Gas Engineers, commencing September 21, a number of papers were submitted, some of a professional kind, dealing with such subjects as the layout and extension of works, and the supply of high-pressure gas, while others dealt with the principles and problems of carbonisation.

Among the latter was the sixteenth Report of the Joint Research Committee of the University of Leeds and the Institution of Gas Engineers, which contained the first results forthcoming from a systematic study of the different factors which influence the results obtained in the carbonisation of coal. The first factor examined was the influence of the size of the coal particles, which was shown to exercise an appreciable influence not only on the strength and nature of the coke produced, but also on the gas yield, this latter fact being traced to a cracking of the tar, which was more pronounced with the charges made up from the smaller sizes of coal. The retort used for the process was of 'Cronite' metal supported by a complete fireclay sheath, which enabled a gas-tight apparatus to be secured working at a temperature of 1000° C. without deterioration. A carbon balance could be struck, and also a thermal balance, which confirmed the deduction previously made that the products of carbonisation contained within 2 per cent. or 3 per cent. as much potential heat of combustion as the original coal.

A paper dealing with somewhat similar subjects was submitted by Mr. T. F. E. Rhead, who described results obtained on the experimental plant of the Birmingham Corporation Gas Department. Mr. Rhead concluded by a plea for closer scientific supervision of the retorting process as essential if it is to be carried out efficiently and economically.

C. B. Marson and J. W. Cobb reported striking results which they had obtained in studying the influence of the ash constituents in the gasification of specially prepared cokes in steam and in carbon dioxide. Working on a coal containing only 1 per cent. of ash, it was found that additions of 5 per cent. of different oxides made, in some cases, great difference in the results obtained. With the same rate of steam supply, the percentages decomposed were 61 for 'pure' coke, and 82, 91, and 98 for the calcium oxide, iron oxide, and sodium carbonate cokes respectively, while the corresponding percentages of carbon dioxide in the water gas generated were 9·2, 5·4, 21·6, and 0·4 respectively. Again, the percentages of carbon monoxide found after passing carbon dioxide at the same rate through the different cokes were 6·6, 29·9, 45·6, and 89·0 for the 'pure' coke, iron oxide coke, calcium oxide coke, and sodium carbonate coke respectively, while the enhanced reactivity was also displayed by the figure for quantity in grams gasified per hour, which was more than twenty times as great for the sodium carbonate coke as for the 'pure' coke. The increased reactivity of these special cokes so tested was, in the main, due to the specific catalytic effect of the added compound, and not to the alteration in physical structure on carbonisation resulting from the addition, which was sometimes itself quite remarkable. The importance of the results in connexion with such subjects as the preparation of a free burning carbonised smokeless fuel is obvious.

The fifteenth Report of the Joint Research Committee of the University of Leeds and the Institution of Gas Engineers was of a preliminary nature, and was concerned entirely with a careful and detailed examination of the conditions which have to be satisfied if trustworthy determinations are to be made, by the iodine pentoxide method, of any carbon monoxide produced in the use of typical gas appliances.

Another report submitted at the meeting was that of the Refractory Materials Committee, in the form of a series of papers. Among these may be mentioned papers by A. J. Dale, entitled "The Testing of Refractory Material for Resistance to Slag Corrosion and Erosion," and "The Control of Silica Brick-Making, based on Load-Test Indications," one by E. J. Vickers, entitled "The Influence of Oxidising and Reducing Atmospheres on Refractory Materials," and another by A. T. Green, continuing his work on "Temperature Diffusivities and Thermal Conductivities in relation to Silica and Fireclay Refractories."

University and Educational Intelligence.

BIRMINGHAM.—The Rev. Hilderic Friend, who recently presented his collections of earthworms to the British Museum, has now given to the biological department of the University a further collection of material, on which he has been working for thirty-six years. This material includes tubes of oligochætes (chiefly enchytræids) and water worms—some of them type specimens and quite unique. The gift also includes a valuable collection of books and MSS. and material relating to the distribution of annelids in Great Britain and Ireland.

The Alcester Rural District Council has presented to the Museum of Anatomy, as a permanent loan, a number of human skulls discovered in the course of some excavations at Alcester.

Messrs. Latch and Batchelor (Wire Rope Manufacturers, of Hay Mills, Birmingham) have offered to the Department of Oil Engineering a scholarship of 60*l*. per annum for three years, to be awarded to a candidate from one of the public schools and tenable in the Department of Oil Engineering as the Latch and Batchelor Scholarship.

Prof. W. Boulton has been elected Dean of the Faculty of Science to succeed Prof. T. Turner. Dr. F. W. Norris has been appointed lecturer in the Department of Brewing.

Prof. Keesom of Leyden lectured to a large and very appreciative audience in the Physics Department, on October 18, on the liquefaction and solidification of helium.

Messrs. Cadbury Bros. have made to the city a munificent gift of more than 150 acres of land, of which 100 acres is to be devoted to the site and grounds of a hospital. The land adjoins the site of the University at Edgbaston, so that the gift will have a far-reaching effect on the medical school of the University and will do much to solve the difficulties arising from the present geographical separation of the University buildings and the General and Queen's Hospitals.

CAMBRIDGE.—Mr. R. W. Ditchburn, Trinity, has been awarded an Isaac Newton studentship. This studentship was founded for the encouragement of study and research in astronomy and physical optics.

LEEDS.—The distinction of emeritus professor has been conferred on Prof. A. G. Perkin, who has recently retired from the chair of colour chemistry.

LONDON.—Subject to the consent of the Chancellor of the Exchequer to proposals put forward by the University, the Senate has authorised definite negotiations with the Duke of Bedford for the purchase of part of the Bloomsbury site.

Dr. Percy Stocks has been appointed as from August 1 to the University readership in medical statistics tenable at University College. Dr. Stocks was educated at Manchester Grammar School (1901–1907) and King's College, Cambridge (1907–11). In 1911 he obtained a medical scholarship at the University of Manchester. Recently he has been medical officer to the Galton Laboratory (1921–26) and also lecturer in vital statistics and epidemiology at University College since 1924. His published work includes several papers on the inheritance of bodily deformity published in *Biometrika* and the *Annals of Eugenics*, and a work entitled "Blood Pressure in Early Life" (Cambridge University Press, 1924).

Dr. C. H. Lobban has been appointed as from August 1 to the University readership in civil engineering tenable at King's College. He studied at Glasgow Technical College and the University of Glasgow. After works experience he became demonstrator in engineering at Glasgow, and later lecturer in engineering at Manchester; he was professor of civil engineering at the University of Madras from 1908 until 1910. Since 1920 he has been lecturer in civil engineering at King's College, London, and has also been consulting engineer in connexion with several important buildings in London and Nottingham. He is the author of a series of seven articles on "Railway Engineering" (1920).

Dr. H. T. Flint has been appointed as from January 1 to the University readership in physics tenable at King's College. He is a graduate in mathematics and physics of the University of Birmingham. Since 1920 he has been a recognised teacher of physics at King's College, London. His published work includes papers on the theory of relativity, and on four-dimensional vector analysis in the *Phil. Mag.*, "A Generalized Vector Analysis with Applications to Electrodynamical Theory" (*Proc. Roy. Soc.*, A, 1925), and "Text-Book of Advanced Practical Physics for Students" (Methuen).

A free public lecture on "Recent Developments in Cosmical Physics" will be delivered by Dr. J. H. Jeans at University College on Tuesday, November 9, at 5 o'clock. No tickets will be required.

NOTICE is given by the Royal College of Surgeons of England that the Thomas Vicary lecture will be given at the College at 5 o'clock on Thursday, November 4, by Prof. G. Elliot Smith, who will take as his subject "The Significance of Anatomy." The Bradshaw lecture will be given on Thursday, November 11, at 5 o'clock, by Mr. E. W. Hey Groves. The subject will be "Reconstructive Surgery of the Hip Joint."

THE Northampton Polytechnic Institute, situated at the Islington end of Clerkenwell, offers in its "Announcements, Educational and Social, for the Session 1926–27" a wide variety of courses. In engineering, full-time courses extending over four years are provided on the 'sandwich' system, students in their first year attending the Institute during each of the three terms, whilst for the second and third years they attend during the first two terms only and spend the remaining five months of each year in the works of industrial firms or, when necessary, abroad. Specialisation begins with the third year, when students choose between civil, mechanical, aeronautical, electrical, and radio engineering. The Department of Applied Optics caters for (1) optical engineers, optical instrument makers, and optical glass workers, this work being co-ordinated with advanced classes conducted at the Imperial College of Science; (2) ophthalmic and dispensary opticians. A Horological Department under the direction of an advisory committee representing the British Horological Institute, the Worshipful Company of Clockmakers, and the governing body of the Institute provide a full-time one-year course designed to attract members of the trade from all parts of the country. Other subjects in which instruction is provided, mainly in the evening, are telegraphy and telephony, industrial chemistry, electro-chemistry, furriering, and domestic subjects and women's trades. Grants-in-aid are received from the Skinners' and Saddlers' Companies. Students are actively encouraged to participate in the social and recreative activities of the Institute, the plant for which includes a 100-ft. swimming-bath and 14 acres of playing-fields.

Contemporary Birthdays.

Oct. 31, 1872. Sir E. J. Russell, F.R.S.
Nov 1, 1857. Prof. John Joly, F.R.S.
Nov. 1, 1876. Capt. Henry P. Douglas, R.N.
Nov. 4, 1855. Prof. Frederick Orpen Bower, F.R.S.
Nov. 5, 1876. Prof. Harold B. Fantham.
Nov. 5, 1848. Dr. James W. L. Glaisher, F.R.S.

Sir JOHN RUSSELL was born at Frampton, Gloucestershire, and educated at Aberystwyth and the Victoria University, Manchester. Head of the chemical department, Wye Agricultural College, from 1901 until 1907, he afterwards joined the staff of the Rothamsted Experimental Station (Lawes Agricultural Trust), succeeding Sir Daniel Hall in 1912 as director. Sir John is the author of important works on general agricultural science, and on soil biology.

Prof. JOHN JOLY'S scientific career has throughout been connected with the University of Dublin. Early he was a demonstrator there of civil engineering and afterwards of experimental physics, while for the past twenty-nine years he has occupied the chair of geology and mineralogy. Since 1901 Prof. Joly has been one of the editors of the *Philosophical Magazine*. President of Section C (Geology) at the British Association's Dublin meeting in 1908, he gave an address on "Uranium and Geology." The Royal Society awarded him a Royal medal in 1910 for his researches in physics and geology. Later the Geological Society allotted him its Murchison medal in recognition of his inquiries respecting the thermal properties of minerals, the relations of radioactivity to geology, and age correlations of the earth. Prof. Joly has made important contributions to the subject of colour photography, also to the theory of biological processes, such as the ascent of sap in vegetation. He is Hon. LL.D. Michigan University.

Capt. DOUGLAS, hydrographer of the Navy since 1924, was engaged in Admiralty survey work from 1897 until 1910; afterwards he was Superintendent of Charts. He is the inventor of various appliances used in navigation.

Prof. BOWER, emeritus professor of botany in the University of Glasgow, was born at Ripon. Educated at Repton, he graduated at Trinity College, Cambridge. Following teaching work in botany at the Royal College of Science, South Kensington, lasting until 1885 (the courses were held in Huxley's laboratory), Prof. Bower removed to Glasgow. In 1909 he was awarded the Linnean Society's gold medal, and in the following year the Royal Society allotted him a Royal medal, both in recognition of distinctive and unremitting services to botanical science.

Prof. FANTHAM was educated at King Edward's School, Birmingham, the Mason College there, University College, London, and Christ's College, Cambridge. Sometime lecturer in parasitology at the School of Tropical Medicine, Liverpool, he became demonstrator in biology at St. Mary's Hospital Medical School, London, and afterwards went as assistant to Prof. Nuttall at Cambridge. In 1917 he was appointed to the chair of zoology in the University of the Witwatersrand, South Africa.

Dr. GLAISHER was born at Lewisham. Educated at St. Paul's School, he passed into Trinity College, Cambridge (of which he is a fellow), graduating second wrangler. Author of many original papers in pure mathematics, and editor of two mathematical journals, the Royal Society awarded him its Sylvester medal in 1913. Dr. Glaisher has been twice president of the Royal Astronomical Society.

Diary of Societies.

SATURDAY, OCTOBER 30.

INSTITUTE OF METALS (North-East Coast Local Section, jointly with Institute of British Foundrymen) (at Neville Hall, Newcastle-upon-Tyne), at 6.15.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section) (at Children's Hospital, Birmingham).

MONDAY, NOVEMBER 1.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—C. E. Shattock: Demonstration of Scrotal Tumours.

SOCIETY OF ENGINEERS (at Geological Society), at 5.30.—Miss A. Ashberry: Some Products of a Small Machine Shop.

CHILD-STUDY SOCIETY (at Central Hall, Westminster), at 6.—Sir M. E. Sadler: Sandford and Merton.

INSTITUTION OF AUTOMOBILE ENGINEERS (Bristol Centre) (at Merchant Venturers' Technical College, Bristol), at 6.45.—G. F. Mucklow: The Effect of Reduced Intake-Air Pressure and of Hydrogen on the Performance of the Slow-speed Solid Injection Engine.

ARISTOTELIAN SOCIETY (at University of London Club), at 8.—Prof. C. Lloyd Morgan: Objects under Reference (Presidential Address).

SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.—Dr. H. Drake-Law: Artificial Colours used in Foodstuffs.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.30.—Presidential Address.

labours of the veterinary departments being devoted to the prevention and cure of disease. There are large areas in Sierra Leone free from tsetse fly, but no attempt has been made to introduce cattle. The researches of the French and the Belgians in the adjacent territories into the breeding of types of cattle immune from trypanosomiasis seem to be unknown to us, although Mr. Ormsby-Gore mentions the fact that there are a few thousand head of a small type of non-humped forest cattle in Southern Nigeria, uniformly healthy, apparently unaffected by the tsetse fly with which they are frequently in contact.

It was the existence of this immune type in Fonta-Djalon, Upper Guinea, Upper Gambia, and the Lower Saloum which led the French to investigate the relation between species, the size of species, and immunity, and to the interesting discovery that susceptibility to trypanosomiasis in all types of domestic or semi-domestic stock increases with their size. Further, it was established that the native herdmen had made use of this fact to produce, by crossing the immune species with the larger zebu (humped) varieties of cattle, the Djakore or Bambara species of cattle which retain much of the original resistance. On these bases crossing experiments were carried out in the Belgian Congo, with marvellous results, according to M. Roubaud, the chief of the laboratory of the Pasteur Institute.

Another aspect of animal husbandry is also emphasised: "Research in the mineral, as well as the vegetable, nutrition of stock appears to be well worth undertaking. The whole question of crossing, selection of bulls, and the improvement of herds is ripe for examination." In regard to plant products, it is recommended that each of the four territories should maintain a central research station, to which should be attached experimental farms, and connected with the principal agricultural training college for natives. The research carried out at these stations "should be co-ordinated not merely in West Africa, but with the similar research which is being carried on in Trinidad and at Amani in East Africa." Scientific workers will welcome the statement: "If we are to develop our tropical possessions we must realise the value of the scientific staff, both in the laboratory and in the field, and we must provide careers in the agricultural departments in the Colonies which will attract personnel possessed not only of high technical qualifications, but of capacity for leadership and ability to inspire others."

Mr. Ormsby-Gore, while recommending a research policy, makes no recommendation as to the priority of research. A fairly comprehensive programme of investigation is laid down, particularly in regard to human, animal, and plant diseases, and the breeding of improved varieties of domestic stock and plants, but what is lacking is a definite recommendation for the allocation of a specific sum to research. What is wanted in tropical Africa is a fund similar to that at the disposal of the Department of Scientific and Industrial Research in Great Britain, which would not depend upon the vagaries of the local directors of agriculture or the local governors. Such a fund might be created by the apportionment of a percentage of an export tax on palm-oil, cotton, cocoa, or any other of the principal products.

The need for further research in tropical diseases and the measures to be taken to secure a healthy and increasing population are emphasised, but not over-emphasised. In the absence of vital statistics, it is impossible to determine whether the population of West Africa is increasing, or stationary, or declining. Mr. Ormsby-Gore states that the general impression appears to be that the native population is increasing, but very slowly and imperceptibly. Where there are statistics available regarding the native population, as in certain parts of South Africa, it is proved that the rate of increase of native population is steadily diminishing. Contact with the white races apparently has this inevitable effect. Generally speaking, it can be said that in spite of the energetic methods adopted to stamp out disease, in spite of the knowledge we have acquired of the diseases which afflict the African populations and the means by which they can be prevented, the native population over the whole of tropical Africa is either stationary or declining in numbers. Bodily disease is not the only determining factor in this result. A psychological factor has to be taken into account. Rivers and others have attributed the decline of primitive populations to the loss of interest in life following upon the breakdown of their institutions, the suppression of their customs, and the atrophy of native arts and crafts on impact with our different institutions and different culture. We are confronted, therefore, with the dual task of disseminating knowledge of the means of preventing disease and getting the natives to apply it, and of arousing interests in new activities to replace those which have been lost.

The identifiable diseases which take the greatest toll of human life and energy in West Africa are malaria, dysentery, yaws, yellow and blackwater fevers, sleeping sickness, and leprosy among tropical diseases, and plague, venereal diseases, smallpox, and tuberculosis among the general afflictions of mankind. Many of these diseases could be dealt with at village dispensaries, if trained dispensers were available. Mr. Ormsby-Gore rightly stresses the need for the provision of centres where natives can be trained in the diagnosis and treatment of the commoner complaints, and for native sanitary orderlies whose duties would include the

destruction of the breeding-places of mosquitoes, both anophelines and Stegomyiæ, the destruction of rats, supervision of the general sanitation of towns and villages, the prevention of water pollution, and the notification of disease. These subordinate medical and sanitary staffs should not be drawn exclusively from the better educated coast natives, but, so far as possible, from every tribe in the interior. " A native is prepared to trust a European medical officer; he is also prepared to pay attention to a man of his own race, but he is not prepared to extend the same confidence to the African from another tribe." Even if he were, it is obviously desirable that knowledge of disease and its prevention should be possessed by some members of every tribe. We must help to supplant the 'medicine man' by the medical man drawn from the same tribe.

Emphasis is also laid on the need for training women for maternity and child-welfare centres. The infant mortality rate is grievously high in western as in all parts of tropical Africa, and the high proportion of still-births to births is one of the most deplorable features of tribal life. For the high mortality rate malnutrition is to be held responsible, but the number of still-births and abortions must be attributed to the prevalence of venereal disease and malaria. It seems fairly well established from the recent researches of Mr. Buxton in Melanesia that malaria is one of the principal determining causes of abortion and still-births. There is no reference, however, to these recent researches in the report before us. The difficulties in finding women sufficiently well educated to undertake the work of maternity and infant welfare are due to the neglect of female education. " The comparatively small provision which has been made for the education of girls as compared with the provision made for boys is very noticeable throughout West Africa." Mr. Ormsby-Gore's plea for going slow in this matter is not one which will commend itself to any well-wisher of West Africa. There is an urgent need for immediate and even precipitate action directed towards raising up a well-educated class of women. Reading the report, one feels that Mr. Ormsby-Gore overestimates the value of hospitals where surgical operations can be carried out, and underestimates the possibilities of schools for the native infants and adults where much could be done to build up the necessary outlook on disease. The creation of a large number of hospitals, which he advocates, while there are very few schools, is as wise as the present habit in Great Britain of spending large sums of money on the maintenance of sanatoria for consumptives but doing practically nothing to destroy the slums which provide the greater number of patients for the sanatoria.

A tremendous importance is attached by Mr. Ormsby-Gore to the need for greater transport development. He instances the remarkable progress made in the export of ground-nuts following the construction of the railway to Kano. Between 1910 and 1925 the exports of this crop from the Kano-Zaria district rose from 1910 tons to no less than 127,000 tons. He shares with Sir Frederick Lugard the belief in the productive capacity of the peoples to make any railway pay, and in the civilising influence of the railway. A considerable part of the report is devoted to detailed consideration of a railway, road, and harbour programme, but only passing reference is made to the need for systematic research into the possibilities of the flexible track vehicle. This type of vehicle, which is already in an advanced stage of development, and has been used by the Empire Cotton Growing Corporation for the transport of cotton from remote areas, possesses the inestimable advantage that it can traverse roadless country. It is a road-maker rather than a road-breaker. If improved, it would enable every part of the tropics, however remote, to be brought within the reach of regular transport services, and thus not only free for productive work thousands of labourers at present engaged in the wasteful system of head-porterage, but would also save the country the expense of making metalled roads, which are expensive to make and more expensive than a railway to maintain.

The report as a whole will repay the closest study by scientific workers. They have every reason to be grateful to Mr. Ormsby-Gore for re-emphasising the urgent necessity for applying the methods and results of science to the problems of tropical development, both in administration and production. A vast field of research is indicated, a field which it may be hoped will be surveyed with the least possible delay. Scientific workers must realise that they have a special responsibility in the matter. The knowledge which can be gained from scientific research is probably the most important factor in the full realisation of the potentialities of the vast British tropical possessions, and it is essential therefore that funds should be forthcoming immediately for the initiation of a bold programme of research. There is not the least excuse for Great Britain to lag behind other Colonial powers in this respect; there is every reason for it to lead the way. It is not enough for Mr. Ormsby-Gore to produce a report which will establish his reputation as the most far-sighted younger statesman of the day. His observations, his vision, and his recommendations must be appreciated by the nation, and this will be possible only if the scientific community assist the nation to a fuller understanding of the value of scientific research in every sphere of national and imperial endeavour.

Echoes of Tennessee.

Evolution and Religion in Education: Polemics of the Fundamentalist Controversy of 1922 to 1926. By Prof. Henry Fairfield Osborn. Pp. xiv + 240. (New York and London: Charles Scribner's Sons, 1926.) 7s. 6d. net.

ECHOES of the Fundamentalist controversy continue to travel across the Atlantic. The present volume consists of a collection of articles and addresses by Prof. H. F. Osborn dealing with the situation created by this strange revival. It is a phenomenon very difficult to cope with, being a product of popular education and democratic government. The only cure is more education of the right sort, but the Fundamentalists are striving to capture the educational machine. Prof. Osborn is aware that a mental atmosphere prevails not very favourable to scientific truth. "I hold," he says, "that the press and the movies are by far the most potent influences upon conduct in America at the present time." He regards the sum of press influence as morally good but intellectually bad, "because it creates what I call the jazz mind and a disproportionate sense of relative values."

The trouble with people at a certain stage is not only that they cannot appreciate evidence, but rather that they have positively no sense of spiritual or religious values. To attach religious value to the historicity of the myths in Genesis is a mark not only of intellectual, but also of religious, myopia. At this stage, one is either a Fundamentalist or a Secularist; it does not greatly matter which, for the two are correlatives. The tragedy of the situation, as Prof. Osborn points out, is that this recrudescence of superstition has broken out just at a time when the conceptions of men of science have become anti-materialistic. He himself says (p. 91): "If I have made a single contribution to biology which I feel confident is permanent, it is the profession that living Nature is purposive."

One remark of Prof. Osborn's seems to us especially noteworthy: "In my opinion religion and science will unite to control the future of mankind. This will be a simplified religion and a reverent science" (p. 177). But what is a "simplified" religion? Apparently Prof. Osborn hopes to get people to agree upon "a simple, elemental, and more or less primeval teaching on which all men, except those who persuade themselves that they are atheists, agree." It would include the Ten Commandments, the Lord's Prayer, the Sermon on the Mount, and "passages from the teachings of St. Paul and other missionaries." But this is the eighteenth-century chimera of natural religion in a new dress. Prof. Osborn overlooks the fact that these enshrinements of religious and moral teachings are based on a definite philosophical outlook, not always formulated, but capable of quite definite formulation.

This 'hang theology' attitude will not work—at least not for long. If the specific Christian view of God goes, the Christian value-scheme will follow, and carry along with it Christian ethics. This strikes us as a surrender. The strength of the Fundamentalist lies in his quite definite scheme of belief; and unless the Modernist or man of science can offer something equally definite and equally religious, he will neither win nor deserve to win. The future will be divided between the Fundamentalists and the Secularists, who alike know what they believe and why they believe it. There is no room for a vague religiosity, at least in a democratic country like America.

We have left ourselves very little space for estimating the more definitely scientific aspects of the book. Indeed, its excellence here should be beyond criticism. Prof. Osborn speaks throughout with the directness, lucidity, and easy freedom of the specialist and experienced teacher. Especially interesting is his exposure of the Fundamentalist misrepresentation of evolutionary teaching as deriving man's descent from apes. "The entire monkey-ape theory of human descent is a pure fiction," he says. The human line of descent is entirely independent of the apes; it is to a common ancestor that the two may be traced. This, perhaps, is all one to the Fundamentalist, in whose arguments caricature and invective take the place of facts and logic. We may hope that the perusal of this book may abate some Fundamentalist prejudices, at least in the case of those whose minds are still capable of reflection. We think that Prof. Osborn has done a public service to his countrymen in preparing and publishing it; it cannot always have been congenial work for a disinterested student of science who stands above the clamours of controversy.

J. C. H.

Prehistory in Britain.

Proceedings of the Spelæological Society for 1925. No. 3, Vol. 2. (University of Bristol.) 3s.

WHEN the editor of NATURE asked me to review the above work, I was particularly pleased to do so. It has always been a source of satisfaction to me personally that I was partly instrumental in turning the attention of the Spelæological Society of the University of Bristol, shortly after the War, towards prehistoric investigations. Previously, though the Society and its predecessor bore an honourable record for researches on underground water-ways, etc., little serious prehistoric work had been attempted. The

work of the 'Spelæos' has barely received the recognition it deserves; most people would be astonished to see how much material has been already collected and classified in the last few years; a visit to the Society's museum—housed in the new buildings of the University of Bristol—has become a necessity for all prehistorians. The difficulty has been that a few years ago—rightly or wrongly—the Society decided to publish its own *Proceedings* instead of combining with one of the older societies for this purpose. Folk as a rule are rather suspicious of new provincial publications of this kind, and it is to combat these suspicions in this particular case that this review is written.

The Society started its prehistoric explorations by having two pieces of rare good luck. I often wonder if my friends the 'Spelæos' realise how fortunate they were! Avelines Hole has proved a most important find of late Palæolithic date, and has yielded a rich and interesting collection of flint implements, not to speak of a harpoon—one of the very few found in Britain and several portions of human skulls. The second 'plum' was the Keltic Age cavern, and this was certainly no small discovery. Although starting off straight away with these first-class sites, members rose to the occasion and very creditable excavations were undertaken and duly published. Lately attention has been turned northwards and investigations started in the Wye valley; of course, Mendip—the first love—is by no means being neglected.

The present *Proceedings* contain a most attractive series of papers; mostly they are concerned with the various activities of the Society, but one or two articles on more general matters by outside contributors are included. The contents comprise: A fifth report on Rowberrow cavern, a third report on excavation of Mendip Barrows, a second report on excavations in the Wye valley, and a note on a Roman site on Bedminster Down; a short account of Guy's Rift, Slaughterford, follows, with a detailed description by Mr. L. H. D. Buxton of the early Iron Age skull found there. Other articles include: A study of certain caves in the north in relation to the ice ages by Messrs. L. S. Palmer and L. S. Lee, a survey of Upper Palæolithic industries from some Mendip caves by Mr. J. A. Davies, a note on the Upper Palæolithic in Britain by Miss D. A. E. Garrod, and a study of flint-flaking by Mr. H. Warren.

Among so much that is interesting it is rather invidious to pick out any special paper, but it is clearly impossible here to discuss such a long table of contents. Perhaps readers will be especially interested in the reports on Rowberrow cavern and the investigations in the Wye valley. The 'Spelæos' started work at Rowberrow several years ago—their first publication on the subject was in the *Proceedings* for 1920–21. Thanks to outside financial assistance, it has been possible to proceed on a large scale and the present (fifth) report gives a very complete picture of the various cultures found there. Quite a number of flint implements occurred, but it has been found that, though a late Neolithic industry is present, they mostly date to more recent periods—some being even Roman in age. Of course, it has been realised for some time past that the introduction of metal into the British Isles did not lead to the complete eclipse of all flint work, and that many of the surface finds are comparatively recent in date, but it is always satisfactory to have fresh confirmation, especially when a definite stratigraphy occurs. The discovery at Rowberrow of pigmy tools—though without, of course, the Tardenoisean burin—in late Neolithic layers is also interesting and confirms the assertions of H. Warren, who claims that some geometric pigmies in Essex are certainly not earlier in time than the late Neolithic and may even date to an early metal age.

Somehow or other the Wye valley seems to have been rather neglected by prehistorians. So long ago as 1919, in a note in the first *Proceedings* of the Society, I urged that attention should be turned to this favoured valley. The results of two seasons' work merely whet the appetite for more. King Arthur's cave—originally excavated in the 'seventies—has naturally first attracted the diggers, and it is surprising what they have obtained from what appeared at first sight a completely emptied chamber. But the whole district is simply riddled with caves and rock-shelters, and it will be astonishing if further investigation in future years does not bring to light other and still more interesting 'King Arthur's caves.'

The current *Proceedings* forms a notable publication, and the Society is to be indeed congratulated: archæologists can no longer afford to neglect its activities.

M. C. BURKITT.

Surfaces, Molecules and Ions.

An Introduction to Surface Chemistry. By Eric Keightley Rideal. Pp. viii+336. (Cambridge: At the University Press, 1926.) 18*s*. net.

THAT the cohesive forces which hold solid and liquid masses together, and produce the phenomena of capillarity at their surfaces, are ultimately identical with the forces producing chemical change, is an idea which has been latent in studies on capillarity since their inception. But the growth of this idea into a living theory, with power to inspire and guide many researches into the structure of surfaces, the surface properties of molecules, and the

mechanism of evaporation, solution, and catalysis, has been delayed until the last fifteen years. Dr. Rideal's book is probably the first in any language to attempt a presentation of all the modern developments of this idea. After an introductory chapter on pure liquids and their surface energy, the author presents Gibbs' adsorption equation—the reappearance of much of the original proof is to be welcomed—and plunges into the most recent work on surface films on liquids. A chapter on liquid-liquid interfaces includes information on emulsions and suggestions for bridging the gap in our knowledge between the theory of capillarity and of solution; solid-gas interfaces are treated with reference to crystal structure and to recent work on catalysis; adsorption, surface reactions, crystallisation, and disintegration are included under solid-liquid interfaces, and the section on electrification deals with the adsorption of ions, the double layer, cataphoresis, the Donnan equilibrium, and other subjects. There are two concluding chapters on the most important points in the theory of colloids, including the theory of Brownian movement, the charge on colloidal particles, and the structure of gels. The effects of adsorption in its manifold forms are traced through a great variety of phenomena.

The book is an able survey of an extensive literature full of interest at the present time. It is written with a keen enthusiasm and abounds in well-chosen references and in original suggestions. Its conception and plan are excellent. But close reading reveals that it is not particularly trustworthy as a text-book, and that it suffers from lack of thorough and critical digestion of the material and from hasty revision. For example, in the table of cross-sections of organic groupings on p. 77, values appear for –NC and CONHϕ, neither of which has been measured, and there are several other mistakes besides. On p. 129 the formula for the rate of growth of tarnish films on metals, as limited by the slow diffusion through the film already formed, is given without proof, and wrongly. It is not quite fair to the uninitiated reader to expect him to recognise the physical factors at work in this phenomenon from a misprinted formula, and no further explanation than that it is "the ordinary diffusion law." Elsewhere a thermodynamical argument is based on the hysteresis of the contact angle as if it were a reversible phenomenon, although it has been shown to be frictional in nature and irreversible; Harkins' 'oriented wedge' theory of the inversion of emulsions is given without noticing that its author has brought forward evidence very damaging to its simple form; and the theory of the very important 'maximum bubble pressure' method for determining surface tension is dismissed with an approximate formula and the remark that it "corresponds closely with that of the drop-weight method," which is scarcely a correct indication of the actual state of these theories. Sugden's development of the first of these methods ought to have been at least mentioned, as it gives not only the most accurate theory at the present time, but also an apparatus which, on the grounds of convenience and accuracy combined, is probably the best now available for ordinary use. Sometimes the author seems merely to have handed his notes to the printer, as when on p. 295 a hypothesis is given and the fact of its having been tested, a few words necessary for grammar are omitted, and the result of the test is not stated; and the nickname "McLewis" surely should not be used in print.

Some blemishes are, however, inevitable in a pioneer work on a rapidly growing subject, and the reader who will consult the original literature to which this book introduces him, when he needs fulness and accuracy, will find the book invaluable. It is alarming that, only a few months after the appearance of the book, it is already seriously out-of-date on some points fundamental to the theory of surface films. The book is likely to be found readable by fully trained students of physical chemistry; other scientific readers may find that the demands made on a previous knowledge of current technical terms and mathematical symbols are too heavy. Those who, like the reviewer, are already engaged in investigations on the subject will find it indispensable; and we may look confidently for fresh students to be attracted as a result of reading it.

Transmission of Stimuli in Plants.

The Nervous Mechanism of Plants. By Sir Jagadis Chunder Bose. Pp. xix+224. (London: Longmans, Green and Co., Ltd., 1926.) 16s. net.

ALL the recent work on cell respiration and nutrition leads to the conclusion that a real similarity exists between these processes in the plant and animal organisms. This being the case, it would seem possible that the mechanism of the transmission of stimuli may also be fundamentally the same in both. The problem of transmission in the plant has not received so much attention as that in the animal, on account of the comparative difficulty of dissecting plant tissues for experiment, but nevertheless a considerable number of theories have been put forward to explain the few known facts. Broadly speaking, the theories hitherto produced fall into two classes: those which attempt an explanation on a mechanical basis and those which incline to the idea of chemical stimulation. Sir

Jagadis Bose introduces a new conception—that of 'physiological excitation.'

None of the older theories has been sufficient to explain all the facts and the extreme rapidity with which a stimulus is effective in *Mimosa pudica* and other sensitive plants: these, when not completely ignored, have always been a stumbling-block. It is therefore of interest that in the present work, Mimosa has been chosen for the subject of the fundamental experiments.

Briefly, Sir Jagadis Bose claims to have found that in Mimosa there exists a definite nervous system which he believes is in practically every way identical with that of the animal. He repeats on this plant most of the classical experiments on animal nerves and nerve-muscle preparations. By means of the most ingenious apparatus he identifies the phloem with the actual conducting tissue; he demonstrates the falling of the leaflets under various stimuli, the time between the application of the stimulus and the response varying with the distance of the leaflet from the point of excitation. He finds that the falling leaflets are confined to the stimulated side except when the stimulus (usually electrical) is intense, when the response travels up one side and down the other; this is taken as evidence for two unilateral conducting strands meeting at the apex of the leaf. The latent period and the rate of transmission of the stimulus have also been measured, and it is found that the phenomena of make-and-break electrical stimulation are the same as in animal tissues.

Mimosa was chosen for these experiments on account of its rapid and definite reactions, but this class of plant stands alone in the vegetable kingdom, and it is doubtful whether theories based entirely on such experiments as these could be applied to all plants. An electrical reaction corresponding to the action current of an animal nerve is said to have been demonstrated for several plants.

In view of the need of confirmatory evidence and of the hostile criticism which this work is likely to evoke from orthodox botanists, it is greatly to be regretted that the experimental conditions are not given in greater detail. We have no doubt that every reasonable precaution was used, but it is hard to reconcile the observation that temperature has a very definite effect on the rate of transmission with entire absence of any attempt to control it in other experiments. Apart from any effect on the plants, the conditions must surely have been very carefully controlled when dealing with such very sensitive apparatus; the reflecting galvanometer used in some of the experiments gave a deflexion of 1 mm. at a distance of 1 metre for a current of 10^{-10} amperes.

Sir Jagadis Bose is to be congratulated on the way in which he has treated the problems and on designing so many instruments for exact measurement. It is difficult to believe, however, that he will succeed in demonstrating in plants a central nervous system, the presence of which he seems to suspect.

Our Bookshelf

Citrus Diseases and their Control. By Prof. Howard S. Fawcett. With Sections on Oriental Citrus Diseases by H. Atherton Lee. (McGraw-Hill Publications in the Agricultural and Botanical Sciences.) Pp. xii + 582. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926.) 25*s*. net.

A LARGE amount of valuable investigation has been carried out during the last twenty years on the etiology and control of citrus diseases in the main producing areas, but no book embracing the results of this work as a whole had been offered to the industry. This deficiency is very adequately met by Fawcett and Lee's volume.

The elder author's work, first in Florida and later in California, has established his name as that of the foremost citrus pathologist, and the book is necessarily, in no small measure, a record of his own investigations, adapted in a clear practical way to the needs of the California and Florida growers.

Lee's first-hand acquaintance with diseases in the Philippines and in parts of China and Japan, the recognition of those present in the Mediterranean region, Australia, South Africa, and the West Indies, and the extensive bibliography, make the work useful also to pathologists.

The arrangement of the matter follows customary lines, and the numerous illustrations are mostly from photographs showing the macroscopic characters of the lesions; many of the plates, in colour, appear strikingly true to Nature. In the treatment of the diseases definitely proved to be caused by parasites, enough is said, doubtless, of the micro-organisms concerned to satisfy the curiosity of the practical man. A number of new terms are proposed, with the view of furthering uniformity in the international nomenclature of plant diseases. These terms, like some which have already been gaining ground, such as gummosis, psorosis, and verrucosis, are based on some salient character of the lesion or gross appearance. The three terms mentioned indicate the difficulties involved: verrucosis is caused by a definite parasite; the cause of psorosis is unknown; gummosis may be due to a number of things, including five parasites at least, so the name of the parasite must be added to define the particular case (Pythiacystis *gummosis*, Diplodia *gummosis*, Botrytis *gummosis*, etc.). Among the rather strange-sounding new terms may be mentioned cancrosis for citrus canker and rubellosis for the pink disease of the tropics, both caused by specific parasites; foliocellosis (frenching or mottle-leaf), endoxerosis (internal decline of the lemon fruit), adustiosis (red blotch), and oleocellosis (oily spot) are non-parasitic diseases.

mechanism of evaporation, solution, and catalysis, has been delayed until the last fifteen years. Dr. Rideal's book is probably the first in any language to attempt a presentation of all the modern developments of this idea. After an introductory chapter on pure liquids and their surface energy, the author presents Gibbs' adsorption equation—the reappearance of much of the original proof is to be welcomed—and plunges into the most recent work on surface films on liquids. A chapter on liquid-liquid interfaces includes information on emulsions and suggestions for bridging the gap in our knowledge between the theory of capillarity and of solution; solid-gas interfaces are treated with reference to crystal structure and to recent work on catalysis; adsorption, surface reactions, crystallisation, and disintegration are included under solid-liquid interfaces, and the section on electrification deals with the adsorption of ions, the double layer, cataphoresis, the Donnan equilibrium, and other subjects. There are two concluding chapters on the most important points in the theory of colloids, including the theory of Brownian movement, the charge on colloidal particles, and the structure of gels. The effects of adsorption in its manifold forms are traced through a great variety of phenomena.

The book is an able survey of an extensive literature full of interest at the present time. It is written with a keen enthusiasm and abounds in well-chosen references and in original suggestions. Its conception and plan are excellent. Citrus Diseases and their Control. By Prof. Howard S. Fawcett. With Sections on Oriental Citrus Diseases by H. Atherton Lee. (McGraw-Hill Publications in the Agricultural and Botanical Sciences.) Pp. xii+582. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926.) 25*s.* net.

A LARGE amount of valuable investigation has been carried out during the last twenty years on the etiology and control of citrus diseases in the main producing areas, but no book embracing the results of this work as a whole had been offered to the industry. This deficiency is very adequately met by Fawcett and Lee's volume.

The elder author's work, first in Florida and later in California, has established his name as that of the foremost citrus pathologist, and the book is necessarily, in no small measure, a record of his own investigations, adapted in a clear practical way to the needs of the California and Florida growers.

Lee's first-hand acquaintance with diseases in the Philippines and in parts of China and Japan, the recognition of those present in the Mediterranean region, Australia, South Africa, and the West Indies, and the extensive bibliography, make the work useful also to pathologists.

The arrangement of the matter follows customary lines, and the numerous illustrations are mostly from photographs showing the macroscopic characters of the lesions; many of the plates, in colour, appear strikingly true to Nature. In the treatment of the diseases definitely proved to be caused by parasites, enough is said, doubtless, of the micro-organisms concerned to satisfy the curiosity of the practical man. A number of new terms are proposed, with the view of furthering uniformity in the international nomenclature of plant diseases. These terms, like some which have already been gaining ground, such as gummosis, psorosis, and verrucosis, are based on some salient character of the lesion or gross appearance. The three terms mentioned indicate the difficulties involved: verrucosis is caused by a definite parasite; the cause of psorosis is unknown; gummosis may be due to a number of things, including five parasites at least, so the name of the parasite must be added to define the particular case (Pythiacystis *gummosis*, Diplodia *gummosis*, Botrytis *gummosis*, etc.). Among the rather strange-sounding new terms may be mentioned cancrosis for citrus canker and rubellosis for the pink disease of the tropics, both caused by specific parasites; foliocellosis (frenching or mottle-leaf), endoxerosis (internal decline of the lemon fruit), adustiosis (red blotch), and oleocellosis (oily spot) are non-parasitic diseases.

The Useful Trees of Northern Nigeria. By H. V. Lely. Pp. xii + 128 + 120 plates. (London: The Crown Agents for the Colonies, 1925.) 10*s.* net.

MR. LELY has rendered a service to African forestry by the preparation and publication of his descriptive account of 128 of the useful trees of Northern Nigeria. This book will be helpful not only to his colleagues but also to forest officers in other African colonies, to which many of the trees described extend their range. The author's method may be commended to the consideration of others who, we hope, will follow his example; as he expresses it, his aim has been to describe and illustrate the material as it appears to be and not only as it actually is from the scientific point of view, avoiding botanical terms except where they have no alternative. Technical descriptions can always be provided by the compiler of a flora, working at home, but information such as that supplied by the author of the work under review can only be given by 'the man in the field.'

If other colonial forest officers will follow Mr. Lely's lead, by giving us illustrated accounts of the dominant trees of their areas, it will be of great assistance to their colleagues and successors, and will help to prevent many erroneous determinations such as are now so commonly met with. Such accounts would tend also to bring to light the still too numerous species not yet identified botanically, and would furnish us with much-needed information as to the 'habit' of the various species discussed.

A few slight corrections ought, perhaps, to be noted for the benefit of African forest officers. The genus Lophira has been retained by Mr. Lely in the Dipterocarpaceæ instead of in the Ochnaceæ, to which family it is now referred. The genera Eriodendron, Ceiba, and Bombax are now usually separated from the Malvaceæ to form a distinct family, the Bombacaceæ; *Eugenia guineensis* is now generally placed in a separate genus, Syzygium, as *S. guineense.* Sir David Prain's revision of the African species of 'Afzelia' under the generic name Pahudia appears to have been overlooked, for *Pahudia africana* (Sm.) Prain appears as *Afzelia africana.*

We sincerely hope that Mr. Lely will feel encouraged to continue the good work until all the trees of his region have been described and figured.

J. BURTT DAVY.

Synonymy of the British Non-Marine Mollusca (Recent and Post-Tertiary). Compiled and Annotated by A. S. Kennard and B. B. Woodward. Pp. xxiv + 447. (London: British Museum (Natural History), 1926.) 20*s.*

THIS work is almost devoid of readable matter, but is nevertheless of fundamental importance to all who are engaged in research on non-marine Mollusca or on the Pleistocene deposits. It gives a list of all the genera, sub-genera, and species (recent and post-Tertiary), with bibliographical references, together with the etymology of the names adopted, and the geological range of the species in Great Britain. The names used are those which, in the opinion of the authors, most nearly accord with the requirements of the International Rules of Zoological Nomenclature. 172 species of gasteropods and 37 of lamellibranchs are recorded, most of which are found fossil in the Pleistocene, and some in the Pliocene deposits. About 16 per cent. of the species are extinct in Great Britain. Some idea of the immense labour involved in the preparation of this work can be formed from the bibliography, which occupies 54 pages.

Memoirs of the Geological Survey, Scotland. The Economic Geology of the Central Coalfield of Scotland. Area 5: Glasgow East, Coatbridge and Airdrie; with Chryston, Glenboig, Greengairs, Slamannan, Caldercruix and Salsburgh. By Dr. C. T. Clough, L. W. Hinxman, W. B. Wright, E. M. Anderson, and R. G. Carruthers; with contributions from Dr. R. Kidston, Dr. G. W. Lee. Second edition, with additions by M. Macgregor. Pp. x + 171 + 13 plates. (Edinburgh and London: H.M. Stationery Office; Southampton: Ordnance Survey Office, 1926.) 5*s.* net.

THIS memoir is a new edition (with corrections and additions) of that on the same area, first published in 1916. In addition to minor corrections and amplifications, Chapter ii. dealing with the Carboniferous Limestone series, in which certain important coal seams occur, has been almost entirely rewritten, whilst there have also been some changes in Chapter iii. dealing with the Millstone Grit. It is evidently of great importance that, as fresh information is available, works such as these should be kept up-to-date and amplified where necessary.

Erde und Weltall. Von Svante Arrhenius. Aus dem Schwedischen übersetzt von Dr. Finkelstein. Pp. vii + 342 + 2 Tafeln. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1926.) 12 gold marks.

THIS is a German translation from the Swedish; it is a combined and revised version of the two earlier works by the author, published in 1906 and 1915. The book deals only with the solar system, with special reference to the earth and geophysics (including atmospheric physics and climatology). It is written in picturesque and discursive style, and there are numerous small illustrations. Many references are made to very recent work.

Solutions of the Examples in a Treatise on Dynamics of a Particle and of Rigid Bodies. By S. L. Loney. Pp. vi + 240. (Cambridge: At the University Press, 1926.) 17*s.* 6*d.* net.

PROF. LONEY has here provided complete and concise solutions to the examples of his well-known treatise on dynamics, which will be very useful to teachers and to those advanced students of applied mathematics who are sufficiently mature to know the legitimate use of such a key.

Physische Erdkunde: die Gestaltung der Erdoberfläche. Von Prof. Dr. Richard Lehmann. Pp. vii + 240. (Braunschweig: Friedr. Vieweg und Sohn A.-G., 1925.) 12·50 gold marks.

THIS is a text-book of physical geography, of the usual type. The processes of development of surface features are described at length, and the illustrations are numerous. The earth's thermal state is mentioned, but radioactivity is not.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Welsh Romani.

I HAVE just read Prof. Turner's review of my "Dialect of the Gypsies of Wales" in NATURE of August 28, and trust you will permit me to make a few comments.

Prof. Turner refers to the "well-established rules of Gypsy," *i.e.* the phonetic correspondences between Sanskrit and Romani, but omits to mention that my book is the first to supply a full and systematic series of these phonetic equations: for the earlier lists of Ascoli and Miklosich are too incomplete to be of service. These equations have been deduced in the first place from examples where the correspondence between a Sanskrit and Romani word is indisputable, and afterwards applied to the elucidation of words the etymology of which is in doubt. Hence my etymologies, which he appears to assign to guess-work, have all been based upon a belief in that "constancy of sound-laws" which he charges me with ignoring. By no other method would it have been possible to arrive at such new derivations as *bār*, 'stone,' from Skr. vaṭa; *bivan*, 'unripe,' from Skr. vimlāna; *lil*, 'book,' from Skr. likhita, *phabai*, 'apple,' by reduplication from Skr. phala, and many others. I am therefore in agreement with Prof. Turner as to the principle that "a given sound in a given dialect will develop in the same way in all words in which it appears under the same conditions," and only question his application of this rule.

In the single example cited by Prof. Turner, namely, Rom. *šukār*< Skr. sukṛta, he emphasises his point by the statement that I give this derivation "without hesitation," although in the vocabulary I first quote Miklosich's śukra, following it by a doubtful "rather perhaps to be connected with Skr. sukṛta"; while in my chapter on the History of Romani Sounds (§ 130) I cite it with a prefixed query mark. My reason for connecting Gypsy *šukār* with Skr. sukrta is the analogy of three other Romani words from the same Skr. √ kṛ, compounded with prefixes ending in a vowel, where the -k-, though intervocalic, remains. These are:

raker- (Gk. Gyp. *vraker-*, Arm. Gyp. *pakr-*), 'to talk,' derived by Finck from Skr. prakṛ, Prākr. pakar- -an etymology which the Sanskritist Ernst Kuhn in 1909 hails as 'sehr glucklich,' explaining as it does the forms in Eastern and Western dialects,

pariker-, 'to thank'< Skr. pratikṛ, Prakr. paḍiker-;

dūrker-, *duriker-*, 'to foretell'<Skr. dūrīkṛ. In stating dogmatically that Skr. sukṛta "would have become something like **sul*"—a word of singularly unGypsy-like appearance Prof. Turner assumes that intervocalic Skr. -t-, if it survives, must necessarily have become European Gypsy -l-; but it might equally well have become -r- (§ 130, No. 3), *e.g.* Skr. pat-:>Prākr. paḍ->Rom. *per-*, 'to fall,'; Skr. prefix prati->Prākr. paḍi->Rom. *pari-*.

Prof. Turner's second adverse criticism arises, I think, from a misapprehension of the scope and purpose of my book. When in my vocabulary, appended to Romani words of Indian origin, I cite Sanskrit, Prākrit, and Hindi forms, I do so with very different degrees of reverence. Sanskrit in almost every case is quoted as the source in which we find preserved the primitive form of Gypsy words, while Prākrit serves mainly to illustrate processes of sound-change which are often identical with those found in Romani. The Hindi words are in an entirely different category, and from the Gypsy viewpoint practically negligible. I supply them (as I explain in § 76) merely to indicate the usage in the central Modern Indian speech of to-day. But since the Gypsies had left India at least 200 years before the rise of Hindi and other vernaculars, these recent forms cannot have affected Romani.

Prof. Turner assumes that where the Hindi word is given by me I regard it in every instance as a true cognate. But this is not so. The distinction between tadbhavas (lineal descendants of Sanskrit words) and tatsamas (modern resuscitations from Sanskrit) is so well-known, and the examples in my vocabulary so obvious, that it would have been superfluous to have differentiated the two classes. He selects for rebuke (with judicious omissions which suggest that I try to connect a Romani word with a Hindi tatsama) the Gypsy *thulo*, 'fat.' In my vocabulary it appears thus: "*thulo*, adj. [Skr. sthūla, 'thick,' 'bulky,' 'gross'; Prākr. thulla; Hind. sthūl; Dard. tūla, tullo, tul, 'fat'}," where the Hindi sthūl stands out prominently as an unmistakable tatsama. Hindi being historically out of account, it seemed to me to be of first importance to the student of Gypsy to direct attention to the fact that an inherited word, which has survived in Romani, should have been lost and artificially restored in the Modern Indian vernaculars. Prof. Turner, writing as though my book were designed as a text-book on Modern Indian dialects rather than a work on comparative Romani, says: "Such an attitude and such mistakes invalidate the whole of [my] comparative work"—a remark which sheds a curious light on the attitude of the "Junggrammatiker."

JOHN SAMPSON.

The University,
Liverpool.

THE main ground of my criticism of Dr. Sampson's book was that in it he pays little regard to the principle of the constancy of sound-laws. In his reply, however, he professes his adherence to this principle; and proceeds forthwith to deny it. For by this method, he says, he arrived at the new conclusion, among others, that *bār*, 'stone,' is derived from Sanskrit *vaṭa*. It is true that initial *v-* regularly becomes *b*, and that intervocalic *-ṭ-* regularly becomes *r*. So far, so good. But it is a well-established law that in European Romani Skt. *ă* followed by one consonant only becomes *e*, as appears to be admitted by Dr. Sampson on p. 44 of his book. Therefore if *bār* is to be derived from *vaṭa*, a special explanation of the presence of *ā* (instead of *e*) is required: Dr. Sampson offers none, nor even indicates the need. He has already betrayed the principle of the constancy of sound laws Actually this word is derived from a Middle Indian **vaṭṭa-* (cf. Pali *vaṭṭo*, 'round, rolling'), common in the N.W. languages, *e.g.* Panjabi *waṭṭā*, which Khowar *bòrt* shows to be from earlier *varta-*.

I regret having seemed to ascribe to Dr. Sampson greater confidence in his etymology of *šukār* from *sukṛta-* than he expressed. by the words 'without hesitation' I intended to imply 'without directing attention to the phonetic irregularities involved in his etymology.' Nevertheless, he still stoutly upholds this etymology. But it behoves him, as a professed follower of the Junggrammatiker he sneers at, to explain why the word has *š* in all the dialects except the Greek (in which *ś* usually appears as *s*). He neither solves, nor even poses, the problem. The

retention of *-k-* he explains on the ground that it is an initial of the second member of a compound. That would be possible if the consciousness of its being a compound was retained up to the time when *-k-* ordinarily disappeared. But the support he gives for this contention is weak, and still further accuses him of deserting the principle of constancy. He derives *raker-*, 'to speak,' from *prakaroti* (which does not mean 'speak,' but 'accomplish'): yet the regular correspondence for Skt. *pr-* is Rom. *pr-* (Asiatic, Armenian, and perhaps English Rom. *p-*). He must therefore explain Engl. *r-*, Gk. *vr-* before he quotes this word in support, and this unfortunate lack not even Prof. Kuhn's "sehr glucklich" supplies. He derives *pariker-*, 'to thank,' from Skt. *pratikaroti*, but omits to explain why *a* appears instead of *e* in the first syllable. He derives *duriker-*, 'to foretell,' from Skt. *dūrīkaroti*, used by a scholiast on Pāṇini in the sense 'remove.' Obviously we have here not a descendant of Skt. *dūrīkaroti*, but a new Romani compound formed of two separate Romani words, *dur(i)* and *ker-*. Finally, he objects to my assumption that Skt. *-t-* would become *l*, and quotes *per-*, 'to fall,' from Skt. *patati*. *Per-* is not derived directly from Skt. *pátati*, but from Middle Indian **paṭati* (cf. Pkt. *paḍaï*), which has given rise to forms like Hindi *parnā*, while *pátati* is to be found in forms of the North-West, like Sindhi *pawaṇu*, Kashmiri *pyonu*.

In my review I quoted only one example of what I considered to be Dr. Sampson's neglect of the principle of the constancy of sound-laws, because in the space at my disposal I wished to deal with other and far more valuable aspects of his book. Nevertheless his pages abound in such examples. Lest I be accused of unfounded criticism, I select a few. *Niser-*, 'to go out,' said to be from Skt. *niṣkṛṣ-*, 'to drag out.' What has happened to the group *ṣk*, which becomes Middle Indian *kk*, and must remain in Romani as *k*? Skt. *niḥsarati*, 'he goes out,' provides a better etymology, which accords with Romani sound-laws. *Kam-*, 'to wish,' from *kāmayati*: yet *-m-* regularly becomes *v*; possibly from a form **kāmya-*, but probably borrowed from Persian *kām*, 'wish', Pehlevi *kāmītan*, 'to wish' *Kerav-*, 'to boil, from *kārayati*, 'to cause to do,' despite the fact that Skt. *ā* regularly remains Romani *a*. It is from a Middle Indian **kaṭhati* (cf Pali *kaṭhito*, 'boiled', Skt. *kvathati*, 'boils'). *Khino*, 'tired,' from Skt. *khinna-*, 'oppressed,' which would have given a Romani form with *χ-* Miklosich's derivation from *kṣīṇá-*, 'worn out,' is correct, for *kṣ* becomes *kh*. *Gōrō*, 'non-gypsy,' from Skt *guru-*, 'preceptor,' with irregular *ō* from *u*. why not (with regular phonetic change) from *gaura-*, 'light-complexioned' (cf. Hindī, *gorā*, 'European')? *Śon*, continental *con*, 'moon,' from *candra-*, with irregular *o* from *a*, an unlikely development of the group *ndr* not otherwise attested: it is from Skt. *jyotsnā*, Pkt. *jonhā*, which would regularly become Rom. *con*. *Thil-*, 'to hold,' is explained as derived from Rom. *ther-* (correctly attributed to Skt *dharati*), but *-r-* does not become *l*, nor does *e* normally become *i*: on the contrary *-t-* does become *l*, and *ṛ* does become *i*, so that *thil-* looks like a formation from *dhṛtá-*, the past participle which has furnished Modern Indian with many present stems. *Dud*, 'light,' from *dyota-*: but *dy* becomes *j*, and *-t-* becomes *l*. *Cārō*, 'bowl,' from *caru-*: but *a* becomes *e*; why not from **caṭṭa-*, H. *cāṭā*, 'bowl for sugarcane-juice'?

This part of Dr. Sampson's work is deserving of animadversion not because he makes mistakes in etymologies—that is, alas, the fate of all etymologers—but because in making them he does not pause to pose or to explain the phonetic irregularities involved. I say again that he has not been true to the principle of the constancy of sound-laws, and (what I did not say before) that he has as a necessary consequence been driven into guess-work. He upbraids me for not mentioning that his book is the first to supply a full and systematic series of the phonetic equations of Romani: I have tried to show that it does not do so.

The second point on which Dr. Sampson takes me to task is that I have wrongly accused him of comparing Sanskrit loanwords in Hindi with Romani words, as if they had been inherited Hindi words. He now says that it is clear that the Hindi words are borrowed, and not inherited; and he quotes § 76 in support. In this paragraph, however, there is no mention of *tatsama* or loanword, but only of Hindi cognates By that most comparative philologists will understand inherited words, not literary loanwords. Further, Dr. Sampson does not confine himself to quoting only loanwords in Hindi, but gives as many, if not more, inherited words. Thus in the passage whence I took the particular example (taken from Part I., p. 52, not from the vocabulary, "with judicious omissions," as Dr. Sampson suggests) we may read: "*t'an tχan*, 'place,' S sthāna, P. ṭhāṇa, H. thān; *t'ulo*, 'fat,' S. sthūla, P. thulla, H. sthūl." Of these two Hindi words, one, *thān*, is inherited and strictly to be called cognate; the other, *sthūl*, is a loanword. Dr. Sampson says that he knows this (though he does not explain what value, if any, the quotation of the literary loanword has); but is he right to assume that all his readers also will know? What, finally, is his principle of selection? Why does he compare in consecutive lines *thüd*, 'milk,' with H *dūdh* (inherited word), but *thuv*, 'smoke,' with H. *dhūm*, *dhūmā* (loanword). If it be, as he says above, "to direct attention to the fact that an inherited word, which has survived in Romani, should have been lost and artificially restored in the Modern Indian vernaculars," he is wrong; for the inherited word exists not only in the Hindi *dhuā̃*, but also in almost every other Modern Indo-Aryan language. There are, in fact, very few, if any, Romani words of Indo-Aryan origin which have not cognates in one or other of the living languages.

No one more regrets the necessity for this criticism of Dr. Sampson's work than myself: for as a description of a particular Romani dialect, and as a most useful collection of other material, it is pre-eminent, and puts all students of Indo-Aryan in general, and of Romani in particular, under a great debt of gratitude to the author. But if he thinks that I considered it "designed as a text-book on Modern Indian dialects," I say at once—μὴ γένοιτο.

R. L. TURNER.

Science and Psychical Research.

I BEG space for a short comment on Dr. Tillyard's remarks in NATURE of October 23, so far as they concern my letter which appeared in the issue of October 2. Dr. Tillyard misrepresented what I said when he wrote that I had given my own interpretation of the words "super-normal phenomena." These were his own words, chosen by me because I regarded them as better fitting this discussion than either "subjects of psychical research" or "spiritualism." For I am aware that although psychical research does certainly include the study of most, if not all, of the phenomena alleged by many to be referable to some 'spiritual' origin, there are many psychical researchers who do not accept this explanation of alleged communications between the living and the dead, but prefer to interpret such communications, and others

said to occur between living persons at a far distance from one another, by attributing them to an unknown power which was long ago named 'telepathy' by one of the founders of the Society for Psychical Research.

Dr. Tillyard, in his review of the "History of Spiritualism" in NATURE of July 31, says that psychical research purports to be the scientific study of what are called "super-normal phenomena"; and divides this study into two parts, calling the first 'physical,' the second 'mental.' In the mental part, however, are included practically all the various 'phenomena' known generally under the term 'spiritualistic.' Seeing that the present discussion has been mainly concerned with these phenomena, I desired to make it quite clear that I was dealing only with that department of psychical research which was concerned with such phenomena as may be strictly called 'ghostly.'

Touching Dr. Tillyard's call upon me to explain what 'trance' is, I reply that I do not know. But although he says he does not know the difference between trance and sleep he knows more than I do about this matter, for he states in NATURE of Aug. 28 that "Usually the medium is in deep trance and knows nothing of what is occurring." I have seen several 'occult' cases in which strange phenomena have occurred during a period when the medium, often invisible but sometimes not so, has been stated to be in trance, and have heard first-hand accounts of many similar cases. But I have never known or heard of any independent examination being made to test the medium's alleged condition. The phenomena produced at séances with trance mediums play an important part in the exhibitions of 'super-normal phenomena,' the reports of which excite popular curiosity and pervade the journalism of to-day.

BRYAN DONKIN.

I CAN find in Sir Arthur Conan Doyle's letter in NATURE of October 16 no explanation or withdrawal of his grave but, as I have shown, entirely untrue accusation that a statement that I made about him in the issue for September 25 was a "pure invention" on my part.

A. A. CAMPBELL SWINTON.

40 Chester Square, S.W.1,
October 16.

MAY I add to—and I hope end—my correspondence with Mr. Campbell Swinton by saying that I regret that I used the term "pure invention" in alluding to one of his statements, since his conclusion was a natural one with the information which he then had at his disposal.

ARTHUR CONAN DOYLE.

October 21.

The Electrical Charges from Like Solids.

THE uncertainty as to the charges arising on insulating solids when rubbed together has ever provided perplexities for the investigator and pitfalls for the lecturer. I have shown in previous papers (*Proc. Phys. Soc.*, 1915, and *Proc. Roy. Soc.*, 1917 and 1926) that a clean solid, say glass, may have entirely different qualities according to the previous treatment of the surface. Ordinary dirt, adsorbed films, temperature change, and, in particular, strain left on the surface by the rough pressure of other solids, are variables which vitally influence surface electrification.

In the present brief note I want to direct attention to the charges found when two *like* solids are rubbed or struck together. Ebonite is very convenient for the purpose. Two rods of this substance are cut from the same sheet and mounted with sealing wax in glass tubes which serve as handles. The free ends of the ebonite are thoroughly but *lightly* scraped with a razor blade and then boiled for a few seconds in water. After drying and cooling, the ebonite surfaces are ready for use. They behave as follows:

(1) Placing the rods across one another, one (A) is rubbed down the other (B). We find A charged $-^{ve}$, $B+^{ve}$. Discharge the rods over, *not in*, a flame. Rub B down A. We find B charged $-^{ve}$, $A+^{ve}$. Thus the rods are identical in behaviour, the 'rubber' in each case becoming $-^{ve}$, the 'rubbed' $+^{ve}$.

When the surfaces behave alike, as above, we call them 'standard.'

There is a real distinction between 'rubber' and 'rubbed,' a much smaller area of the former than of the latter taking part in the rub; and of the two, the rubber attains at the rubbing point a higher temperature. Hence, the rubber is more likely to yield and be greatly strained under the tangential forces applied in friction.

(2) Continued rubbing brings about a change of effect; the rubber, gradually losing its strong $-^{ve}$ quality, becomes first neutral and then more and more $+^{ve}$. When in the neutral condition, the rubber may be $-^{ve}$ or $+^{ve}$ according as the rub is light or heavy. Also at this stage it is sometimes possible to obtain one charge, say, $+^{ve}$, from a direct stroke, $-^{ve}$ from a reverse.

(3) By continuing the rubbing, the rubber becomes definitely $+^{ve}$ and remains so for the actual surface rubbed even after days of inaction. I propose to call the new state of surface, produced by rubbing, the 'strained' state.

(4) The strain can be removed by boiling the rods in water for a few seconds or more, according to the amount of strain. If both rods are considerably strained, it is possible by boiling each in turn for short periods to make first one, then the other $-^{ve}$, until finally both are restored to the pristine standard state of no strain. It should be remarked that after boiling the rods are allowed to cool before rubbing.

(5) If the rods have been brought by rubbing to the intermediate state (see (2) above), suppose one rod, A, is slightly $+^{ve}$ to B. Then warming A makes it $-^{ve}$ to B. Next, warming B makes it $-^{ve}$ to A again. The rise in temperature of the surface need be only, say, 50°, and can be done by the heat from a carbon glow lamp.

(6) Sharp glancing blows of one rod on the other, whether the surfaces be standard or strained, give rise generally to contrary, *but unequal*, charges on the rods. The sum total charge is $-^{ve}$. If these impacts are oft repeated the sum total charge may be very great, and each rod may be $-^{ve}$.

In all these experiments the charges are considerable and can be easily observed with a sensitive gold-leaf electroscope.

The above behaviour of ebonite is found also with like specimens of caoutchouc, celluloid, shellac, resin, sealing wax, paraffin wax, charcoal, sulphur, glass, mica. I have found no exceptions to the rule, but that remarkable solid, caoutchouc, reveals its idiosyncrasies, in triboelectricity as in other well-known phenomena, thermal and elastic. In caoutchouc the rubber has a $+^{ve}$, not a $-^{ve}$, tendency due to rise in temperature.

Each material must be rendered standard as defined in (1) above, but the dual process of scraping and boiling, adopted with ebonite, is clearly not universally applicable.

From the above experiments three general principles, which I think are new, emerge:

(*a*) *Really identical surfaces charge one another according to a definite rule* (*Expt.* 1).

(*b*) *Friction between initially identical surfaces causes these to become strained, the strain being revealed by the nature of the charges arising, and by the fact that heating restores the surface* (*Expt.* 2, 3, 4, 5).

(*c*) *Rough impact between like bodies in general leaves them with unequal charges* (*Expt.* 6).

The earliest lessons inculcated in text-books on electricity are: first, that, to produce charges by rubbing, the two solids used must be different in nature; secondly, that the two charges are equal in amount and opposite in sign.

Both these principles, as we see, are erroneous, although the second one is true for the special case when the two solids are slowly rubbed, and not struck, together. In ebonite we find, after impact, a net - ^{ve} charge The equal + ^{ve} charge has therefore escaped to the air.

There is food for reflection in these results. Since solids of like chemical, and even physical, nature can charge one another, we have hope of explaining all those baffling results so well known to all who have carefully experimented in contact electrification. For these results show that the physical state of a solid surface, being liable to great variation, is a factor of prime importance.

If small defilements, or strains, or temperature changes be imposed on the surface, they concentrate just where, on the actual superficies, their influence may fundamentally affect the surface characteristics. Some investigators in the past, finding erratic results, losing patience, have even dared to describe the effects as 'fortuitous.'

No sound information in this subject can be garnered unless the specimens used are carefully cleaned and otherwise prepared.

Two rods of any insulator, *e.g.* glass, ebonite, caoutchouc, cut from the same sheet, and merely wiped with a duster, are almost invariably different in surface qualities; on rubbing, one will charge + ^{ve}, the other − ^{ve}.

There is one interesting speculation deducible from the principles enunciated above. The old problem as to the genesis of electric sand storms and dust storms in Nature may find a solution from the two principles (*a*) and (*c*). For here we have like particles striking together and giving rise to a net charge on the particles and an opposite charge in the air.

This class of research is simple-seeming. But those who have spent time on the subject will allow that it is very baffling, those who have not done so, will at least remember that despite great efforts by physicists the subject has not yet passed the pioneer stage. The most important point in the technique is the production of a standard surface for the material used. Then if, in any experiment, effects become involved or difficult of interpretation, it is easy to reproduce the standard surface and begin again. This principle is emphasised in a recent paper by Mr. Jex and myself (*Proc. Roy. Soc.*, June 1926). P. E. SHAW.

University College,
Nottingham.

Origin of Yolk in the Eggs of Scolopendra.

IN a previous paper (*Proc. Camb. Phil Soc. Biol. Sci.*, October 1924) on the eggs of the centipede, *Lithobius forficatus*, one of us (V. N.) described two kinds of yolk, albuminous and fatty. The albuminous yolk is preceded by nucleolar extrusions of a remarkable type, and its origin seems to be associated with them, although no evidence could be adduced that they are *directly* transformed into the albuminous yolk. It was further shown that the juxta-nuclear Golgi apparatus fragments into small granules and small crescent-shaped Golgi elements. The former grow in size and give rise to the fatty yolk.

Miss S. D. King (*Scientific Proc. Roy. Dub. Soc.*, vol. 18) confirms the above account of the association of the albuminous yolk with the nucleolar extrusions, but in her opinion the albuminous yolk arises directly from the nucleolar extrusions. With regard to the Golgi apparatus, she admits that it fragments into small granules. Furthermore, she describes fatty yolk, but "the origin of this fatty yolk is doubtful, but it may possibly be connected with the Golgi apparatus, although no evidence in support of this theory has been discovered." In our opinion Miss S. D. King is doubtful about the origin of fatty yolk from the Golgi apparatus, because "both Mann-Kopsch and Da Fano material was studied, but the latter gave such favourable results that it was used *almost exclusively*" (italics ours). Now, it is well known that the Da Fano method fails to show fat in finished slides, while the Golgi apparatus is preserved. On the other hand, the Mann-Kopsch method preserves both Golgi apparatus and fat, and thus enables one to study the transformation of the former into the latter. Furthermore, Flemming-without-acetic, which Miss King has used, shows fat, but not the Golgi apparatus, at least in the egg of Lithobius.

In view of the above conflicting evidence, it was thought desirable to work out the origin of yolk in the eggs of the centipede, Scolopendra. Our observations on the eggs of this centipede strongly confirm the earlier observations of one of us on *Lithobius forficatus*. At the very beginning of the growth period of the egg of Scolopendra, the nucleolus buds off round bodies into the cytoplasm. This process lasts for some time, until at a particular stage it ceases and the nucleolar extrusions in the cytoplasm completely disappear. The extrusions do not fragment in the cytoplasm as they do in the case of *Lithobius forficatus*. After the disappearance of the extrusions there is a long pause; later, albuminous yolk puts in its appearance, and seems to arise *de novo* in the cytoplasm, as is the case in spiders (Von Bambeke, *Arch. de Biol.*, 1897, and Nath, NATURE, May 15, 1926), although the possibility remains that the material of the nucleolar extrusions which have disappeared may contribute towards the formation of the albuminous yolk. At this stage the egg has assumed a large size and the nucleus lies just below the egg membrane. The mitochondria are granular and form a ring all round the nucleus in the youngest egg, which, however, is thicker on one side. They increase in number and ultimately fill up the whole egg.

The behaviour of the Golgi apparatus is remarkable. In the youngest eggs it consists of a few juxta-nuclear rings and crescents. In Mann-Kopsch preparations the rings appear like vacuoles with a sharp chromophilic rim and a central chromophobic area (idiosome). The crescents also show a distinct idiosome material. The Golgi elements increase in numbers, so much so that the whole egg is full of them. The vacuole-like Golgi rings swell up and are directly transformed into the fatty yolk spheres which contain free unsaturated fat, as is shown by their blackening in Flemming-without-acetic, and their quick decolorisation in turpentine, both after Mann-Kopsch and F. W. A. When the fatty yolk spheres are blackened by osmic acid they appear solid, but when they are being decolorised in turpentine they appear like vacuoles with a black rim and clear contents exactly like the Golgi rings. Gradually the black rim also becomes colourless and the sphere remains as a clear white vacuole. An exactly similar process takes place in the eggs of spiders also. Furthermore, we find that the fatty yolk spheres are never smaller than the Golgi rings,

as should be the case if they were to arise *de novo*. Again, they appear only after the Golgi rings have increased both in numbers and size.

Lastly, we wish to emphasise the fact that in all eggs in which the Golgi apparatus is said to give rise to yolk (for reference see NATURE, May 15, 1926), such yolk is *always* fatty. This in itself is confirmatory of the above view, because the Golgi material is supposed to be a lipoid combined with a proteid.

A full account will be published later.

Kammerer's Alytes.

MAY I be permitted to reply briefly to Dr. Noble's letter on Kammerer's Alytes which appeared in NATURE of October 9? There are several questions involved: first, whether Dr. Noble was right in his statement to the British Association in 1925, that Kammerer's specimen did not show a genuine nuptial pad, because the characteristic glands were absent, and that the glands, not the spines, were diagnostic of these pads.

Champy, in his paper on the subject, states that the nuptial glands are merely the normal skin glands enlarged, and this is confirmed by Dr. Przibram's letter to NATURE of August 7.

Secondly, Dr. Noble makes the statement that the glands in Kammerer's controls shown in America were the same size as those in the sections of the pad.

This statement I can readily accept. I have photographs before me as I write both of Kammerer's earlier sections, sent to Bateson in 1919, and of his later ones exhibited in Cambridge in 1923. In the former the cornification of the epidermis is not so strongly developed as in the latter, and the disparity in size between the glands in the sections through pad and control is slight. In the latter, as stated, the glands in the pad are double the size of those in the control and the cornification is very strong. Kammerer obtained many of the modified males and reared them through several generations, and the acquired peculiarities became intensified in later generations.

As to the date at which the Alytes specimen was 'faked,' there are two passages in Dr. Noble's description which completely give his case away. His letter suggests that Dr. Kammerer perpetrated a wicked fraud on the scientific world. Dr. Noble could find no spines on the specimen in Vienna, and saw blackened patches on *both* hands: I saw spines and have a photograph of them, and on one of the hands I saw no blackened patch whatever.

Dr. Noble's reference to the large-eyed Proteus shows that he fails to grasp its bearing on the question. I consider it the most wonderful object ever exhibited to a scientific audience. The larval Proteus does not, as Dr. Noble suggests, possess an eye: it has, like other blind cave-animals, only the embryonic rudiment of one. If Dr. Noble can find other 'casual' examples of blind cave-animals developing large eyes, I shall be glad to hear of them.

Both the Alytes and the Proteus specimens are examples of the same phenomenon—a phenomenon termed by Prof. Semon 'ecphory'; that is, the revival of ancestral features by the reinstating of the ancestral environment. This process required for its completion five or six generations in Alytes and in Proteus only one, but it is essentially the same thing in both; and to try to represent the skilled experimenter who produced the Proteus as a clumsy trickster seems to me to be both unjust and unworthy.

I do not propose to discuss the merits of the inheritance of acquired characters in the present issue, but as Dr. Noble seems unconscious of the rising tide of Lamarckism, let me point out that Kammerer's conclusions are being confirmed by workers dealing with quite different animals, the last and most spectacular of these confirmations being the paper on the inheritance of habit by rats, read at the Oxford meeting of the British Association by Prof. William McDougall.

If Dr. Noble will forgive me for lapsing into his own expressive American, let me gently entreat him "to get on the band-waggon." Habit as the chief factor in evolution and the inheritability of acquired habits are accepted by leading systematists, palæontologists, and embryologists. Every year adds to the recruits, and I hope that Dr. Noble will join them. If he does, I am sure that he will "get the bulge" on many of his countrymen.

South Kensington, S.W.7.

The Anomalous Flocculation of Clay.

SOME further experiments have been performed in these laboratories which clear up the discrepancies between the experiments described in a previous letter on the above subject (NATURE, May 1, p. 624) and those of Messrs. Kermack and Williamson (NATURE, June 12, p. 824).

The following table gives the times required to flocculate a 0·1 per cent. purified clay suspension at various concentrations of sodium and calcium chlorides and hydroxides:

Concn Ca'' ion.	Time required for flocculation.		
	$Ca(OH)_2$.	$CaCl_2$	Two equivalents of chlorides to one of hydroxide.
0·001	7 hours	14 min.	6 hours
0·002	28 min.	10 ,,	32 min.
0·003	2 ,,	7 ,,	12 ,,
0·004	1·5 ,,	6 ,,	4·5 ,,
0·005	1·5 ,,	6 ,,	3·5 ,,
0·010	1·5 ,,	6 ,,	1·5 ,,
0·014	1·5 ,,	6 ,,	1·5 ,,
Concn Na ion.	NaOH	NaCl	NaCl : NaOH = 2 : 1.
0·05	2 hours	13 min.	2 hours
0·1	32 min.	13 ,,	32 min.
0·2	22 ,,	14 ,,	24 ,,
0·5	20 ,,	17 ,,	17 ,,
0·9	15 ,,	18 ,,	14 ,,

These results show that calcium hydroxide is a less powerful coagulant than calcium chloride, and actually tends to stabilise a suspension containing the latter salt, provided that the time of flocculation is longer than about twelve minutes.

If the concentration is such that coagulation takes place in 6 minutes or less, then calcium hydroxide flocculates more rapidly than the chloride at equivalent concentrations.

The results for sodium, on the other hand, suggest that even this latter effect should not be called anomalous, as at a concentration 0·9 normal, sodium

(*b*) *Friction between initially identical surfaces causes these to become strained, the strain being revealed by the nature of the charges arising, and by the fact that heating restores the surface* (*Expt.* 2, 3, 4, 5).

(*c*) *Rough impact between like bodies in general leaves them with unequal charges* (*Expt.* 6).

The earliest lessons inculcated in text-books on electricity are: first, that, to produce charges by rubbing, the two solids used must be different in nature; secondly, that the two charges are equal in amount and opposite in sign.

Both these principles, as we see, are erroneous, although the second one is true for the special case when the two solids are slowly rubbed, and not struck, together. In ebonite we find, after impact, a net $-^{ve}$ charge. The equal $+^{ve}$ charge has therefore escaped to the air.

There is food for reflection in these results. Since solids of like chemical, and even physical, nature can charge one another, we have hope of explaining all those baffling results so well known to all who have carefully experimented in contact electrification. For these results show that the physical state of a solid surface, being liable to great variation, is a factor of prime importance.

If small defilements, or strains, or temperature changes be imposed on the surface, they concentrate just where, on the actual superficies, their influence may fundamentally affect the surface characteristics. Some investigators in the past, finding erratic results, losing patience, have even dared to describe the effects as 'fortuitous.'

No sound information in this subject can be garnered unless the specimens used are carefully cleaned and otherwise prepared.

Two rods of any insulator, *e.g.* glass, ebonite, caoutchouc, cut from the same sheet, and merely wiped with a duster, are almost invariably different in surface qualities; on rubbing, one will charge $+^{ve}$, the other $-^{ve}$.

There is one interesting speculation deducible from the principles enunciated above. The old problem as to the genesis of electric sand storms and dust storms in Nature may find a solution from the two principles (*a*) and (*c*). For here we have like particles striking together and giving rise to a net charge on the particles and an opposite charge in the air.

This class of research is simple-seeming. But those who have spent time on the subject will allow that it is very baffling; those who have not done so, will at least remember that despite great efforts by physicists the subject has not yet passed the pioneer stage. The most important point in the technique is the production of a standard surface for the material used. Then if, in any experiment, effects become involved or difficult of interpretation, it is easy to reproduce the standard surface and begin again. This principle is emphasised in a recent paper by Mr. Jex and myself (*Proc. Roy Soc.*, June 1926). P. E. SHAW.

Origin of Yolk in the Eggs of Scolopendra.

IN a previous paper (*Proc Camb Phil Soc Biol Sci.*, October 1924) on the eggs of the centipede, *Lithobius forficatus*, one of us (V N) described two kinds of yolk, albuminous and fatty. The albuminous yolk is preceded by nucleolar extrusions of a remarkable type, and its origin seems to be associated with them, although no evidence could be adduced that they are *directly* transformed into the albuminous yolk. It was further shown that the juxta-nuclear Golgi apparatus fragments into small granules and small crescent-shaped Golgi elements. The former grow in size and give rise to the fatty yolk.

Miss S. D. King (*Scientific Proc. Roy. Dub. Soc.*, vol. 18) confirms the above account of the association of the albuminous yolk with the nucleolar extrusions, but in her opinion the albuminous yolk arises directly from the nucleolar extrusions. With regard to the Golgi apparatus, she admits that it fragments into small granules. Furthermore, she describes fatty yolk, but "the origin of this fatty yolk is doubtful but it may possibly be connected with the Golgi apparatus, although no evidence in support of this theory has been discovered." In our opinion Miss S. D. King is doubtful about the origin of fatty yolk from the Golgi apparatus, because "both Mann Kopsch and Da Fano material was studied, but the latter gave such favourable results that it was used *almost exclusively*" (italics ours). Now, it is well known that the Da Fano method fails to show fat in finished slides, while the Golgi apparatus is preserved. On the other hand, the Mann-Kopsch method preserves both Golgi apparatus and fat, and thus enables one to study the transformation of the former into the latter. Furthermore, Flemming-without-acetic, which Miss King has used, shows fat, but not the Golgi apparatus, at least in the egg of Lithobius.

In view of the above conflicting evidence, it was thought desirable to work out the origin of yolk in the eggs of the centipede, Scolopendra. Our observations on the eggs of this centipede strongly confirm the earlier observations of one of us on *Lithobius forficatus*. At the very beginning of the growth period of the egg of Scolopendra, the nucleolus buds off round bodies into the cytoplasm. This process lasts for some time, until at a particular stage it ceases and the nucleolar extrusions in the cytoplasm completely disappear. The extrusions do not fragment in the cytoplasm as they do in the case of *Lithobius forficatus*. After the disappearance of the extrusions there is a long pause; later, albuminous yolk puts in its appearance, and seems to arise *de novo* in the cytoplasm, as is the case in spiders (Von Bambeke, *Arch. de Biol.*, 1897, and Nath, NATURE, May 15, 1926), although the possibility remains that the material of the nucleolar extrusions which have disappeared may contribute towards the formation of the albuminous yolk. At this stage the egg has assumed a large size and the nucleus lies just below the egg membrane. The mitochondria are granular and form a ring all round the nucleus in the youngest egg, which, however, is thicker on one side. They increase in number and ultimately fill up the whole egg.

The behaviour of the Golgi apparatus is remarkable. In the youngest eggs it consists of a few juxta-nuclear rings and crescents. In Mann-Kopsch preparations the rings appear like vacuoles with a sharp chromophilic rim and a central chromophobic area (idiosome). The crescents also show a distinct idiosome material. The Golgi elements increase in numbers, so much so that the whole egg is full of them The vacuole-like Golgi rings swell up and are directly transformed into the fatty yolk spheres which contain free unsaturated fat, as is shown by their blackening in Flemming-without-acetic, and their quick decolorisation in turpentine, both after Mann-Kopsch and F. W. A. When the fatty yolk spheres are blackened by osmic acid they appear solid, but when they are being decolorised in turpentine they appear like vacuoles with a black rim and clear contents exactly like the Golgi rings. Gradually the black rim also becomes colourless and the sphere remains as a clear white vacuole. An exactly similar process takes place in the eggs of spiders also. Furthermore, we find that the fatty yolk spheres are never smaller than the Golgi rings,

as should be the case if they were to arise *de novo*. Again, they appear only after the Golgi rings have increased both in numbers and size.

Lastly, we wish to emphasise the fact that in all eggs in which the Golgi apparatus is said to give rise to yolk (for reference see NATURE, May 15, 1926), such yolk is *always* fatty. This in itself is confirmatory of the above view, because the Golgi material is supposed to be a lipoid combined with a proteid.

A full account will be published later.

The Anomalous Flocculation of Clay.

SOME further experiments have been performed in these laboratories which clear up the discrepancies between the experiments described in a previous letter on the above subject (NATURE, May 1, p. 624) and those of Messrs. Kermack and Williamson (NATURE, June 12, p. 824).

The following table gives the times required to flocculate a 0·1 per cent. purified clay suspension at various concentrations of sodium and calcium chlorides and hydroxides:

Time required for flocculation.

Concn. $Ca^{\prime\prime}$ ion.	$Ca(OH)_2$	$CaCl_2$	Two equivalents of chlorides to one of hydroxide.
0·001	7 hours	14 min.	6 hours
0·002	28 min.	10 ,,	32 min.
0·003	2	7 ,,	12 ,,
0·004	1·5	6 ,,	4·5 ,,
0·005	1·5	6 ,,	3·5 ,,
0·010	1·5	6 ,,	1·5 ,,
0·014	1·5	6 ,,	1·5 ,,
Concn. Na ion.		NaCl.	NaCl : NaOH = 2 : 1.
0·05	2 hours	13 min	2 hours
0·1	32 min.	13 ,,	32 min.
0·2	22 ,,	14 ,,	24 ,,
0·5	20 ,,	17 ,,	17 ,,
0·9	15 ,,	18 ,,	14 ,,

These results show that calcium hydroxide is a less powerful coagulant than calcium chloride, and actually tends to stabilise a suspension containing the latter salt, provided that the time of flocculation is longer than about twelve minutes.

If the concentration is such that coagulation takes place in 6 minutes or less, then calcium hydroxide flocculates more rapidly than the chloride at equivalent concentrations.

The results for sodium, on the other hand, suggest that even this latter effect should not be called anomalous, as at a concentration 0·9 normal, sodium

hydroxide was definitely a better flocculant than sodium chloride, while with the chloride-hydroxide mixture, this effect started at a concentration of 0·5 normal.

A preliminary experiment with a 0·1 per cent. suspension of highly purified amorphous silica gave the following results :

	Concentration required to flocculate in 1 hour.	
	Sodium.	Calcium.
Chloride .	No flocculation in 10 hr. in 1 *N* solution	No flocculation in 10 hr. in 1 *N* solution
Hydroxide .	0·13 *N*	0·0015 *N*.

Thus both sodium and calcium hydroxides were far better flocculants than the corresponding chlorides. The writer suggests that if the term 'anomalous' must be used, it should be applied to the coagulation of silica by electrolytes rather than to the coagulating powers of calcium and sodium salts.

Wellcome Tropical Research Laboratories,
Khartoum, September 20.

The Anomalous Dilatation of Invar.

IN *Arkiv f. Mat., Astron. o. Fysik*, vol. 19 B (1925), Messrs. C. Benedicks and P. Sederholm gave a short account of dilatation measurements of invar in which they claim to have found a new property of this well-known material. Raising the temperature of an invar wire quickly by 50°, they find the coefficient of expansion has sensibly the normal value, *i.e.* 13×10^{-6}, at the first moment of heating. After 3 minutes a contraction sets in, a steady state being reached after 12 minutes.

In order to repeat their experiment, I cut a strip $120 \times 1{\cdot}5 \times 1$ mm. from an old piece of invar forged out to 1 mm. thickness, and drew this into a wire of diameter 0·5 mm., 60 cm. long. This was clamped at one end, stretched with a force of 1 kgm. or less by a spiral spring at the other end, and heated to 50° C. by passing a current through it. A micrometer microscope focussed on a scratch near the free end enabled changes of length to be measured to within 1μ.

No trace of the new effect was found. The wire took its final length in any case 10 sec. after starting the current, as well as after cutting it off. The cold drawn wire contracted 10μ on heating ; after annealing at a red heat it expanded 6μ (coefficients approximately $0{\cdot}5 \times 10^{-6}$ resp. $+0{\cdot}3 \times 10^{-6}$), which shows that the wire was indeed the best quality of invar.

The above-mentioned authors detected by metallographic methods the existence of a second phase in invar, and then looked for an effect of a possible heterogeneous transformation on the thermal expansion. May I suggest that such an effect was found long ago by the exhaustive researches of M. Guillaume, in the form of a small thermal hysteresis which lasts for half an hour at 100° and a few days at 40° ? These times would seem more probable for a transformation in the solid state than 12 min. at room temperature.

As Mr. Benedicks used a wire only 8 cm. long, it may well be that a lag of some kind in his measuring arrangement—about which he gave no details—is responsible for his result.

Groningen.

Biological Research in the Tropics.

DURING the months July to September this year I was enabled to do some research work on protozoan parasites at the Imperial College of Tropical Agriculture in Trinidad, B.W.I., thanks to the generosity of the governing body in granting me free facilities there.

As I feel that the possibilities of the College as a centre for tropical research are not sufficiently known to biological workers at home, I venture to direct attention to the fact that for research workers in almost any branch of tropical biology, there is no more convenient place for headquarters than the College. Though, of course, its teaching activities deal more exclusively with agriculture, the governing body and the Principal, Dr. Leake, were most generous in allowing me facilities for prosecuting my research, which was not connected directly with agriculture.

At the present time the only tropical research laboratory easily accessible to British workers is the one at Kartabo, British Guiana, run by Mr. Beebe under the auspices of the New York Zoological Society. Trinidad has the advantage of involving a shorter journey, and the biological worker will find large laboratories, which will soon be very well equipped, thanks to the new government grant. But, of course, the main point of importance to the biologist in the tropics would be the abundance of tropical forms, and here Trinidad compares favourably with other West Indian islands, as it is the most tropical of them all, and the flora and fauna are more South American than West Indian in affinities. There are large tracts of primitive forest which are under government control and form wonderful collecting grounds.

To a worker who can spend only a short time in the tropics, the presence of an expert staff such as that at the Imperial College of Tropical Agriculture can be invaluable, especially when backed by the valuable entomological, etc., collections which the College possesses. The College works in happy unison also with the Department of Agriculture, where again one found the most able and ready assistance on the part of the local experts, including my friend Mr. Urich, who possesses an unrivalled knowledge of the island fauna.

On these grounds, and on others which are too numerous to enumerate here, I wish strongly to urge that biologists who desire to do tropical research could not do better than obtain permission to work at this College, permission which, I have no doubt, will be granted in all suitable cases.

The University, Manchester.

Magnetic Storms and Wireless Communication.

IT was reported a few days ago that communication with Canada, by the new beam system of rays of short wave-length, had been completely blocked by a magnetic storm. Why should this be ? The fluctuations of magnetic force are but slight, and one might expect the rays to arrive by an altered path. May we assign a deeper and more fundamental cause ? That the magnetic storm is itself due to an incursion of free electrons into the upper atmosphere, in such numbers as to upset all the ray-paths and twist them out of regularity. The number of foreign electrons need not be very great. The only alternative seems to be oscillation of the magnetic field, so rapid as to be comparable with the time of transit of the ray : which is very unlikely.

JOSEPH LARMOR.

Cambridge, October 26.

Aspects of Physical and Mental Inheritance.[1]

By Prof. R. RUGGLES GATES.

ONE of the most striking facts in modern biology is the discovery that hereditary differences commonly behave as independent fixed units, handed on generation after generation according to various characteristic but simple laws. The differences so transmitted may be large or they may be very minute, but they in some way maintain their identity throughout the welter of events which constitute the passage from one generation of adults to another: that is, the maturation of the germ cells and the development of the individual. Clearly a physical difference maintained in successive generations among individuals developing in the same environment must be due to an initial difference in the germinal material. Such differences are, moreover, as a rule equally inherited through either the egg or the sperm in crosses. The only structural materials in the germ cells of higher organisms which fulfil these requirements for transmission are the chromosomes.

These minute bodies in the nucleus evidently constitute the essential nexus between generations, in so far as the widespread Mendelian differences are concerned, but in plants certain characters may be controlled by plastids in the cytoplasm. It has furthermore been proved in certain plants and animals that visible differences in the chromosomes are accompanied by external differences in the resulting organism. Just as the cell theory of organic structure long ago emerged into fact, so the chromsome theory of inheritance has become a fact. This does not mean, however, that the chromosomes alone are concerned in inheritance.

An abundance of evidence from many sources leads to the view that the chromosome is a complicated structure composed of smaller units. The theory that these units or genes are arranged in linear fashion in the chromosomes, has been connected chiefly with the name of Morgan, because of his extensive studies of heredity and mutation in the fruit-fly, Drosophila; but its origin is really much older. While this theory of linear arrangement is not yet established, it may be said that no other reasonable theory has yet been put forward to explain the phenomena of crossing-over which have been so extensively investigated in this fly, and to a lesser extent in various other organisms.

We have, then, a picture of the chromosomes as containing large numbers of differentiated areas or groups of particles which, while in the uncompacted state, activate and control or determine the growth and differentiation of the cytoplasm and hence the development of the individual. Such conceptions are necessary to explain the unitary behaviour in inheritance of innumerable characteristics in man as well as in other organisms.

While, however, the units must be abstracted and considered separately for purposes of investigation, yet they form the elements of an extraordinarily complicated system and they cannot exist apart from it. Eyes may be blue or brown, and the difference is inherited as a unit, but the blue eye can only develop as a part of the whole system to which it belongs.[2] Here I am in fundamental agreement with the views expressed by Dr. Myers. Just as the developed character cannot exist apart from the organism to which it belongs —you cannot separate the serration from a leaf margin or the shape of the nose from that organ—so in the germplasm the various structural elements making up the configuration, though each produces its own effect through chemical action or structural arrangement, are interdependent in the system to which they belong. Mendelian inheritance consists in the substitution of one such unit for another which occupies the corresponding position in the architecture of the germplasm.

The phenomena of heredity are made possible by these structural arrangements within the organism, the body being composed of cells each with its nucleus, that nucleus containing two sets of chromosomes of corresponding structure, one derived from each parent. Thus are we woven out of the warp and woof derived by mitotic division from two parental sex cells, making a garment infinitely finer in texture and more intimately blended in its structural elements than any fabric. Yet the fact remains that these elements maintain their identity and usually segregate out again sharply when new germ cells are formed.

The orderliness of development in its minutest details, the interrelations and interfunctionings of the chemical and structural elements as they arise, impress every biologist deeply with their regularity and stability. The phenomena of individual development are thus as remarkable in some respects as those of evolution itself. In heredity all these potentialities of the organism must pass over the very narrow bridge of the two germ cells, one of which contributes little more than a nucleus. How this miracle of orderly development is accomplished we can only dimly picture in detail. But the ubiquitous facts of heredity continually emphasise the amazing orderliness of development.

It is sometimes stated that the clear-cut segregation which is so characteristic of Mendelian heredity applies only to abnormalities, and that normal racial and specific differences do not follow such laws. The fact that related species often differ visibly in their chromosome equipment certainly leads to many departures which may more or less completely obscure Mendelian phenomena in crossing. De Vries formerly took up the position that species and varieties differ in their behaviour on crossing. But there is nothing in the more recent work to show that such differences as exist are really fundamental in our present point of view, although they are certainly important. Variety differences are often single sharp units, while specific differences are more apt to represent accumulations of many, often multiple, differences, or chromosome differences which have come about in other ways than by simple Mendelian mutations. Interspecific sterility,

[1] Contribution to a joint discussion on "Heredity in its Physical and Mental Aspects," before Sections D (Zoology), H (Anthropology), and J (Psychology) of the British Association at Oxford on August 9.

[2] That this does not necessarily include the whole organism is shown by the recent tissue culture work of Strangeways and Fell, in which eye rudiments excised from embryo chicks continued their development.

however, all too frequently prevents crosses being made from which evidence of the nature of the differences could be obtained. There is some evidence, however, both in animals and plants, that in related species the germplasm is similarly constituted.

In the case of man, there is no evidence that the process of inheritance of racial characters differs in any important respect from that of abnormalities. In eye colour—a typical racial character—blue and brown have long been regarded as a Mendelian pair, and while different degrees of brown exist, there is evidence that each segregates sharply from blue. In my book "Heredity and Eugenics" the inheritance of a large number of abnormalities was considered, each following its own Mendelian law.

More recently I have considered the inheritance of racial differences[3] in man. Here multiple factors appear often to be characteristic, as in skin colour and stature. But everything indicates that inheritance of stature and cephalic index follows the same rules as the inheritance of size and shape in other organisms. Present knowledge indicates that the size factors in man differ in no important respect from those of rabbits or even of plants. Moreover, there is every indication that in interracial crosses, where stature and cephalic index are usually regarded as racial diagnostic features, the laws of inheritance of these differences are exactly the same as within a single human family. The more recent investigations indicate that far too much importance has been attached to cephalic index as a racial character, and the same is true to a lesser extent of stature. But it will be some time before a satisfactory analysis of head shape in terms of size and shape factors can be attempted.

Turning now for a moment to mental inheritance, I do not propose to discuss any of the philosophical views of the relations between mind and body, although I am inclined to adopt some such interpretation as that of Lloyd Morgan, namely, that the life of the organism can equally be viewed as a system of physiological or of mental events, without solving or attempting to solve the problem of their interrelations the one to the other. But from the biological point of view, as Prof. Dendy wrote, "It is only in so far as they are related to the brain [I should prefer to say the nervous system] that the discussion of the inheritance of mental characters can have any meaning." The analogy which is sometimes drawn between heredity and memory is really an attempt to explain the less obscure by comparison with the more obscure, or from the point of view just expressed it represents a jump from the physiological to the mental interpretation instead of adhering consistently to one or the other.

In one sense mental and physical inheritance are on exactly the same basis, for in both cases inheritance can only be determined by comparing parents with offspring or the latter with each other, and noting similarities and differences. Such comparisons lead to the clearest evidence of mental inheritance. But it should be recognised that observation of the fact of inheritance is one thing and explanation of how it comes about is quite another. Owing to the difficulty of defining and determining mental characters, progress in the study of mental inheritance has been retarded. Probably few psychologists would now deny the fact of mental inheritance, but biologists must look to them for an analysis of the mind which will enable us to determine what are the units which are really being inherited. Psychologists themselves are only beginning to consider these questions. McDougall's work has been most useful in the preliminary analysis of mental differences from a biological point of view.

When Galton began his studies of mental inheritance the faculty psychology was current, and he naturally made use of its conceptions. But now that the conception of the mind as made up of faculties has become obsolete and various other methods of analysis have taken its place, we still need an analysis of the mind which will be more biological in its characterisation. McDougall writes of the "structure of the mind," but scarcely in the sense in which a biologist would hope to see the term used.

There appear to be two possible lines of approach to a biological analysis of the mind from an hereditary point of view: (1) By the study of mental evolution; (2) by comparison of the mentality of related individuals. As regards mental evolution, the study of animal behaviour shows that increasing complexity of the nervous system is paralleled by increasing mental complexity or powers of reaction. This is clear to any one who compares, for example, a Paramœcium, a starfish, and an ape. Elliot Smith has pointed out in some detail how the mental evolution of man himself has taken place through increasing complication in the structure of the fore-brain. The mind has become an instrument for the recognition, confluence and co-ordination of relationships.

That many mental differences are the result of germinal variations arising in the nervous system is indicated by such extreme cases as (*a*) tumbler pigeons, (*b*) a race of goats which becomes partially paralysed when frightened,[4] and (*c*) in man, feeble-mindedness. It is questionable in how far any other source of mental variations is required to explain mental evolution. The cases cited are semi-pathological, but the smaller, normal differences which have been less studied are likely to show similar origin and hereditary behaviour.

There are no doubt many ways in which the human mind can be analysed and its elements classified; but I believe it will be found with mental, as with physical, inheritance that the only way to determine what are the inherited units is by comparing the mentality of parents with that of their children and relatives. The difficulties of such comparison are of course increased by the facts of proximity and imitation. But the *differences* which appear will often be more significant than the similarities. We have already seen that studies of physical heredity require that the organisms should develop in a similar environment. Obviously the same is true of mental inheritance; but as individuals develop they choose their own mental environment according to their inherited

[3] "Mendelian Heredity and Racial Differences," *Journ Roy. Anthrop. Inst.*, **55**, 468-482, 1926.

[4] It appears not improbable that the 'death-feigning' instinct of certain insects and other animals has arisen in a similar way through germinal variations in the nervous system.

tastes and aptitudes. In the biographies of great men it often appears that escape from their early environment was their only means of finding self-expression for their inherited mental qualities.

From the point of view I am expressing, mental inheritance is just as real as physical inheritance, and a suitable mental environment is just as necessary for the development of mental characters as a suitable physical environment is for the development of physical characters. Further, the mental environment is extremely complex and intimate in the way it impinges upon the developing individual. One of the remarkable things about organisms, however, is the stability they often show under altered conditions of development, and this appears to be as true of mental as of physical characters. Mental tests apparently show that inherent intelligence, for example, does not develop or grow with the growth of the individual.

Another method by which mental inheritance has been studied is by the comparison of the mentality of identical twins. Galton, the pioneer in this field, cites many remarkable cases of such similarity, in some of which the twins were separated. More recently, many cases have been studied in some of which the separation took place at an early age, making it possible to study the effects of differences in upbringing upon the mental development and the innate abilities. While the mental environment is by no means negligible, and is often profound in its effects on the early development of the mentality, yet it seems clear that innate, *i.e.* inherited, differences persist, which are little if at all affected by the circumstances of life.

There is another matter which, I believe, adds greatly to the complexity of human behaviour. In 1923 I first suggested that when the individual is germinally heterozygous for a pair of contrasted character traits, they may both come into expression in his activities at different times. Indeed, this appears more likely than that there should be complete dominance of a mental character over its allelomorph. I am now looking upon traits of character as different methods of reacting in given circumstances. Since every one is doubtless heterozygous for many such character differences, this would help to account for some of the complexities as well as inconsistencies in human behaviour. Cases of multiple personality are possibly to be explained as more extreme examples of the same kind.

Finally, I should like to reiterate that what is most required now in the study of mental inheritance is an analysis of the mind by psychologists from an inheritance point of view. Psychologists have been so engrossed with the mind as such in its manifold activities that they appear to have neglected the kind of comparative psychology of individuals which is necessary for this purpose.

The Relation between Velocity of Wind and Wave.

By Dr. VAUGHAN CORNISH.

MANY years ago an investigation was begun by me to determine the relative velocity of wind .nd wave in deep water when the former has operated or a sufficient time to produce a constant condition, nd with sufficient sea-room. The results are given in he *Quarterly Journal of the Royal Meteorological Society* or April last, and, at the invitation of the Editor of NATURE, some of the points of interest are brought ogether in this article.

The relation between velocity and period of deep-sea vaves given by the ordinary formula for waves of nfinitesimal height, namely, velocity in statute miles per hour = period in seconds multiplied by 3·493 agrees vith that observed for ocean waves of conspicuous limensions[1] sufficiently for the discussion of phenomena o numerous and irregular.

By timing the rise and fall of spots of spent foam ıpon the water, it is possible to determine from on board ship the period of both the wind-waves and of swell running at the time, whether crossing or concurrent. Employing this method I have never recorded waves with a speed greater than that of the wind, as has been done by other observers, an anomalous result which I attribute to mistaking a heavy swell for the wave when they are concurrent. Observations on a river at turn of tide, when the foam-spots were carried by the current first down-wind and then up-wind, have shown that their wind-drift is small relatively to the other nagnitudes concerned.[2]

[1] See the author in *Jour. Roy. Soc. Arts*, Nov. 1, 1912, " Ocean Waves," and the *Field*, Feb. 13 and 27, 1915, " The Measurement of Waves at Sea."

[2] ... of Wind, Wave and Swell on the North Atlantic Ocean."

In the course of a voyage between Trinidad and Ushant, in very deep water all the time and free from considerable currents on every day but one, the speed of the waves was compared with the average speed maintained by the wind *for one hour or more*, as recorded by a Robinson anemometer fully exposed upon the bridge. When there was no crossing swell to interfere with the development of the waves, their speed was only 1·85 statute miles per hour less than that of wind, which had a sustained average velocity of 20 miles per hour. Thus there was blowing over the wave-crests only a ' light air,' the ' force 1 ' of Beaufort's scale, sufficient to drift the smoke issuing from a chimney but not strong enough to give direction to a wind-vane.

When hove-to in the Bay of Biscay in the storm of December 21, 1911, I determined the speed of the waves as 47·15 miles per hour, when the velocity of the wind, according to the logged Beaufort number, was 52·5 m.p.h. During the exceptionally stormy winter of 1898–99, when I was living within sight of the beach of Bournemouth Bay, the greatest period of a long-sustained series of breakers was 19 seconds, corresponding to a speed in deep water of 66·4 m.p.h. This was recorded on the afternoon of December 29. Gales in the North Atlantic from December 25 to December 29 were logged at 11 and 12 of Beaufort's scale, which correspond to wind velocity of 68 and greater than 75 miles per hour respectively. The greatest wind velocity on land during this winter, as recorded by instruments, was 70-76 miles per hour sustained for one hour.

The breakers above referred to, which were 139 in number and occupied three-quarters of an hour in arrival, were preceded in the morning by five groups

of a few breakers with longer period, corresponding to a deep-water speed of 69·5 m.p.h. The interval between the beginning of the first and the end of the last was 52 minutes, which strongly suggests that they were waves from the squall-struck portions of the stormy sea which outran their neighbours. The time occupied in arrival by the individual groups was from 1 to 2 minutes, which is normal for the duration of a short squall. The figures so far given suggest that the maximum speed of waves is somewhere about $\frac{8}{10}$ths that of the wind as maintained for one hour, and that a squall lasting for a minute or two can speed-up waves which have already been developed. Once when the waves were flattening down in a dying storm in the North Atlantic, I actually saw a travelling squall increase by some feet the height of the few waves subject to its force.

The observations during the fine-weather voyage on which an anemometer was used provide important evidence of the effect of crossing swell in hampering the development of waves by wind. The restriction of height was palpable to the eye. The restriction of speed was measured. With no swell, or with a concurrent swell, as in the Trades, the speed of the wave was only 1·85 m.p.h. less than that of the wind, but with a swell following obliquely the difference was 3·725 m.p.h., and when crossing at right angles or meeting the waves, 7·2 miles per hour.

A result of practical importance to seamen and meteorologists emerged from the observations on days of crossing swell. When this was oblique to the waves the curl, or break, on the water was considerably deflected and therefore ceased to be a trustworthy indication of the direction of the wind.

The following explanation is suggested of the effect of swell to hinder the wave-making action of wind. When there is no swell and the waves have attained considerable steepness a series of travelling eddies is established in the adjacent air with permanent undulations above, and this arrangement nurses the waves. If, however, a swell be also running, the pattern of the inequalities changes all the time, continually deforming the superimposed air, and making its action irregular. If the swell meet the waves, the pattern undergoes rapid change, and the rhythmic action of the wind is greatly hindered; if it follow the waves their pattern changes slowly and the rhythmic action of the wind is less impaired. When the swell cuts squarely across the waves the surface is patterned in cups and cupolas instead of ridges and furrows, which tends to set up air-whirls with vertical instead of horizontal axis, a condition which imposes an additional hindrance to wave-making.

The extent to which swell kept down the waves when crossing obliquely or squarely suggests that the rapid rise of waves on large lakes is not solely due to peculiarities of local winds but is aided by the fact that no residual swell hampers the action of the wind, as usually happens when it comes on to blow at sea. There is one condition at sea, however, when the development of waves is more rapid than in lakes, namely, when it comes on to blow in the direction of the swell already running and with a speed greater than that of the swell. This was the condition which so quickly created the huge regular waves of December 21, 1911, in the Bay of Biscay.

OBSERVATIONS BETWEEN TRINIDAD AND USHANT.

(Speed of wind as maintained for about one hour measured by Robinson anemometer.)

DIFFERENCES OF SPEED BETWEEN WIND AND WAVE, GROUPED ACCORDING TO DIRECTION OF SWELL.

Direction of swell	Character of swell	Date of observation (1914)	Amount by which speed of wind exceeded that of wave	Average difference of speed in statute miles per hour.
Concurrent with waves	High, quick period, slow progression	Feb. 18 ,, 19	1·2 2·5	1·85
	Quick period, slow progression	,, 20 ,, 21	3·9 3·3	3·725
Following the waves obliquely	Slow period, quick progression	,, 28 (P.M.) Mar. 1	3·3 1·4

Mars in 1926.

By Dr. W. H. STEAVENSON.

THE present apparition of Mars is, for observers in the northern hemisphere, the most favourable that has occurred for many years. The planet, which was at opposition on November 4, made its closest approach to the earth on October 27, on which date its distance was approximately 42,600,000 miles and its apparent diameter 20″·4. On August 22, 1924, the distance was 8,000,000 miles less and the apparent diameter so great as 25″·1 (practically the maximum possible), but on this date the planet, at its greatest altitude, was not more than 21° above the horizon of London; whereas, on October 27, 1926, it crossed the meridian at an altitude of 53°. This increase of 32° was more than sufficient to make up for the shrinkage in apparent diameter, with the result that observers in Great Britain have, in general, been able to obtain more satisfactory views than at the closer approach of two years ago. Not until 1941 will there occur an equally favourable combination of altitude and apparent diameter.

In 1926, as in 1924, it is the southern hemisphere of Mars that is presented most favourably for observation, and this always happens at close oppositions of the planet. The Martian season at the time of opposition was not, however, quite the same on each occasion. In 1924 the planet was most favourably placed for observation during the early summer of its southern hemisphere, whereas in 1926 the summer solstice of this hemisphere occurred more than two months before opposition, so that we have a satisfactory seasonal overlap in the observations made in the two years.

The results of this overlap have been very evident

this year in the reduced size of the South Polar cap at the date of opposition, and also in the more advanced development of the usual seasonal changes in the dark markings. These changes, both of colour and intensity, are now firmly established facts, and can be predicted with considerable accuracy. But almost more interesting are those less regular changes of form and intensity which have not yet been found to conform to any definite law. They thus provide an element of variety in our observations of the planet, and, as they are often on quite a large scale, afford opportunities of useful and interesting work to the possessors of moderate-sized telescopes.

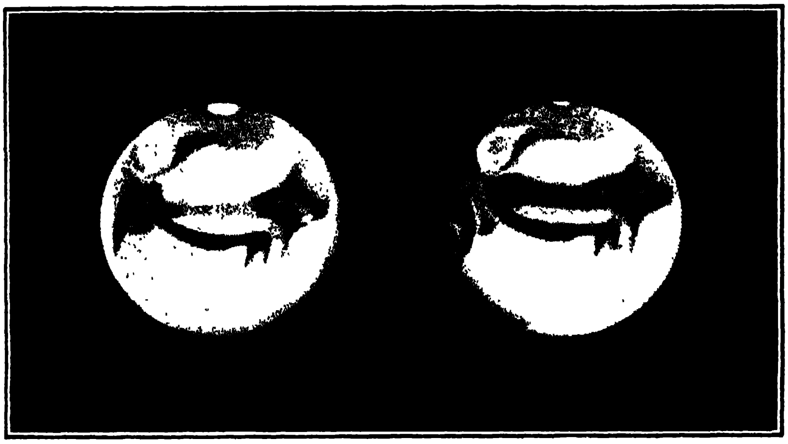

FIG. 1.—Aspects of Mars, September 1924 and October 1926, showing changes in the characters of *Sinus Sabaeus* and *Pandorae Fretum*.

Several changes of this kind have actually occurred since 1924, and some of them have been sufficiently extensive to be visible with quite small instruments. Figs. 1 and 2 show two of the more conspicuous alterations that have so far been noted. Just below the centre of the disc in the two views forming Fig. 1 is a dark belt-like marking. This, the *Sinus Sabaeus*, is nearly always a conspicuous feature; but above it, and separated from it by a lighter strip, is another dark streak, known as *Pandorae Fretum*, which is subject to marked changes from time to time. It will be observed that, whereas in 1924 it was faint and tapered towards the left, it was in 1926 much darker and approximately of the same breadth throughout. So far as the increase in intensity is concerned, the change is partly of a seasonal character, though the darkening took place earlier in 1926 than in 1924. But in the latter year the marking never attained quite the same breadth, so that to this extent the change is anomalous. More striking still has been the change observed in *Solis Lacus*, shown in Fig. 2. This marking, which lies in a region often referred to as the "Eye of Mars," will be readily recognised on both sketches just above the centre of the disc. Irregular changes in the size and outline of the *Lacus* have occurred several times during the past century, but for some years now it has generally appeared roughly pear-shaped, with a thick 'stalk' connecting it with the dark areas on the left. It was of this shape in 1924, as indicated by the first sketch, but since then a complete transformation of its outline has taken place. This, as will be seen, has been brought about by a wide extension of the free end of the 'pear' in a northerly direction, and this extension is much deeper in tone than was any part of the marking in 1924. Further, minor changes in the neighbouring regions will also be noted.

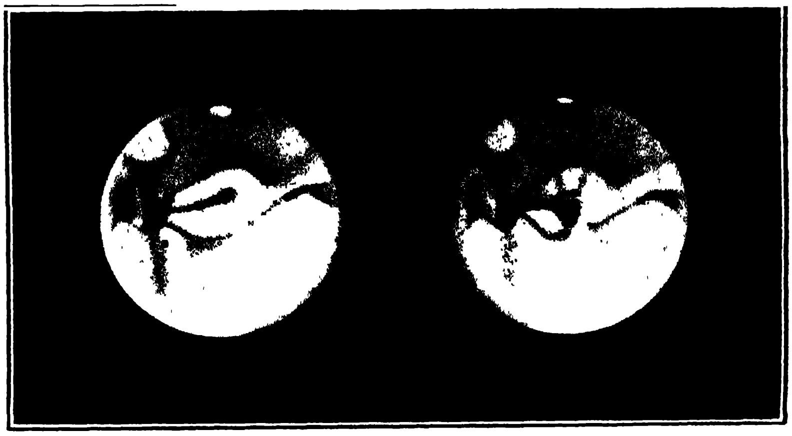

FIG. 2.—Aspects of Mars, October 1924 and October 1926, showing changes in the character of *Solis Lacus*

A satisfactory explanation of such gross changes as these, affecting thousands of square miles of the planet's surface, cannot at present be advanced; but if we assume, as now seems reasonable, that the dark areas of Mars represent tracts of vegetation, it appears possible that the irregular effects observed are due to seasonal abnormalities, such, for example, as the occurrence of unusually wet or dry summers.

There is need, however, for more study before we can reach confident conclusions upon the matter. Fortunately, the observations necessary are not of great delicacy, being in fact well within the range of the instruments commonly at the disposal of amateurs. In the writer's opinion, much valuable time and trouble has been wasted in the past in attempts to observe and delineate the more minute details of the surface of Mars. Such fine detail can at the best be only imperfectly seen in common instruments, and there is room for much difference of opinion as to its precise nature. On the other hand, the extensive modifications of outline and intensity already described are quite beyond all question, and present to us a most interesting problem to which there is good hope of an ultimate solution. Observations made on these lines will increase in value with the lapse of time, and will for many years to come provide profitable work for much smaller instruments than were at one time thought necessary for a successful study of the planet.

News and Views.

LORD BALFOUR presided at the first meeting of the Imperial Conference Research Sub-Committee held on October 25. In his opening speech he re-emphasised the points made in Mr. Amery's address to the Empire delegates the previous week. Research is more important to the British Empire than to any other great power. The Empire in its different parts is confronted with a bewildering variety of problems of almost baffling complexity, the solution of which depends upon the success of the efforts of a considerable body of research workers and the effective co-ordination of their work. Reference was made to the co-ordinating machinery already developed, in which the Department of Scientific and Industrial Research, the Development Commission, the Medical Research Council, and the Royal Society participate. Much of the work undertaken by those bodies is of interest to the Dominions and Colonies, but it is an open question whether the existing machinery is adequate to the needs of the tropical countries of the Empire with their special needs and problems. Representatives of the Dominions followed Lord Balfour with accounts of the efforts being made in their respective countries to apply science to the solution of their particular problems, the representatives of Australia and New Zealand paying warm tributes to the assistance they had received from Sir Frank Heath during his recent visit. Mr. D. T. Chadwick said that the devolution of larger powers to the Provinces in India had been a serious obstacle to the effective co-ordination of research. Mr. Ormsby-Gore, who wound up the discussion, spoke of the isolation of the research workers in tropical colonies of Great Britain, their difficulties of inter-communication, and their dependence on the prosecution of research in the Dominions and Great Britain, and the more effective distribution of the results obtained. There is a scarcity of scientific investigators in the tropics, to remedy which he urged the provision of more highly paid posts such as would induce promising scientific workers to enter the Colonial Service.

AT the third meeting of this committee Mr. J. W. Dulany gave an account of the progress of research work in the Irish Free State. He was followed by Sir William Clark, Comptroller-General of the Department of Overseas Trade, and Dr. A. W. Hill, who described respectively the functions of the Imperial Institute and the Royal Botanic Gardens, Kew, in connexion with Empire research. The reference made to the potentialities of the Imperial Institute as a co-ordinating centre for imperial activities in scientific research is welcome in view of the sceptical attitude of some of the Dominion representatives regarding its work and functions expressed at the meeting of the Imperial Conference held in 1923. The Institute has been persistently starved for funds, the contributions of the Dominions and the Tropical Colonies having been niggardly in the extreme; its scientific staff has met with every kind of discouragement for years, having been inadequately paid, given no security of tenure, and forced to work with inadequate laboratory accommodation and equipment; and much of the work for which it was originally intended has been handed over to other bodies, *e.g.* the Imperial Entomological Bureau and the Imperial Mineral Resources Bureau. Nevertheless, it has a nucleus staff, the members of which have striven for years in the face of these various difficulties to investigate the problems in connexion with the utilisation of the plant and mineral resources of the Empire and to act as a clearing-house for Imperial researches. Properly endowed it could become a very important factor in the co-ordination of Empire research, and it is to be hoped that the awakening of the Dominions to the importance and meaning of scientific research means that they will be prepared to give this institution the support it deserves.

THE speech on Empire air transport by Sir Samuel Hoare, Secretary of State for Air, at the Imperial Conference on October 28, may be taken as giving the collective views of his engineering staff. It would be interesting to have individual opinions, and to compare their sum with their resultant. With regard to fighting forces, the need for aircraft is a *chose jugée*; every belligerent will acquire the most numerous and effective aircraft it can get, from its own or neutral industry, for scouting, bombing, and fighting. Civil air transport has been proved over so wide a range of conditions that its extension to an Empire network is practically a question of finance. Airship service in war seems to be ruled out by the restriction that an airship must never come within range of an aerodrome or an aeroplane carrier. With regard to civil transport by airship, the record of service is adverse to the hope that even lavish expenditure will maintain regular services over Empire routes, and a schedule of 2½ days to Canada, 5 days to India, 6 days to Cape Town, 11 days to Australia, and 13 days to New Zealand, seems to outrun present knowledge. The technical staff concerned is working hard to reduce the difficulties inherent in the design of these vast structures, lighter than the turbulent atmosphere which sustains and buffets them, but the increase of size and change of form, by which it is hoped to solve some of the problems, demands extrapolation far beyond previous experience.

FOLLOWING the address of the Secretary of State for Air to the Imperial Conference, interesting accounts were given by the Dominion premiers and the Under-Secretary of State for India of the development of the air services for which they are responsible. The progress which has been made since the last Imperial Conference appears to be most gratifying and opens up romantic possibilities. It was evident that these appealed strongly to Mr. Amery, who summed up the discussion. He drew a picture of the isolated white worker in the tropics making business calls in his own aeroplane and flying to a bungalow in the nearest hills for a week-end rest. He remarked

on the potentialities of the aeroplane in connexion with forest, fishery, and geographical surveys. The use of aeroplanes for the extermination of insect pests in the American cotton plantations area opened up the possibility of its extended use to the extermination of the tsetse fly in Africa. He struck a welcome note when he mentioned the discoveries which have been made from the air of long-forgotten cities, an old sacrificial way to Stonehenge, and archæological treasures in Sind, remarking that the use of the aeroplane in archæological research, one of the least material of researches, is not unworthy of the notice of the British Empire.

THE first department of anthropology in Australia has just been established in the University of Sydney. Funds for this purpose have been provided by the Commonwealth Government and the Governments of the various Australian States. Prof. A. R. Radcliffe-Brown, for some years past professor of social anthropology in the University of Cape Town, has been appointed to the new chair and took up his duties at the beginning of July. Provision has been made for including anthropology as a subject for the B.A. and M.A. degrees, and it is also proposed to offer a diploma in anthroplogy similar to that offered at Cambridge. Plans are being made for a special course of training in anthropology to be given at Sydney to cadets entering the Administration of the Mandated Territory of New Guinea. Special courses are also being provided for officials in New Guinea and Papua, missionaries and missionary students, and others who are unable to attend the University for a year and therefore cannot .e the full diploma course. The Rockefeller Foundation has placed at the disposal of the Australian National Research Council a sum of money for anthropological research in Australasia. The funds to be released in any one year are to be determined by the amount contributed for anthropological studies from other sources with a limit of 20,000 dollars a year. The Australian National Research Council has appointed a committee on anthropological research to advise on the expenditure of these funds, and plans are now in active preparation for carrying out researches in physical anthropology and ethnology.

THE report on the excavations at Lubaantun, British Honduras, on behalf of the British Museum, recently presented to the Trustees, of which a summary appeared in the *Times* of October 28, makes interesting reading. It is more than likely that this site will prove one of the most important in Central America in its bearing on the obscure question of the origin and early history of Maya culture Not only is the site the largest, but it is also probably the earliest of Maya centres. Its extent, and the number and size of its buildings, including the hillside terraces which aroused so much interest when first reported, demand a very high antiquity for the period of its inception. The work must have been continued over a very long time as well as required the efforts of a numerous and highly organised population. Further, the pottery and the plaques and figurines from surface finds correspond with the artistic style of "Early Maya" on such early sites as Copan and Quirigua, obviously a product of a long period of development, so that when the lower strata at Lubaantun are excavated, discoveries illuminating for the early history of the Maya may be expected. In many respects the Lubaantun site has proved to be unique in Maya culture. Of the four styles of architecture found on the site, one style of building which employed huge blocks of stone, large enough almost to justify the title 'megalithic,' was not hitherto known in Central America, though it occurs in Peru; while a so-called 'in-and-out' style is new in American architecture.

SENATOR MARCONI gave a very interesting James Forrest lecture to the Institution of Civil Engineers on October 26, when he discussed radio communication, with special reference to waves of short wave-length—that is, to high-frequency waves. It is common knowledge that the ether is becoming very congested with radio waves of certain frequencies. It is necessary, therefore, in order to utilise radio communication to the utmost, to extend the range of commercial frequencies. It was first pointed out that many uses can be made of radio waves, particularly in controlling mechanisms such as targets, torpedoes, and aeroplanes at a distance. It is probable also that electric power will soon be transmitted through the ether over moderate distances. The difficulty that has to be overcome is to project the waves in a parallel beam so as to minimise the dispersion and diffusion of the energy into space. A few years ago, radio engineers were much more confident about their formulæ than they are to-day. Applying them logically, they found it necessary to use very large amounts of power and enormous and expensive aerial systems to ensure communication to great distances. Consequently the high working costs prevented any substantial reduction in telegraph rates. Senator Marconi said that the whole theory and practice of the art is being revolutionised. Until quite recently long-distance transmission was carried on exclusively by employing wave-lengths lying between 8000 and 30,000 metres (37·5 to 10 kilocycles per sec.) The Post Office Station at Rugby, for example, uses waves having frequencies of 16 kilocycles per sec. The total power used at this station is 1400 kilowatts. Many similar stations are operating in other parts of the world, their cost being of the order of 500,000*l*.

FOR the last ten years Senator Marconi, with the help of Mr. C. S. Franklin, has been experimenting with high-frequency waves. In 1923 and 1924 very satisfactory results with waves having 3260 kilocycles per sec. were obtained. It was found that the daylight range steadily increased as the frequency of the waves was increased, the absorption decreasing very rapidly the higher the frequency was made. These results, Marconi said, cannot be explained merely by refraction, as the signals received over world distances are thousands of times stronger than indicated by the refractive theory. The Australian tests showed that with 9370 kilocycles per sec. it was possible to communicate for more than 23 hours out of the 24. With these high-frequency

waves the dimensions of the aerials and reflectors are reduced proportionately and very little power is required. The Marconi Company has been given the contract to make high-frequency stations for Imperial communications. At the Bodmin station for communicating with Canada, thermionic valves generate the necessary high-frequency currents of 11,500 kilocycles per sec. Communication with Canada at the rate of 2500 letters per minute over the whole circuit has been maintained for hours at a time. With these waves 'atmospherics' interfere very little. Even thunderstorms in the vicinity of the receiving station only cause interference when they are inside the angle of the receiving reflector. The high-power low-frequency stations in Great Britain are receiving and transmitting to America at an average speed of twenty words per minute for 18 hours a day. The low-power high-frequency stations, however, can work at least five times as fast over the same distance and for the same time. We are yet a very long way from being able to utilise radio waves to anything like their full extent. Their range of usefulness can be very greatly extended, and this will occupy the attention of engineers for many years to come.

A VALUABLE survey of the development and present position of the chemistry of the proteins was afforded on October 28 to fellows of the Chemical Society, when Prof. S. P. L. Sorenson, of Copenhagen, delivered the Hugo Müller lecture. The work of Mulder, of Proust and Braconnot, of Liebig, of Cramer, and of Hopkins and Cole on the composition of protein substances was mentioned, Emil Fischer's view that they consist essentially of amino-acids united by -CO · NH- linkings for many years formed the general foundation of all such researches, but recent work invites a modification of that conception. Prof. Sorenson is of opinion that conclusive evidence in favour of Troensegaard's pyrrole-ring structure is lacking, although it is clear that linkings other than those of the simple peptide type are present. It is, in fact, highly probable that some part of the nitrogen is present in heterocyclic structures, probably diketopiperazine rings. The observation, however, that none of the usual proteolytic enzymes attack diketopiperazine, whilst polypeptides are readily decomposed by erepsin, supports Abderhalden's contention that the diketopiperazine section of the protein molecule probably exists in a labile, tautomeric form, a consideration which the lecturer discussed in some detail. Further, he said, it is absolutely necessary to submit to closer examination the question as to how compounds having the assumed structure will behave towards proteolytic enzymes before attempting to reach decisive conclusions regarding the constitution of protein substances. Such investigations are being carried on by Waldschmidt-Leitz and his collaborators.

PROF. SORENSEN turned next to the problem of the characterisation of individual proteins, in which small differences in the elementary composition are of relatively great importance. So, also, it is essential to distinguish between integral constituents and adherent or loosely-bound substances. Linderstrøm-Lang has succeeded in obtaining casein fractions containing different amounts of phosphorus, naturally raising the question whether it is possible to prepare casein free from phosphorus, yet still able to give the rennin reaction. In egg-albumin the phosphorus content is practically constant, and that element appears to be intimately associated with the rest of the molecular complex; but only a small part of the coagulable phosphorus of the serum-proteins is precipitable by alcohol. Hence it appears that the phosphorus is but loosely associated with the serum-protein complexes. Purification of the two proteins concerned by precipitation with alcohol at -4° gives results entirely in harmony with this conclusion. Prof. Sorensen's estimate of the molecular weight of the egg-albumin molecule is 34,000, corresponding with about 380 nitrogen atoms. By the application of electro-analysis to egg-albumin solutions, it is possible to reduce the phosphorus content to a value not far removed from that required if one phosphorus atom is present in such a molecule. Similar results have been obtained by long-continued storage in ice.

THE Zentralanstalt for meteorology and geodynamics at Vienna was founded in 1851, at the instance of the Vienna Academy of Sciences; the seventy-fifth anniversary of the Institute therefore falls this year, and at the suggestion of the Director, Dr. F. M. Exner, the Academy has celebrated the event by issuing a *Festschrift* dedicated to the Institute. The volume, of about 200 pages, contains 13 papers by Austrian and German geophysicists, among the authors being Ficker, Exner, W. Schmidt, A. Wegener, Defant, Conrad, and A. Wagner. Wegener describes observations of twilight bows and zodiacal light made in Greenland in connexion with J. P. Koch's expedition of 1912-13, the last twilight bow appeared to be produced by the atmosphere at a height of not less than 700 km., an elevation unparalleled among atmospheric phenomena except by the aurora. The other papers, too numerous to summarise, are mainly meteorological, but there is one relating to variations of seismic activity in regions of folding, and another on the influence of the earth's rotation on the course of rivers.

THERE are now two international organisations which deal with meteorology: the International Union of Geodesy and Geophysics and the International Conference of Directors. By mutual arrangement, the former concerns itself only with the scientific side of meteorology, while the practical application is left entirely to the latter. The Conferences of Directors are held every six years, and at each a number of Commissions is appointed to deal with various aspects of practical meteorology, membership of which is not limited to members of meteorological services. Eight such Commissions met in Zurich on September 13-20. The British representatives were: Dr. G. C. Simpson, president of the Commission for the Réseau Mondial; Lieut.-Colonel E. Gold, president of the Commission for Synoptic Weather Information; Dr. C. Chree, president of the Commission for Terrestrial Magnetism and Atmospheric Electricity; Sir Gilbert Walker;

Sir Frederic Stupart (Toronto); Mr. C. J. P. Cave; Mr. C. Stewart (Pretoria); and Mr. R. A. Fisher. Afterwards the International Meteorological Committee met in Vienna on September 23-28 under the presidency of Prof. van Everdingen (Holland). The following are amongst the chief decisions reached: A system of visual gale warning signals, for day and night, was adopted for all national services, and agreement was reached as to the conversion of velocities read on anemometers into Beaufort Numbers for weather telegrams. The International Cloud Atlas—prepared in 1895 by Messrs. Hildebrandsson, Riggenbach, and Teisserenc de Bort—has for some time been out of print; a new atlas is to be prepared which will contain a new set of photographs and the proposed changes, for the consideration of the Conference of Directors meeting in 1929. An anonymous donor has generously provided funds for the purpose. Throughout its history the International Meteorological Committee has had no permanent staff and no funds. All secretarial work and the publication of the reports of the meetings have been undertaken by one or more of the national meteorological offices. It has now been decided that the time has come to establish a secretariat to look after the records of the Conference, Committees, and Commissions, to arrange the meetings, and to publish the records.

SCIENCE Service, the endowed organisation that supplies scientific news to ephemeral publications in the United States, has made a new departure by issuing its "Weekly News-Letter" in printed form to individual purchasers. The copy before us contains sixteen pages ($10\frac{3}{4}$ in. × $8\frac{3}{4}$ in.), more than six of which are occupied by matter relating to the Service and by 'fillers,' the arrangement being such that any article can be cut out without damaging any other. To facilitate the indexing of cuttings, each article bears a key-word above the title and a date at the end. The price is the very moderate one of 5 dollars per annum, or 10 cents per copy, but teachers, professors, librarians, and club-leaders may obtain each issue for 6 cents. The idea of penetrating the class-room is good, and the matter should be useful for enlivening the teaching of science and geography. In style, the articles and notes are crisp and restrained, and although in some articles the language could have been simplified, as a whole they are better written than the scientific news items that occasionally appear in our daily press. They are, however, somewhat marred by the headings, which betray the inaccuracy born of sensationalism and the love of alliteration. Thus, the title "Ice Cream from Crude Oil" is chosen for a description of recent work on the use of certain petroleum constituents as raw material for making edible fats and other natural products; and an article entitled "Fighting Forest Fires with Weather Service" contains nothing about combating fires, but is an interesting account of work undertaken by the U.S. Weather Bureau in forecasting atmospheric conditions that favour the occurrence and propagation of forest fires (which are stated to do 16 million dollars' worth of damage every year). In a country like Germany, and to a less extent the United States, a publication of this kind should find a good market; in Great Britain, where scarcely a single scientific periodical is to be seen on a railway bookstall, or in a bookseller's shop, its chance of success would be very small.

THE opening meeting of the Illuminating Engineering Society on October 26 was, as usual, devoted to reports of progress and exhibits of novelties in lamps and lighting appliances, photometric instruments, etc. The summary of progress during the vacation presented by Mr. L. Gaster contained several interesting items of news, such as the references to the inclusion of provisions requiring sufficient and suitable lighting in the new Factory Bill now before Parliament, and to the formation of an Illuminating Engineering Society in Holland. The address also summarised experiences during Mr. Gaster's recent visit to the Continent, where illuminating engineering is being keenly studied. In view of the widespread propaganda on lighting and the efforts being made in all countries to develop the commercial exploitation of illuminating engineering, the need for the maintenance of a scientific and impartial attitude on the part of the illuminating engineering societies in the various countries was strongly emphasised. Another lengthy report, read by Mr. J. Y. Fletcher, surveyed progress in electric lighting during the past year. Afterwards there were a number of interesting exhibits. Developments in lighting on the railways were dealt with by Mr. S. G. Elliot (Underground Railways), and Mr. A. Cunningham (Southern Railway). A new form of daylight-factor meter was shown by Mr. H. Buckley of the National Physical Laboratory, Teddington, and the latest model of the Holophane Lumeter photometer by Mr. H. Allpress. Other exhibits included the new Sheringham reflector yielding a light visually resembling daylight in colour, the internally frosted electric incandescent lamps, and some pleasing forms of decorative lighting units of the enclosed type.

WITH the control over epidemic diseases which has been obtained in recent years, and with the increasing proportion of elderly persons in the population, cancer has come to be one of the most important killing diseases. On September 20 and the following days, an international conference, organised by the American Society for the Control of Cancer, was held at Lake Mohonk, New York State, and was attended by representatives from most European countries. The various papers and discussions brought out nothing of a very novel character, but they made clear the steady advance which is being achieved in diagnosis and treatment, and in an understanding of what cancer is. The results were issued to the public in the form of an agreed statement which should be helpful. The conference says that cancer (1) is not contagious or infectious, (2) is not hereditary, and (3) can, so far as is at present known, be controlled only by attention to personal hygiene and by early diagnosis and treatment. The interest and co-operation of the lay public have done much to

improve general healthiness; we may hope that equally good results will follow in dealing with cancer.

DR. RUDOLF ABEL, professor of hygiene, University of Jena, delivered two lectures under the Chadwick Trust on October 19 and 20, taking as his subject "The Development and Present State of Public Health in Germany." The lecturer first described the bad hygienic conditions formerly prevailing in Germany. It was only after the foundation of the German Empire in 1871 that practical care of health was developed, and the conversion of Germany from a mainly agrarian State into an industrial one, with the development of the towns that followed this change, took place without disaster, thanks to the improvements in sanitary conditions which had likewise been proceeding. Public Health administration and legislation were then discussed. The Medical Officer of Health in Germany is a State official paid by the State, but the cost of hygienic institutions and sanitary work is borne by the community. During the last fifty years the death rate has diminished more in Germany than in England, so that now the two countries are nearly on a level. As regards infectious diseases in Germany, notification of and inquiry into the cases, isolation and disinfection, are very similar to those obtaining in England. The campaign against tuberculosis is carried on by means of dispensaries, visits to the family, sanatoria and hospitals, and by education of the people on a large scale. Venereal disease increased much during the War, but is being dealt with by free consultations and treatment. Alcoholism diminished during the War owing to shortage of alcoholic beverages, but has since shown a recrudescence and is being combated by licensing regulations, clinics, and temperance societies. Maternal and child welfare is being cared for by special legislation, and infant mortality is declining, though it is still higher than in England. Industrial hygiene has been regulated in detail by many legal enactments. Housing conditions are not good in German towns; there is much over-crowding and a great shortage of accommodation. Very much is also being done for the social welfare of the poorer classes.

PROF. W. J. HUSSEY, Associate of the Royal Astronomical Society, Director of Detroit Observatory, Ann Arbor, U.S.A., died very suddenly on Thursday last, October 28, in London, at sixty-four years of age. He had arrived from America a few days before, and was to have sailed the next day for South Africa, where he was to have set up a 27-inch telescope on a site to be chosen—probably Bloemfontein.

THE Norman Lockyer Lecture of the British Science Guild will be given in the Goldsmiths' Hall (by kind permission of the Goldsmiths' Company) on Tuesday, November 23, at 4 P.M., by Prof. J. S. Huxley, who will take as his subject "Biology and Human Life." Tickets for the lecture may be obtained on application to the Secretary, British Science Guild, 6 John Street, Adelphi, London, W.C.2.

AT the annual statutory meeting of the Royal Society of Edinburgh held on October 25 the following officers and new members of council were elected: *President*, Sir James Alfred Ewing; *Vice-Presidents*, Dr. W. B. Blaikie, Sir Robert Blyth Greig, Prof. T. H. Bryce, Prof. E. T. Whittaker, Dr. James Currie, Dr. A. Crichton Mitchell; *General Secretary*, Prof. R. A. Sampson; *Secretaries to Ordinary Meetings*, Dr. A. Lauder, Prof. W. Wright Smith; *Treasurer*, Dr. J. Watt; *Curator of Library and Museum*, Prof. D'Arcy W. Thompson; *New Members of Council*, Mr. J. W. Peck, Dr. J. Ritchie, Prof. R. Stanfield, Dr. A. L. Turner, Dr. G. W. Tyrrell.

THE sum of 400*l*. is allocated in each calendar year by the Institution of Petroleum Technologists to the advancement of research in petroleum technology and its basic sciences, and the Council is prepared to receive applications for assistance from this fund. Applicants proposing to engage in research in a university institution must be recommended by the professor under whom they propose to work. Applications from full members of the Institution require no additional support. Applications for grants from this fund must be received by the Secretary not later than December 1. Application forms may be obtained from the Secretary of the Institution at Aldine House, Bedford Street, Strand, London, W.C.2.

MESSRS. Automatic and Electric Furnaces, Limited, 173-175 Farringdon Road, London, E.C.1, inform us that they have a complete series of lantern slides, illustrating electric furnaces for hardening, tempering, carburising, annealing ferrous and non-ferrous metals, glass, etc., together with component parts of such furnaces, automatic temperature controls, and wiring diagrams, connected with various forms of circuits. These slides are available for the use of engineering societies and other technical associations.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant lecturer on electrical engineering at the Government Technical Institute, Insein, Burma—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (November 15). A Physicist to the Radio-Therapeutic Department of the Cancer Hospital—The Secretary, Cancer Hospital, Fulham Road, S.W.3 (November 20). A mistress of mathematics and science in the training department of the Dow Hill Girls' School, Kurseong, Bengal—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (November 27). A lecturer in physics in the Queen's University of Belfast—The Secretary (December 4). A junior technical officer at an Admiralty Experimental Establishment, with good practical knowledge of the design, manufacture and testing of wireless telegraph apparatus, and small alternating and direct current appliances—The Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1. An assistant chemist under the Empire Cotton Growing Corporation for soil investigations in the Sudan—Dr. E. M. Crowther, Rothamsted Experimental Station, Harpenden.

Research Items.

THE RAINMAKER AMONG THE LOTUKO, S. SUDAN.—In *Sudan Notes and Records*, Vol. 8, No. 2, Prof. C. G. and Mrs. Seligman have published notes on material relating to social organisation collected among the Lotuko of the Southern Sudan in the winter of 1921–1922. The Lotuko are organised into a number of independent territorial groups, each including a number of villages and divided into clans. At its head is a rainmaker (*Kobu*, fem. *nobu*), who is commonly referred to as "Sultan" by any Arabic-speaking Lotuko. He is the religious as well as the temporal head of the community. Both parents of a rainmaker should "have rain," though individuals with rain descent on the male side only have attempted to set up as rainmakers. They are not confined to any particular clan, but vary in different localities. Yet the clan gains prestige from his membership and his seat is looked upon as the headquarters of the clan. This tends to a territorial grouping of clans. A male rainmaker succeeds to the office on the death of his father, but a female cannot perform rain ceremonies until she is married to a rainmaker. A pool, Itaraba, has a sacred character and is associated with a semi-mythical rainmaker who is said to have lived five generations ago. In this pool live the crocodiles who are the deceased rainmakers of the Igago clan. A gourd of its water plays an important part in the rainmaking ceremony.

GYPSY MARRIAGE IN ENGLAND.—Mr. T. W. Thompson, who has been engaged in investigating gypsy marriage customs for some years, publishes in the *Journal of the Gypsy Lore Society*, Series 3, Vol. 5, Pt 1, the results of a detailed analysis of a number of records of marriages contracted in some of the leading gypsy families in the nineteenth century. From these it is deduced that descent in the direct line and common parentage are bars to matrimony, notwithstanding a case of marriage to a grand-daughter, and one of a half-brother and sister. There has been a number of cases of marriage between uncle and niece, and aunt and nephew, the latter less frequently, and usually uncles have preferred their brothers' to their sisters' daughters The mating of first cousins has been exceedingly common in some families, and first cousins marry more frequently than second cousins. There is also a marked preponderance of ortho-cousin over cross-cousin marriages, which reflects a definite tendency towards marriage within the family circle. On the other hand, certain southern groups seem to show a preference for cross-cousin marriage, and generally with daughters of a mother's brother rather than a father's sister. It is suggested hypothetically that the Indian proto-gypsies possibly practised a two-clan exogamy, such as actually exists among Indian nomads classed as 'gypsies,' and that on quitting India they had a marked tendency to wed near kindred. Further, that while sojourning on the upland stretches between India and Armenia under the influence of Iranians and Arabs, they weakened the hold of exogamy and strengthened the tendency to alliances between close blood relatives. Polygyny occurs sporadically and the marriage of two or more brothers to two or more sisters is specially common. Further, a polygynist's wives have more often than not been sisters. Formerly it may have been usual to wed a deceased wife's sister and for a young widow to wed a brother-in-law, also it may not have been permissible to wed a younger sister before an elder In addition to the sororate and the levirate there is evidence for the custom which exists among the Santals of India by which a man might cohabit with his wife's sisters before their marriage.

THE INSECT FAUNA OF THE DUTCH EAST INDIES.—Two recent supplements to *Treubia*, the official zoological journal of the scientific institutes at Buitenzorg, are of special interest to entomologists. The supplement to vol. 6 (April 1926) is devoted to an extensive monograph of the Tabanid flies of the Dutch East Indies by Dr. J. H. Schuurmans Stekhoven, jr. This work forms a bulky volume of 552 pages with 18 excellent three-colour process plates of representative species. The fact that certain Tabanids play a significant part in the transmission of the disease known as 'surra' has evidently prompted the large amount of study and collecting that has been entailed in the production of this important monograph. It is probable that *Tabanus striatus* is the most prevalent mechanical transmitter of that disease in the East Indies, but it is very uncertain whether or not other species and genera of these blood-sucking flies may also be implicated Altogether 266 species of the family are fully described in this work, and many are new to science. The supplement to vol. 8 (July 1926) consists of a very detailed study of the immature stages of Malayan Thysanoptera by Mr. H. Priesner. This work forms, unquestionably, one of the most careful and accurate accounts of the post-embryonic forms of those insects that has so far appeared anywhere. The abundance of material at his disposal has enabled the author to construct family, generic, and specific keys to the identification of both primary and secondary larvæ, while his descriptions are greatly enhanced in utility by the 16 plates illustrating numerous structural features.

THE RESPIRATORY EXCHANGE OF THE MUSSEL.—In a very interesting paper in the *Biochemical Journal* (vol. 20, No. 4, 1926, p 289) Mr. J R. Bruce describes an apparatus by means of which he studied the gaseous metabolism of a stock of common mussels, *Mytilus edulis*, L., kept in a large concrete tank at the Marine Biological Station, Port Erin. For the experiments, equal samples were taken from the stock at fifteen roughly equal periods between March 1925 and April 1926; oxygen was determined by Winkler's method and carbon dioxide by an indicator method elaborated by the author It was found that the oxygen requirements rose and fell in close agreement with the rise and fall of the temperature during the year, and also, though to a slighter extent, depended on the oxygen pressure. By making corrections for variations in these two factors, a third variation in oxygen intake was made evident which followed closely the reproductive cycle, there being an increase of 30 per cent. per unit weight of wet tissue between July and March, the period in which the reproductive reserves (largely glycogen) are being built up after the depletion consequent on the spawning of the previous spring. A point of the greatest interest is furnished by the disparity between the respiratory quotients at different periods, it being at its lowest in June and July and rising to a maximum in March. This is apparently associated with the changing chemical composition of the tissues during the period when glycogen is being stored, the drop from March to May corresponding to the period of fat formation preliminary to spawning in May.

THE MECHANISM OF GEOTROPIC CURVATURE.—We are still 'in the dark' as to the mechanism which is responsible for the different geotropic curvatures manifested by shoot and root, and recently another

suggestion has come from Polish sources. F. Tondera directs attention to the early work of Kraus, who showed that the amount of water in the tissues on the upper and lower side of a horizontal axis may be different, and suggests that the gravitational influence on sap distribution will be different upon the cortex of a root, from which water is moving inwards to the stele, and the cortex of the shoot, which is evaporating water and receiving a fresh supply moving outwards from the stele. He concludes that as a result the gravitational effect upon a horizontal root may reinforce and increase the natural sap movement on the upper side of the root and the lower side of the shoot, thus causing downward (positive) geotropic curvature in the first case and upward (negative) curvature in the second. His paper in the *Bulletin International de l'Académie polonaise des Sciences et des Lettres*, 8 B, 1925, contains very little experimental evidence; but the theory recalls in some respects the suggestion recently put forward by Ricôme in the *Rev. Gén. de Botanique*.

THE ROCKS OF JAN MAYEN.—The first comprehensive collection of rocks from the hitherto little known island of Jan Mayen was made by Mr. J. M. Wordie in 1921. This material has now been studied petrographically by Dr. G. W. Tyrrell, and the results, together with seven new analyses, are recorded in the *Trans. Roy. Soc. Edin.* (vol. 54, Pt. 3, No. 10, Oct. 2, 1926). The most abundant rocks appear to be trachybasalts with subsidiary trachytes and ankaramite (ultrabasic olivine basalt) and they occur as lava-flows or small intrusions. Trachyandesites and plateau-basalts are also known, but so far only as blocks and pebbles in a volcanic conglomerate. The only previous analysis of first-class importance was made by Dr. H. F. Harwood of a trachybasalt described by Prof. A. Holmes in 1918. The new analyses now recorded show that the suite as a whole is of mildly alkalic character with titanium dioxide ranging up to nearly four per cent. Holmes's deduction of a richly titaniferous belt in the Brito-Arctic Province stretching from Greenland to the Hebrides thus receives further support. The original magma appears to have been of trachybasaltic composition, differentiation having produced sub-magmas of trachytic and ultrabasic extremes. The specimens of plateau-basalt seem to be more ancient than the exposed lavas and they probably represent the underlying basement of the island.

SPANISH PETROLOGY.—The Iberian Peninsula consists structurally of three main tectonic features: a central plateau of pre-Cambrian and Palæozoic rocks which were extensively invaded by granites towards the close of the Carboniferous; a southern Betic Cordillera of folded rocks, and a similar northern folded belt forming the Pyrenees and Cantabrian Mountains. Hitherto little has been known of the chemical characters of the Carboniferous granites, but in a recent paper this deficiency is made good by Dr. H. S. Washington (*Journ. Wash. Acad. Sci.*, Sept. 19, 1926). All the specimens studied, of which four have been analysed, are simple biotite granites of approximately average composition, the uniformity in this respect being especially noteworthy. The later igneous rocks of the folded and faulted borders are strikingly different, as they include a wide variety of alkaline, mostly soda-rich, types. It is pointed out in a comparative survey that a similar contrast between granitic horsts and alkaline peripheral regions is shown by many other areas, such as the Canadian, Brazilian, and Fenno-Scandian shields. The distribution of soda rocks around older granites is regarded as unfavourable to the hypothesis that they are derived from basaltic magmas by assimilation of limestones.

WEATHER IN SAMOA.—The report of meteorological observations for 1923 made at the Apia Observatory has recently been received. Magnetic, meteorologic, and seismic observations are given in detail. Magnetic disturbances were not numerous during the year, and those which occurred had little effect upon the declination. The mean air temperature for 1923 was 26°·08 C., while the normal for the years 1890–1923 is 25°·78 C. The total rainfall in 1923 was 3772·6 mm. and the normal is 2688 mm. The abnormal rainfall was largely due to the unusual precipitation during March, when rain was general throughout the Samoan Islands; at Alsisa the fall for the month was 117·82 in. (2993 mm.) This unusually heavy precipitation was the result of a circular storm which originated to the south-west of Samoa and was considered by residents to have been the most severe in twenty-five years. It caused general damage to roads and public works and resulted in considerable reduction of the copra output for the year. Of 119 earthquakes 79 were local and had their epicentre within 100 km. of the observatory; six earthquakes were reported as felt by people living in Apia and vicinity. Between June 1 and December 31 eighty-one balloons were sent up, and thirty nine of these were followed to a height of 5 kilometres or more. The greatest altitude observed was 21 kilometres, on December 19. Grateful acknowledgment is expressed of substantial grants from the Carnegie Institution of Washington and from the British Admiralty.

INVAR STEEL BALANCE BEAMS.—The issue of the *Proceedings of the Physical Society of London* for August 15 contains a paper by Mr. J. J. Manley on the properties of a precision balance with beams of invar steel, which was shown by Messrs. Oertling at the Exhibition of Apparatus held by the Physical and Optical Societies in January last. The great rigidity of the beam reduces the bending under load and gives a sensitivity independent of the load. The small coefficient of expansion of invar was not found to make the resting point of the beam independent of temperature, and Mr. Manley attributes this to relative movements of the knife edges themselves. The magnetic field has its effect on the beam, but any error due to this may be eliminated by using Gauss's method of double weighing. In the discussion of the paper, Mr. Gould stated that the effect of temperature changes on the invar steel balance of the National Physical Laboratory was of the same order of magnitude as that found for balances with gun-metal beams as usually made.

THEORY OF AIRSCREWS.—Recent developments in vortex theory in its application to airscrews has enabled the behaviour of a propeller under normal working conditions to be examined, but the theory breaks down in the vortex ring state and in part of the windmill brake state. Some recent empirical extensions of the theory based on general theoretical arguments have provided some information regarding the general nature of the characteristic curve. These are embodied in a report by H. Glauert (Aeronautical Research Committee, R. and M. No. 1026, H.M. Stationery Office, 3*d.* net). The experimental data are analysed to determine the form of the characteristic curve for those regions for which the vortex theory is inapplicable or inaccurate. An empirical form of the characteristic curve has been determined fitting the experimental data and connecting up with the theoretical curves in the propeller and windmill brake

state, but its precise form will remain somewhat uncertain until further experiments are available from an open jet tunnel. Further developments along these lines are clearly indicated in the near future.

SUPRACONDUCTIVITY. — W. Meissner, *Zeit. für Physik*, vol. 38, p. 647, 1926, has recently examined the low-temperature resistance of single crystals of cadmium, gold, and zinc, and of very pure specimens of iron, nickel, platinum, and silver in the form of wires. Although measurements were made at temperatures so low as 1·3° absolute, no indication of the phenomenon of supraconductivity was found with any of these metals. It thus appears that supraconductivity may only be exhibited by a particular group of metals, although it is still possible that at temperatures lower than 1·3° absolute the above metals may exhibit it.

THE MOLECULAR WEIGHTS OF THE PROTEINS.—Analytical and physical-chemical methods indicate that the proteins have very large molecular weights; *e.g.* the smallest, of egg albumin, is approximately 34,000. Recent work on the lowering of the freezing-point of phenol had yielded values between 200 and 600, and it was suggested that these values represent the true molecular weights of the units of a large aggregate which is stable in water but dissociates in phenol. This hypothesis does not agree with analytical evidence, and it is disproved by some experiments of E. J. Cohn and J. B. Conant, described in the July issue of the *Proceedings of the American National Academy of Science*. They found that the freezing-point depression depended on the method employed to dry the protein, and they therefore made use of the system phenol + anhydrous calcium chloride + hydrated calcium chloride. This has a sharp melting-point unaffected by small amounts of water and by the proteins, and it is concluded that no evidence exists for dissociation into units of low molecular weight.

MOISTURE AND SURFACE ACTION.—The current number of the Royal Society's *Proceedings*, 112, A 762, contains a communication by Prof. W. A. Bone, embodying the principal results of an inquiry, begun in 1908 and continued up to the present date, to determine whether or no moisture have any specific influence upon the combustion of carbonic oxide at a heated surface. The surfaces tried were: 1. Refractory firebrick at 500° C. 2. Granular nickel oxide at 200°. 3. Granular copper oxide at 210°. 4. Gold gauze at 240°. 5. Silver at 300°. 6. Porous porcelain at 500°. The experiments have been carried out with the exceptional care and caution characteristic of all Prof. Bone's work. It appears that the immediate consequence of progressive drying is always to increase the effect of the surface, presumably by removing the film of water molecules by which action is retarded. The ultimate effect, which is usually observed only after a prolonged drying, is to diminish greatly or even stop combustion. Although the ultimate effect of drying the metallic surfaces was practically to stop combustion, on readmitting moisture the activity of the surface was in time restored. The effect on porcelain was peculiar: ultimately not only was the influence of the catalyst greatly diminished but also it was not regained on reintroducing moisture.

A WIDE-FIELD BINOCULAR MICROSCOPE.—The advantages of binocular vision in microscopical work has led to an increased use of the binocular instrument, which consists of two juxtapositioned microscopes complete in themselves, by means of which the object is seen with a true stereoscopic effect. The introduction of a Porro erecting system to each of the two body tubes gives the further advantage that the image is viewed in its true position and not inverted or reversed. We have recently seen a specimen of a wide-field binocular microscope of this type which has been put on the market by Messrs. Bausch and Lomb, Ltd., of 37 Hatton Garden, London, E.C. The instrument is provided with 2 pairs of eyepieces and 3 pairs of objectives, by means of which magnifications varying from 7, with a field of view of 25·4 mm., to 30, with a field of view of 8 mm., can be obtained. Each objective is provided with centering screws, and each pair is mounted in a substantial base. The achromatic eyepieces have a very high eye-point, which permits prolonged observations to be made without undue fatigue. The microscope may be detached from its horseshoe base and placed directly on any surface which it is desired to examine. It may also be mounted on the end of a counter-balanced horizontal arm, which is capable of swinging round a vertical rod attached to a solid base or clamped to a bench. By means of these attachments, the microscope may easily be brought into position over a large area under examination. The instrument is thus adaptable to a great variety of circumstances and its range of usefulness for examining specimens under comparatively low magnification is almost unlimited.

HEAT CONDUCTION IN STEEL.—It is so generally believed that a fine-grained metal is essentially isotropic, that a paper by C. Benedicks, H. Bäckström, and P. Sederholm on "Anomalies in Heat Conduction as investigated in Spherical Steel Specimens," read at the Stockholm meeting of the Iron and Steel Institute, is of more than usual interest. The variation in the temperature gradient of uniformly heated steel spheres in different directions is so great as 1 : 8·5; the electrical resistivity, however, showed variations in different directions not exceeding the ratio 1 : 1·05. These variations in the thermal conductivity, of quite a different order of magnitude from those in the electrical conductivity, are probably connected with irregularities in the macrostructure. The thermal conductivity of a solid metal must represent two independent phenomena, (1) purely thermal, and (2) thermo-electrical. The latter involves eddy currents having such directions as to facilitate heat transfer by the Thomson effect. This part of the heat conductivity must be high for a metal possessing (*a*) a high electrical conductivity, and (*b*) a high Thomson coefficient. If a considerable part of the heat conductivity of, say, carbon steel is due to an inner thermo-electrical heat transfer, even small heterogeneities will thus be able to exert considerable influence on these thermo-electric currents, and may easily direct them into special preferential paths. From a practical point of view, there are two items to be specially considered. On one hand the transfer of heat in a massive steel piece will cause temperature irregularities of a possibly unfavourable character, especially as regards corrosion. On the other hand, the total heat transfer increases considerably with increasing dimensions of the metallic object on account of this electrical heat convection. In spite of the scarcity of available data, it seems justifiable to range the added dissolved elements in steel in the following order, so far as their influence on the thermal conductivity is concerned: Nickel, manganese, hardening carbon, aluminium, silicon, indicating that the thermal conductivity of iron is lowered least by 1 *atomic* per cent. of nickel, more by magnesium, and so on. Cementite carbon exerts only a slight influence.

begun until last year, when Mr. Frankfort carried it to its conclusion.

Naville's other scientific work related chiefly to the "Book of the Dead," of which he published the first critical edition. He was always specially interested in the religious side of Egyptian culture, and published a short work on "Egyptian Religion."

Naville was always proud of his knowledge of England, in the fortunes of which he took steady interest. In fact he was politically almost an Englishman, and showed his partiality by his impassioned defence of our action in the Boer War, when he published many pamphlets in all tongues in our favour, gaining rather an unenviable notoriety thereby on the Continent. He was a man of the courage of his opinions, and a keen polemist, as his attacks on "the Higher Criticism" of the Old Testament and his long disputes with the German Egyptologists on the question of the Semitic origin of the Egyptian language or the succession of the Thutmosids show; and in polemic he by no means always came off second-best.

Naville possessed many British and foreign degrees, was an Hon. F.S.A. and foreign associate of the Institute of France. During the War he was a prominent member of the Central Red Cross Committee at Geneva, over which he presided. No notice of him would be complete without a word regarding his devoted wife. Mme. Naville (*née* de Pourtalés) assisted him enormously in his work by copying descriptions, piecing together fragments of monuments, and so forth; her knowledge of Egyptology was considerable, and he always emphasised the value of her assistance to him in his scientific work. H. R. HALL.

DR. FRANCIS WARNER.

THE passing of Francis Warner has removed one of the last of the group of physicians and physiologists who studied movements and gaits, attitudes and postures in the 'seventies of the last century. Much of the study was conducted by means of pneumatic tubes connected with Marey's recording tambours. This phase of Warner's work was set out in his well-known work, "Physical Expression," and in his Hunterian lectures to the Royal College of Surgeons. Modern electrical methods and kinematography have modified and extended the conclusions then reached. Warner's clinical observations on the postures and movements of nervous and defective children made at the East London Hospital for Children, and later supplemented at the London Hospital, still remain standards for all observers.

In the early days of compulsory elementary education, it was soon found that many children were unable to profit by the facilities offered; in some instances, such as those who were blind or deaf, the need for special schools was obvious and was soon supplied in gradually increasing measure, but in the case of others with mental or physical defects, public opinion was more slowly influenced. It is largely to Dr. Warner's efforts in investigating the conditions of some 10,000 children in the London elementary schools and to his labours on a series of commissions that the present provision in London, unequalled anywhere in the world, came into being. Warner made a great point of observing the child at rest and while performing certain very simple movements, such as looking at an object or holding the hands straight in front of the body with the palms down. He directed attention to slack or convulsive postures of the hand which indicated nervous instability, to the knitting of the eyebrows, which might indicate nervous strain or hypermetropia, to muscular overaction of various kinds.

For some years Warner's tests formed a large part of the examination of children suspected of needing special education, and though they have been supplemented and in part replaced by tests of the Binet-Simon pattern, and other tests of power of performance and of adapting thought and movement to new requirements, they are still an essential item of a complete examination. Above all things, Warner stressed the point that an examination should be dynamic rather than static, that evidences of defect as shown by stigmata, then popular as supposed indices of mental status, were as nothing compared to that derived from actual movements and performances.

Dr. Warner was one of the first of a series of school hygienists and child students, who did much himself and, by his example and ready help and advice, laid the foundations of the present system of care for the health of scholars and the comfort and sanitation in the broadest sense of our schools.

PROF. CARLOS SPEGAZZINI died on July 1 of this year. He was born on April 20, 1858, at Bairo, Italy, and was a pupil of the late P. A. Saccardo at Padua. In 1878 he contributed his first paper on mycology, a study of coprophilous fungi, to the short-lived periodical *Michelia*, which Saccardo edited. He published a series of notes on the diseases of the vine and began to issue fascicles of dried specimens ("Decades mycologicæ Italicæ"). In 1880 he went to the Argentine as professor of natural history at Buenos Aires. The number of fungi recorded for the Argentine was then thirty-nine. Spegazzini worked this virgin soil to the full and until his death made continuous contributions to the mycological flora, extending his investigations to most countries of South America. His work was that of a general systematist, and in the thousand or so new species he described, practically all groups are represented. His work appears to be much more carefully done than is usual in such mass production, and is illustrated by clear and attractive drawings. Spegazzini not only accomplished an enormous amount of mycological work but also published numerous papers on Phanerogams, specialising during the last few years more particularly on Leguminosæ. Odd papers on all sorts of subjects testify to his great interest in general natural history and science.

WE regret to announce the following deaths:

Sir Edward Busk, sometime Vice-Chancellor and Chairman of Convocation of the University of London, and a member of the governing bodies of the Imperial College of Science and Technology and of several well-known schools, on October 29, aged eighty-two years.

Mr. R. N. Lennox, formerly assistant to the late Sir James Dewar at the Royal Institution, on November 1.

News and Views.

THE King has approved of the following awards this year by the president and council of the Royal Society: A Royal medal to Sir William Hardy for his pioneer work on colloidal chemistry and the theory of lubrication. A Royal medal to Prof. A. V. Hill for his distinguished work on the physical and chemical aspects of muscular contraction. The following awards have also been made by the president and council: The Copley medal to Sir Frederick Hopkins for his distinguished and fruitful work in biochemistry. The Rumford medal to Sir Arthur Schuster for his services to physical science, especially in the subjects of optics and terrestrial magnetism. The Davy medal to Sir James Walker for his work on the theory of ionisation and ionic equilibria in solution. The Darwin medal to Dr. D. H. Scott for his contributions to palæophytology, particularly in relation to the period of coal. The Hughes medal to Admiral Sir Henry Jackson for his pioneer work in the scientific investigation of radio-telegraphy, and its application to navigation.

THE following is a list of those recommended by the president and council of the Royal Society for election to the council at the anniversary meeting on November 30:—*President*—Sir Ernest Rutherford; *Treasurer*—Sir David Prain, *Secretaries*—Mr. J. H. Jeans and Dr. H. H. Dale; *Foreign Secretary*—Sir Richard Glazebrook. *Other Members of Council*—Sir Hugh Anderson, Dr. F. W. Aston, Prof. L. Bairstow, Prof. F. O. Bower, Sir Archibald Garrod, Prof. E. J. Garwood, Sir Thomas Heath, Prof. J. P. Hill, Dr. P. C. Mitchell, Prof. R. Muir, Sir John Parsons, Sir Robert Robertson, Mr. A. A. C. Swinton, Sir Gilbert Walker, Sir James Walker, Mr. W. C. D. Whetham.

THE announcement that Sir Alfred Yarrow has made a donation of 10,000*l*. to the funds of the British Association is of particular significance, as showing the appreciation of scientific study and research by a great leader of industry. A few years ago another pioneer of engineering science—Sir Charles Parsons—made a like gift to the Association; and it may be hoped that the generous lead thus given will be followed by other representatives of progressive industry which benefit directly or indirectly by the advancement of scientific knowledge. Sir Alfred Yarrow, feeling that the present urgent needs of the British Association, in its work for science, should receive precedence over provision for the distant future, has made it a condition that his gift should be expended, as to both capital and interest, within a period of twenty years. Sir Charles Parsons has expressed himself similarly with regard to his gift. Through these gifts, and by the provision for their use in a single generation, the Association will be able to strengthen its powers of obtaining general attention for the objects of science, and of affording more steady assistance to scientific research in directions indicated as desirable during the deliberations of its various sections at the annual meetings.

WE learn with great pleasure that no less an artist than Sir William Orpen has consented to paint the portrait of Prof. J. A. Fleming, whose many friends and admirers, as we have already announced, are raising a fund for this purpose. The portrait is to hang in University College, London, with which Prof. Fleming has been so long and honourably connected, and no doubt Sir William Orpen's willingness to paint the picture is in part due to the fact that Sir William Orpen himself received his early artistic training at the Slade School, which is part of University College. A replica of the portrait is also to be presented to the Institution of Electrical Engineers, as representing the great scientific profession and industry for the advancement of which Prof. Fleming has done so much. In the popular view no doubt Prof. Fleming is chiefly known as the inventor of the famous 'valve', which, adapted as it has been in many forms to radio telegraphy and telephony, has made broadcasting possible. His other great activities as a teacher, and especially as a writer, must not, however, be forgotten. His many works, on alternating electric currents, on electric lamps, on electrical testing, and on electric wave telegraphy, are standard volumes, while his reminiscent account, "Fifty Years of Electricity," makes the most delightful and inspiring reading. It is an open secret that many years ago Prof. Fleming would, but for his unfortunate deafness, have been elected president of the Institution of Electrical Engineers, and to add to his many other qualifications for honour, he is well known as one of the most skilled and popular experimental lecturers on electrical subjects in the world. The subscription list for the portrait is still open, and intending contributors are asked to send their donations as early as possible to the honorary secretary of the Fund, Prof. W. C. Clinton, University College, Gower Street, London, W.C.1.

THE new science laboratories of the University College of North Wales, Bangor, were declared open on Tuesday, November 2, by Sir Joseph Thomson. A tour of inspection of the laboratories was made in the morning, and in the afternoon Sir Joseph addressed a gathering of about eighteen hundred people in the Pritchard-Jones Hall of the College. The science laboratories form part of the North Wales Heroes' Memorial, and consist of five separate buildings, which house the six Departments of Physics, Chemistry, Botany, Zoology, Agriculture, and Forestry. When completed, the whole memorial, which includes a memorial arch and a bursary fund in addition to the laboratories, will have cost a sum approaching 150,000*l*. Of this amount about 120,000*l*. has already been subscribed. The afternoon meeting was presided over by Lord Kenyon, president of the College. He read and presented to Sir Joseph Thomson an address in album form, and the laboratories were then thrown open to the public. The buildings are of one storey, with the exception of the agricultural block, which has two storeys. Each block covers a floor space of about

10,000 square feet. All the heating, gas, water hydrant, and electric mains which serve the different rooms are run in brick trenches under and between the buildings. By this means all the pipes and cables are readily accessible. Special mains have been laid by the Corporation. The physics block is furnished with a liquid air plant, and accommodation is provided for about 100 students and a dozen research men. Each research room is furnished with electric power supplies of 400 volts D.C., 200 volts D.C., 150 volts from a battery (any voltage from 2 to 150 volts in steps of 2 volts can be obtained), and alternating current at about 220 volts and 50 cycles. The main laboratories, of which there are three, and the lecture rooms are provided with the same electric power supplies. The floors are of concrete, which is covered with cork lino for insulation purposes. The cable carrying the electric power and the battery leads run along shallow ducts in the floor. The department is furnished with a well-equipped workshop. A small hut has been erected a few yards away from the main physics building in which measurements in radio-activity will be conducted. The general lay-out and equipment of the other blocks are similar to those of the Physics Department.

THERE has recently appeared in the *Daily Express* a series of articles by leading men of science under the general title of "The Mystery of the Universe." The contributors are the Astronomer Royal (Sir Frank Dyson), Profs. Plummer, Eddington, and Andrade, Sir Oliver Lodge, and the Bishop of Birmingham (Dr. Barnes). The first four writers confine themselves in the main to an exposition of the leading facts and generalisations of modern physics and astronomy; Sir Oliver Lodge attempts "to weave together the four preceding articles and draw scientific conclusions"; and the Bishop of Birmingham considers the same material in relation to the much-discussed question of the connexion between religion and science. It is a matter for satisfaction that one of the principal London newspapers should publish such articles as these, and we hope the example will be followed by other daily papers from time to time. The influence of science on the life of the community is far greater than is commonly realised, and it is in every way desirable that at least the general outline of current research should be given as wide a publicity as possible. Nor can it be too strongly emphasised that this should be done by experts, and not by the ordinary reporter who, however well instructed he may be, has in practice often failed lamentably to give even an intelligible, much less an accurate, account of scientific matters. We offer our congratulations to the *Daily Express* on the excellent lead it has given in this direction.

A NOTEWORTHY feature of the series is that it deals exclusively with the physical sciences. Of the six contributors (considering only their scientific qualifications), three are astronomers, two physicists, and one a mathematician. This would perhaps seem fitting if the utilitarian aspects of science were in question, but they are scarcely mentioned; the emphasis, as the title indicates, is laid on the unknown and the unapplied, and the fundamental relationships between science, religion, and philosophy form the background, concealed or expressed, of the whole. The exclusion of biology is to be regretted, for a symposium on the mystery of the universe which includes no discussion of life from the scientific view-point, must necessarily be unbalanced. The expressed conclusion that physical discovery brings us no nearer to a solution of the problem of the nature of life and mind makes the omission even more striking. If, however, we may take the subjects dealt with, and the manner of their treatment, as indicative of the trend of public thought in these matters, the change from the bitter squabbles of the last century between would-be advocates of religion and science is as welcome as it is complete. There is no longer a *conflict* between religion and science; there is a *relationship*, perhaps not yet discovered completely, which we seem to be able to approach with greater chance of success along the road of cosmic physics than along that of biology. This is, perhaps, the greatest advance which scientific philosophy has yet made.

THE authorities of the Science Museum at South Kensington have instituted a series of exhibitions of apparatus used in, and results obtained by, recent research, and the first of the series is now open to the public free. It deals with work which has been carried out at the National Physical Laboratory in the Departments of Physics, Metallurgy, and Engineering. The new hygrometers for cold stores, new thermal insulators, protectors against X-rays, new high vacuum pumps, apparatus for predetermination of the acoustical properties of halls, the composition of steels and other alloys, and the detection of defects in their interior by X-rays, furnaces for metallurgical investigations, and methods of testing the lubricating properties of oils under pressure are all shown, and later in the month it is proposed to show some of the results which have been obtained by the Adhesives Research Committee of the Department of Scientific and Industrial Research. These exhibitions will enable the general public to understand readily the advances which are now being made by research workers in science and how they may be applied in industry.

FOR some time past many students and others interested in Africa have felt that a special organisation, framed on an international basis, is urgently needed for the study of African linguistics and culture. Such an institution was desirable not only to continue work such as that carried on by the Hamburg Colonial Institute before the War, but also to collate, supplement, and extend the work of existing organisations such as, in England, the African and Geographical Societies and the Royal Anthropological Institute. The aim of the projected organisation was practical as well as scientific: it was intended not merely to promote African studies in the widest possible sense; it was proposed that it should, as the result of such studies, lay down lines for, and participate in, educating and training the African

native, by stages suited to his mentality and culture, for the inevitable clash of cultures when he has to meet conditions arising out of the European occupation and exploitation of his country. As a result of invitations issued after a conference held in London in September 1925, a considerable body of influential support has been obtained. The International Institute of African Languages and Cultures, as the new organisation has been named, will include among its members accredited representatives of the African Society, the Advisory Committee on African Education of the Colonial Office, of which the Secretary, Major Hans Vischer, has accepted the vice-directorship of the Institute, the Royal Anthropological Institute, the School of Oriental Studies, the Advisory Committee on Bantu Studies in South Africa, the National Research Council of the United States, the principal universities and learned societies interested in African studies of France, Belgium, Italy, Germany, Austria, and Sweden, and the missionary societies, both Roman Catholic and Protestant. Sir Frederick Lugard will act as chairman of the executive council. M. Delafosse, the well-known authority on Africa, and Dr. D. Westermann, equally well known as an authority on African linguistics, will be joint directors. An extensive programme of work, to a great extent but not entirely, linguistic, has already been mapped out. Further particulars of the Institute and terms of membership may be obtained from the temporary offices, Lever House, Blackfriars, London, E.C. 4.

THE *Rand Daily Mail* for September 20 contains a notice of a conference to be held at Potchefstroom which will endeavour to prove scientifically "that no reconciliation is possible between Scripture and evolutionary science, and that evolution is a false dogma of pagan origin and anti-Christian character." Among the points to be proved are the following: That the Bible alone explains the origin, essence, and final purpose of things. That there is a generally accepted theory of evolution, but there are no experimental proofs. That the facts of palæontology do not point to the gradual development of forms, but are explicable on the hypothesis of catastrophic change. That the fabulous age of the earth ascribed to it by geologists is an uncalled-for speculation. That the intimate connexion between man and the apes has not yet been proved. With regard to man and the apes, that descent is not the relationship between them has already been pointed out to the Fundamentalists of America by Prof. Osborn; but as for the other points raised, it is not our business to refute, but to direct attention to them If they were raised seriously in the interests of scientific truth, there would be no cause for uneasiness; but as this is evidently a definite effort on the part of a theological faction to influence and organise ill-informed public opinion, we must regard it in a very serious light. Those who suppose that the cause of religion is helped by this sort of thing are deceiving themselves; there is nothing that can possibly damage it more than this ill-advised propaganda. It is especially dangerous in countries where democratic institutions are combined with a not very high standard of general education. Sinister possibilities lurk behind this agitation, obscure as it may seem to those in England. Democracy, when it takes to persecution, can rival Torquemada, for from its verdict and sentence there is no appeal.

IN the *Nineteenth Century* for October Sir Frank Beaman has an article on "Psychology and Crime." He seems to be annoyed at the suggestion that psychology can have anything to offer towards the understanding of the criminal. With the actual administration of the law as it stands the psychologists would be quite in agreement with the writer. If the facts prove incontestably that A killed B, and if it is the law that any person who kills another is to be hanged, there is no more to be said. In law, though, as in other branches of knowledge, difficulties soon arise as to the exact connotation of the words and the exact sphere of application. It should be noted, too, that insanity is always "legal insanity"; insanity has a purely legal significance and has no place in medicine. Nearly half the article is by way of introduction, and we are given Sir Frank Beaman's views, expressed with dogmatic fervour, on the human factor in various sciences, political economy, the statistical method (which is very fallacious), the ignorance of medical practitioners (they do not know why some otherwise quite normal people are literally poisoned by eggs or by gooseberries), the variety of the human body, Mendelism (greatly over-vaunted), evolution (a question-begging term), psychology (the least trustworthy of the sciences), psycho-analysis (morbid and sensational), spiritualism (pretentious), the morbid taste of the general public, etc. The actual problem seems a little lost against this background. The general method is not unlike the Bellman's "What I tell you three times is true." There is something to be said for the more usual form of the statistical method.

THE Greenland expedition of the University of Michigan returned to America in September under the leadership of Prof. W. H. Hobbs, who gives, in *Science* of October 8, a short account of the work done during the summer. The base of the expedition was on Maligiak Fjord, fifty miles east of Holsteinsborg, where a meteorological station was set up. Pilot balloons were sent up to test the direction of the upper air currents. Some ninety balloons were traced to an average height of 7000 metres, several to 10,000 and one to 14,000 metres. Three meteorographs, with records intact, were recovered from *ballons-sondes* which had reached considerable elevations, in one case more than 1500 metres. An exploring party under Prof. Hobbs ascended the ice-sheet 100 miles east of Holsteinborg. Pilot balloons were traced to a maximum height of 5500 metres and wind observations were made at three-hour intervals at the surface. Self-registering meteorological instruments have been left at Holsteinborg to be used throughout the winter. Tidal observations were also undertaken. Prof. Hobbs plans to return to Greenland next summer with a larger expedition and to continue his studies of Greenland winds both on the margin and in the interior of the ice-sheet.

AN interesting correspondence in recent issues of the *Times* shows that the sound of the 'concentration shoot' at Portland on Saturday afternoon, October 30, was heard at great distances in the midland counties. There are records from Long Wittenham, near Abingdon (98 miles from Portland), Shipton-under-Wychwood and Shotover in Oxfordshire (103 miles), Bourton-on-the-Water in Gloucestershire (104 miles), Eton and Chertsey (108 miles), Bosbury in Herefordshire (112 miles), and Dunchurch near Rugby (141 miles). The wind at three of these places was roughly in the direction opposite to that of Portland. Moreover, the sounds were very distinct. At Eton and Bosbury the observers were working in their gardens. At Shotover, according to the president of Trinity College, Oxford, "the noise was so loud that we thought that it might proceed from some explosion at the Morris Motor Works, which lie to the south of the hill." The remarkable point about these observations is not so much the great distances of the places, but the unusual loudness of the sounds, which suggests that the places mentioned lie in an outer sound-area separated from the source by a silent zone.

THE paper read by Messrs. J. Beard and T. Haldane to the Institution of Electrical Engineers on November 4 was a very timely one, as they discuss the possibility of standardisation in the design of the systems used for distributing electric light. It seems certain that in ten years' time the supply of electricity to consumers in Great Britain will be at least doubled. It is very advisable, therefore, that piecemeal extensions of the various supply networks such as have sufficed in the past should no longer be made. The present time is most suitable for getting all the benefits of standardisation. The suggestions made are very helpful. Engineers have just adopted 230 volts as the standard pressure. One of the reasons for adopting this somewhat odd number is that when a three-phase system is used and 230 volts is used for lighting, 400 volts is available for power. As one of the pressures is equal to the other multiplied by the square root of three, it is impossible to make them both decimal In the system of distribution proposed by the authors, the distributing pressure from the substation would be at 11,000 volts. It would then be transformed down to 400 volts and 230 volts by a four-wire three-phase distributing system. Continuity of supply is secured by having a duplicate high voltage supply. The low voltage cables are very convenient, having four equal cores inside a lead covering. The costs, however, which are independent of the load, are very large, the main item being the high cost of excavation for the distributor cables. This accounts for the rapid rate at which the total costs per unit delivered decrease with the load. If the load is doubled they are reduced by about one quarter. In our opinion, the adoption of a standard system such as that suggested by the authors would be in the interest both of the industry and of the country.

A PROPOSAL for a meteorological cruise in the Atlantic in 1927 is suggested in the *Meteorological Magazine* for September. The cruise is to honour the memory of Colonel Chaves, the founder of the Meteorological Service of the Azores. The meteorological observations from the Azores were transmitted free by the Portuguese Government and have in the past added much to the possibility of successful forecasting of the weather in the British Isles. There is an eclipse of the sun on June 29 next year, of which the line of totality crosses the Irish Sea, and this is suggested as a starting-point. It is proposed that the cruise should occupy about 25 days, beginning with June 28. Readers of the *Meteorological Magazine* and others disposed to join in such a cruise are asked to communicate with Mr. C. J. P. Cave, vice-president of the Royal Meteorological Society, or with Sir Napier Shaw, lately Director of the Meteorological Office.

To the four series of picture postcards devoted to precious stones, and the two series representing decorative stones, the British Museum (Natural History) has now added two further series (D9 and D10) of cards illustrating crystals (London: British Museum (Natural History). 1s. each set). As before, each set consists of six attractively printed cards, accompanied by an explanatory leaflet. The leaflet includes a masterly little essay on crystallography, ranging in its scope from Steno's fundamental law of angles, announced in 1669, to the work of Laue and the Braggs on X-ray analysis. The first set of cards gives examples of cubic, tetragonal, hexagonal, and rhombohedral crystals; and the second of the remaining systems and of twin-crystals. Both in accuracy and attractiveness of reproduction, and in educational value, these new series fully maintain the high standard achieved by previous issues.

SENATORE G. MARCONI has been elected an honorary member of the Institution of Electrical Engineers.

DR. W. H. STEAVENSON, who contributed the article on Mars to our issue of November 6, has been elected president of the British Astronomical Association in succession to the Rev. C. D. Percy Davies.

IT is gratifying to note that Mr. Mackay, who for several seasons past has been engaged in excavation at Kish in Mesopotamia, has been engaged by the Archæological Survey of India to work on the sites in the Indus Valley on which remains of the earliest culture yet known in India, including the famous pictographs of Sumerian type, were discovered. Mr. Mackay's knowledge of Mesopotamia will be invaluable in these excavations should further material bearing any resemblance to Sumerian antiquities be brought to light.

THE Trustees of the Beit Fellowships for Scientific Research announce that Sir Otto Beit has promised to hand over to them a further sum of 15,000*l*. This will enable the Trustees to make all their appointments to fellowships for two years, instead of one year as has happened in the past. The fellowships are tenable at the Imperial College of Science and Technology, South Kensington, and since the foundation of the fund in 1913 there have been eighteen appointments. The extension of tenure will add considerably to the value of the fellowships from the point of view of the promotion of fundamental research.

SIR FLINDERS and Lady Petrie and other members of the British School of Archæology will leave in the course of a few days for Palestine, where the winter will be spent on excavating Egyptian remains in the southern area of that country. As announced since last season, the School, for the present at any rate, will discontinue work in Egypt itself owing to the difficult conditions in which archæological research has now to be carried on. While it is not possible at this moment to mention any specific object in view, there are many problems requiring investigation. The work of the expedition will depend upon circumstances; but no doubt Sir Flinders Petrie hopes to secure further evidence bearing upon the Badarian culture, which, on his view, reached Egypt through Palestine.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A professor of physiology in Presidency College, Calcutta—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (November 20). A Principal of the Municipal Technical College, Dewsbury—The Secretary for Education, Town Hall, Dewsbury (November 20). A Warden of the Farm Institute and Experimental Station at Askham Bryan, near York—The Joint Clerks, Yorkshire Council for Agricultural Education, County Hall, Beverley (November 30). An assistant horticultural instructor under the Kent Education Committee—The Director of Education, Springfield, Maidstone (November 24). An assistant lecturer in chemistry at University College, Swansea—The Registrar, Singleton Park, Swansea (November 27). A Vice-Warden for Ashburne Hall of Residence for Women Students of Manchester University—The Honorary Secretary, Ashburne Hall, Fallowfield, Manchester (November 29). An assistant lecturer in agricultural chemistry in the University of Leeds—The Registrar (November 30). A radiologist in the medical department of the Federated Malay States—The Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1 (December 4). An assistant in the department of zoology of the National Museum of Wales—The Director, National Museum of Wales, Cardiff (December 4). A professor of physical chemistry in the University of Bristol—The Registrar (December 10). A teacher of geography and mathematics at the Borough Polytechnic Institute—The Principal, Borough Road, S.E.1.

Our Astronomical Column.

COMETS.—Neujmin's periodic comet, 1916 II., has been detected by its original discoverer, Mr. Neujmin (presumably at the Simeis Observatory, Crimea), on Nov. 5 at $1^h\ 37{\cdot}0^m$ U.T. in R.A. $10^h\ 10^m\ 56^s$, N. Decl. $18°\ 20'$, magnitude 14·5. The date of perihelion deduced from the R.A. is Jan. 15·93, 1927, from the Decl. Jan. 15·80, 1927. The evidence is, on the whole, against the identity of the doubtful object photographed in 1920 with the comet, but is not yet decisive. The comet is approaching both sun and earth, so should become considerably brighter. The following corrected ephemeris is for 0^h U.T.:

		R.A.		N. Decl.		log r	log Δ
Nov.	16	10^h	$43{\cdot}1^m$	14°	36′	0·1680	0·1411
	20	10	54·9	13	1		
	24	11	6·7	11	22		
	28	11	18·5	9	38		
Dec.	2	11	30·2	7	50	0·1546	0·0922

A doubtful object (comet or minor planet) of the twelfth magnitude was discovered by Prof. J. Comas Sola, of Barcelona, Nov. $5^d\ 0^h$, R.A. $2^h\ 56^m\ 36^s$, N. Decl. $6°\ 31'$; daily motion -1^m, south 3′. Later: Mr. B. M. Peek and Mr. G. Merton confirm the cometary character of the observations on the morning of November 10.

GIACOBINI'S COMET AND THE METEORIC DISPLAY OF OCTOBER 9.—Mr. W. F. Denning writes: "It appears certain that on October 9 the earth intersected a point in the orbit of Giacobini's comet, but that this point was about two months in front of the comet. The latter is due at perihelion on about December 10 next, so that taking the rate of velocity of the meteors at $14\frac{1}{2}$ miles per second, as computed by the Rev. M. Davidson, the comet's place on October 9 was about 77 millions of miles distant along the orbit from the point of intersection with the earth on the above date. In 1900 the nearest approach of the two orbits was about $5\frac{1}{2}$ millions of miles, but perturbations since that date have sufficiently disturbed the orbit of the comet to make it intersect that of the earth at this return. Had the comet arrived at perihelion two months earlier this year, the conditions would then have favoured a meteoric display of exceptional grandeur. Dr. A. C. D. Crommelin's position for the cometary radiant is $265° + 54°$, Mr. Prentice's radiant for the meteor shower was $263° + 54°$, and the radiant of the fireball of October 9, as deduced by Mr. King and myself from a number of observations, is $262° + 55°$, so the agreement is very good and near β Draconis."

MARS.—*Popular Astronomy*, Nos. 7 and 8, contain Report No. 37 of Prof. W. H. Pickering on the 1924 apparition of Mars. He commences with a discussion of the rotation period, and concludes that when allowance is made for Marth's change in the adopted position of Mars' axis in 1896, the period now generally employed, $24^h\ 37^m\ 22^s{\cdot}65$, represents the observations of the last fifty years. The research is complicated by the considerable changes of size and shape to which some of the dusky markings are liable.

In discussing various drawings of 1924, Prof. Pickering notes that there is considerable agreement among observers as to the position of the canals, but there is much personality as to the width assigned to them. An objection frequently brought by M. Antoniadi against the objective reality of the canals, based on their being drawn straight when far from the centre of the disc, is answered by a careful observation of the canal Amenthes Thoth on October 19 and 20, 1924, it was respectively 16° east and 16° west of the centre of the disc. The curvature was clearly reversed in the two drawings, which corroborates the objective reality of the marking, and its close adherence to a great circle.

Proceeding to the question of the nature of the canals, Prof. Pickering notes his own opinion that the supposition of their being artificial explains more facts than any other, and that the regular patterns, such as pentagons and stars which were seen in 1892, 1907, and 1924, point in the same direction. He does not claim it as more than an hypothesis, but he considers that it is rendered more probable by his own observations of Martian clouds in 1922, and Dr. Wright's photographs in infra-red light in 1924, which indicated a considerable amount of atmosphere.

Research Items.

AN EARLY ESKIMO CULTURE IN ALASKA.—In a communication issued by the Victoria Memorial Museum, Ottawa, Mr. Diamond Jenness, Chief of the Division of Anthropology, reports on the results of four months' field-work in Alaska, where he excavated ancient ruins and studied local dialects with the object of determining the origin and antiquity of an Eskimo civilisation which has left traces in Canada extending from the Mackenzie River Delta to Hudson Bay. At Wales, the point of Alaska nearest to Asia, ruins were discovered belonging to four distinct periods, all preceding the discovery of Alaska by Europeans. The remains of the second period resembled very closely those of the oldest known ruins of Arctic Canada. Excavations on the Diomede Islands confirmed those at Wales, and revealed a still earlier culture, of which there is no trace in Canada. The most characteristic feature of this culture was a style of curvilinear engraving unlike anything known of Eskimo art elsewhere, ancient or modern. Its source must be sought either among neighbouring Indian tribes or in north-east Asia. In regard to the former suggestion, it is to be noted that local Eskimo folklore and traditions show strong Indian influence, to be seen also in the masked dances, the use of body armour of bone or ivory, and certain sounds in the language. An antiquity of some 1000 to 1500 years is tentatively assigned to the earliest culture.

DIDINGA WITCHCRAFT.—In *Sudan Notes and Records*, vol. 8, Mr. J. H. Driberg, in the course of notes on Didinga customary law, refers to the penalties imposed on witches and wizards, and gives some indications of the character of the belief among these people. The practice is very prevalent and is usually associated with the use of poison. The influence of the evil eye is greatly feared, but does not belong to witchcraft proper, to which, however, the habit of bestiality, presumably a sexual abnormality, is attributed as a practice intended to injure live-stock. The wizard attains his object by dances. To secure the death of a man, a dance is performed at night at his door; to injure his crops, the dance takes place in the crops, but not necessarily at night. The dead are disinterred by wizards, who are fond of dancing by new graves. A wizard caught performing his dances invariably begs for compassionate treatment and proffers a spear, an axe, or a bracelet, which, if accepted, is carefully hidden away. Notwithstanding promises of amendment, the wizard continues his dances, the evidence in the form of the objects accepted as ransom accumulating until the wizard is seized and arraigned before a council, by which he is sentenced to death and hanged. A goat is sacrificed at his funeral. The wizard's powers are transmitted to another, with or without his knowledge, by a certain drug served in a pot of beer. Involuntary witchcraft so induced is an adequate plea at trial provided the principal wizard who was responsible is denounced. The wizards are all highly strung and hysterical, and are capable of self delusion to such an extent that they believe themselves invisible when dancing on cultivated ground.

FISH PASSES.—In a very interesting paper (*Fisheries, Scotland, Salmon Fish.*, 1926, II. Edinburgh and London: H.M. Stationery Office, 4*s.* 6*d.* net), Mr. W. L. Calderwood gives accounts of different salmon passes that have been constructed from time to time. These descriptions, together with photographic illustrations, show the gradual evolution of the modern type of pool pass from the original ladder pass, through such forms as the Bracket pass and many others fitted with baffle arrangements. There are many factors to be borne in mind in building a pass, and it is largely from the comparative failure of previous types that the most modern forms have been evolved. Of special importance in the British Isles is the fact that spring-running salmon are not jumpers, and will not face a strong rush of white superaerated water when that water is cold (below 40° F.). For such fish, then, the gradient of the pass must be easy, with no falls necessitating jumps; the velocity also must be sufficiently slow and regular to allow plenty of black water. Of paramount importance is the position of the outflow of the pass; this should be near to the obstruction to be avoided and close to the usual lie of running fish; it should also discharge a sufficient flow of water to be attractive. The protection of the inflow from flood water and the carrying of stones and gravel into the pass is necessary. The most modern pass consists of a series of pools with only slight drops between, a protected entrance for the water and an arrangement of movable sills, worked by floats, ensuring the passage of the same flow of water through the pass at all levels of the river, whether in flood or drought. Plans of two new passes designed by Mr. Rook for the river Tummel are given.

FUNGAL SYMBIOSIS.—In a communication to the Reale Accademia delle Scienze dell'Istituto di Bologna (*Rendiconti*, Vol. 29), Prof. Fausto Morini describes three examples of the parasitic existence of one fungus on another. In the case of a spermogonial form of *Phyllosticta parassitica* growing on the perithecia of *Uncinula salicis*, the injurious effect of the parasitic organism on the development of the host is apparent from the diminished number and size of the ascospores. In the second case, the host consists of a species of mucor resembling, in the ramification of the sporangiophore hyphæ, a reduced and modified form of *M. racemosus*, although it appears to be allied also to *M. corymbosus*. The parasite, a species of Piptocephalis, differing slightly from *P. Freseniana*, especially in the characters of the haustorial hyphæ, penetrates the mycelial hyphæ of the mucor and branches freely therein. The third example is that of *Piptocephalis microcephala* on *Pilobolus crystallinus*. A scheme of classification of the principal fungal symbioses is appended to the paper.

ABNORMAL FERN PROTHALLI.—Miss E. Schindler has found that the spores of *Asplenium septentrionale*, *A. trichomanes*, *Dryopteris filix mas*, and *Polypodium vulgare* will germinate when submerged beneath a liquid nutrient medium. Under these conditions they give rise to long filamentous structures, the cells dividing generally only by walls in one plane. These filamentous prothalli branch fairly freely. Neither the normal meristematic growth of the prothallus nor the formation of archegonia, follows in these prothalli unless they succeed in raising themselves out of the liquid medium into the damp air above it; antheridia occur sometimes on the submerged prothalli when growing in nitrogen-free culture media. This work was carried out by Miss Schindler at Cracow, under the guidance of Prof. Rouppert, and is published in the *Bulletin International de l'Académie polonaise des Sciences et des Lettres*, No. 5-6 B, June 1925.

POTATO MOSAIC AND TEMPERATURE.—The so-called 'virus' diseases are occupying considerable attention at present, and although 'leaf-roll' of potato is the form to which is attributed the greatest

potency in inducing degeneration in English potato crops, those forms of mottled or puckered foliage connected with 'mosaic' are not infrequently reported. Considerable interest therefore attaches to the American experience recorded by C. M. Tompkins (*Phytopathology* **16**, 581-610, September 1926) as the result of his work at the Department of Plant Pathology, University of Wisconsin. Tompkins reports that air temperatures of 23° to 24° C., even though only occasionally prevailing, are sufficient to mask completely the existence of mosaic in diseased stock when judged by the ordinary diagnostic symptoms. If the plants are afterwards kept at lower temperatures, characteristic mosaic symptoms are again developed. On the other hand, under histological examination the leaves of the diseased plants in which the disease is masked are said to show marked deviation in structure from healthy leaves, both palisade and spongy parenchyma of the mesophyll being very regularly arranged so that air spaces are almost completely eliminated.

FOSSIL LEAF-BEDS IN VICTORIA.—In Miocene times in Victoria, the country adjacent to the shoreline, then 40 to 70 miles inland from the present coast, was in places marked by a lacustrine phase. It was then that large lake deposits were formed consisting of ferruginous mud or slime, fine pipe-clay or silty material. Into these lakes were swept large quantities of leaves of the Miocene forest and brush. The leaves are well preserved and are now found in the ironstones and pipe-clay deposits in seven localities in Victoria. These fossil leaf-beds have been found at Pitfield, Bacchus Marsh, Berwick, Bogong, Cobungra and Dargo Through some recent studies of the Tertiary flora of the sandstone and quartzite of Narracan in Gippsland (*Proc. Roy. Soc. Vict.* Vol. 38, 1926, pp. 183-191), Frederick Chapman has added several new forms to the known list of fossil plants from the earlier localities mentioned. The Narracan flora comprises a eucalyptus of a modern coastal type, the myrtle beech (Nothofagus), the flame tree (Sterculia), the kanooka (Tristania), the cinnamon, and other Australian genera. Although of Miocene age, these deposits contain several types of leaves still existing in Victoria, mingled with others now belonging to areas situated in lower latitudes, as New South Wales and Queensland. Another point clearly established in this paper is the relatively older age of the Narracan leaf-beds as compared with the leaf beds in the brown coal of Morwell and Yallourn

MESOZOIC GEOLOGY OF ALASKA.—*Bulletin* 776 of the U.S. Geological Survey, by G. C Martin, 1926, contains a valuable record of the advances made in Alaskan geology during the present century. Mesozoic history provides by far the most important clues to the present structure of the Peninsula, and has a direct bearing on the mineral resources. At the end of the Palæozoic there was a widespread emergence of the land accompanied by intense and long-continued vulcanism. Profound marine submergence followed in Upper Triassic times, but the sea withdrew from the entire area during the late Triassic and early Jurassic, and the rocks already deposited were folded. Marine transgression began afresh in the Lower Jurassic, and widespread vulcanism again broke out, culminating in great granitic intrusions with accompanying formation of ore deposits. The Jurassic was brought to an end with vigorous uplift and erosion. The sea again swept over Alaska in Lower Cretaceous times, receded at the beginning of the Upper Cretaceous, and then advanced again. Finally, the submergence of the Upper Cretaceous slackened, marshes were formed and coal-beds deposited. The end of the Mesozoic and the beginning of the Eocene were marked by the complete withdrawal of the sea, a renewal of folding movements and intense vulcanism, intrusion, and mineralisation. A geological map of Alaska is now in preparation and will shortly be available.

ECONOMIC GEOLOGY OF CANADA.—The Geological Survey of Canada has published on this subject an extremely valuable and well-illustrated memoir by G. A Young (No 1 of the *Economic Geology Series*). Having regard to its physical features and geological structure, Canada is naturally divisible into six major regions. The Arctic archipelago and the Hudson Bay lowland contain extensive deposits of coal. The Canadian Shield is a U-shaped area bordering Hudson Bay, made up of ancient rocks, in which have been developed the Sudbury nickel-copper mines which are the world's chief source of nickel, the spectacular gold mines of Porcupine and Kirkland Lake, and the rich silver deposits of the Cobalt district. In the Appalachian and Acadian region are the asbestos deposits of south-eastern Quebec and the coal-fields of Nova Scotia. In the St. Lawrence region to the south occur the salt beds and petroleum fields of Ontario. The Interior Plains lie between the Canadian shield and the mountains to the west, and are underlain by vast reserves of coal. The Cordilleran region borders the Pacific, and in addition to extensive coal-fields it is noteworthy for the wealth of its placer gold-fields, copper-gold ores, and silver-lead-zinc ores. It is noteworthy on the negative side that Canada does not rank as a producer of aluminium, tin ores, or of precious stones. An excellent geological map accompanies the memoir, and a mineral map in which every important occurrence is numbered; an annotated list gives details of each.

TWILIGHT PHENOMENA.—In the *Denkschriften der Schweizerischen Naturforschenden Gesellschaft*, **62**, 1926, there are two memoirs only, of which the first, of 190 pages, is by P Gruner. It is the second of a series by this author, under the general title of "Contributions to the knowledge of twilight phenomena and of the Alpine glow"; the former paper (of 154 pages) gave a historical-chronological review of Swiss observations and publications on twilight colours and the Alpine glow The present paper is a similar review of non-Swiss observations and publications on twilights, atmospheric-optical disturbances, and related phenomena As the extent of the memoir indicates, the author has cast his net widely and summarises an immense mass of literature, which he also indexes under the names of authors, with references, forming a bibliography. The subject is so large when the term "related phenomena" is interpreted generously, as in this case, that completeness is neither attained nor to be expected. But the memoir should be of real value to investigators whose work bears on these fields

THE LAW OF SPEED RECORDS.—In 1906, Prof. A. E. Kennelly published a paper on "An Approximate Law of Fatigue in the Speeds of Racing Animals," noticed at length in NATURE, vol 75, p. 463. In this he showed that if L is the length of the race in metres, T the time occupied by the winner in seconds, and V the mean speed in metres per second, we have approximately

$$T = \frac{1}{c} L^{9/8} = \frac{c^8}{V^9},$$

whatever the type of race. If log L is plotted against log T, for example, different types of race give parallel straight lines. Prof. Kennelly has now published a second paper, "Changes during the Last Twenty Years in the World's Speed Records of Racing Animals"

(*Proc. Amer. Acad. Arts. Sci.* vol. 61, No. 11, 1926), in which the records created since the first paper was written have been included. Only two classes of events show an appreciable general increase in speed, men swimming by about 10 per cent., and horses running by about 2 per cent. In all other cases the new records fit reasonably well to the lines previously given. The records for horses, running or pacing, show as before far the best fit to the straight-line law, and bicycling records still form an apparent exception to the rule. The conclusion deduced that speed should be maintained at a uniform level throughout the race is in accord with the work of A. V. Hill.

DIAMAGNETIC GASES. Recently, E. Zehrer (*Zeit. für Phys.* vol. 37, p. 155, 1926), using an independent method, failed to confirm the experimental results obtained by Glaser, namely, that the specific susceptibilities of the diamagnetic gases hydrogen, nitrogen, and carbon dioxide were dependent on the pressure. It is therefore interesting to note that G. W. Hammar (*Proc. Nat. Acad. Sci.*, Oct. 1926), who employed the same method as Glaser, has found these susceptibilities to be independent of the pressure over a range from zero to one atmosphere. In searching for a possible source of error which might explain Glaser's results, Hammar found that a slight trace of moisture produced the effects described by Glaser, and he suggests that the difference between the two sets of results may be due to an adsorbed layer of water vapour on the surface of the test body. Hammar also directs attention to the need of greater reliability in the determination of the susceptibility of gases, since two of the latest and most careful determinations of the susceptibility of oxygen differ by 4·5 per cent., although each observer claims an accuracy of 0·1 per cent.

HEAT TREATMENT OF GAS CYLINDERS. -The second Report of the Gas Cylinders Research Committee, which has recently been issued, is concerned with the periodical annealing of cylinders. It was a recommendation of the Home Office Committee of 1895 that all cylinders of wrought iron or mild steel should be annealed every four years. On the other hand, the present Committee, in its first Report of 1921, considered that cylinders of 0·45 per cent. carbon steel should not require re-annealing during their life of fifteen to twenty years. The later experiments show that annealing, which is usually conducted at 650° C., and may be continued for many hours, is harmful. If the steel be overstrained and then annealed, the structure is altered, the ferrite and lamellar pearlite being replaced by ferrite with globular cementite, the size of the particles increasing with the time of annealing. This change is accompanied by a fall in the tensile strength and by an increase in brittleness, as shown by the Izod test. On the other hand, normalising, or heating to a temperature 50° above the critical point and then cooling in air without exposing to draughts, has no evil effects, and the injury done by overstraining followed by annealing may be almost completely corrected by such a treatment. The proper temperature is 900° for a 0·25 per cent. carbon steel and 850° when the carbon is 0·45 per cent. With properly made cylinders, a single normalising treatment after manufacture is all that is necessary. As it has been supposed that rough handling, involving jarring, may induce brittleness, experiments on the effect of repeated hammering have been made, with the result that the steel is not found to be rendered brittle by such treatment.

THE SUPPOSED REGENERATION OF ENZYME ACTIVITY. —During the past few years, various investigators have published experimental results which appear to indicate that certain enzyme solutions are able, after being boiled for some minutes, to recover partially their lost enzymic activity. Experiments made by Prof. Ivo Novi, and described in the *Rendiconti della R. Accademia delle Scienze dell' Istituto di Bologna* (Vol. 29), help to prove, as was shown by Pasteur more than sixty years ago, that such phenomena are not observed when care is taken to prevent access of air borne micro-organisms to the solutions.

HEATS OF CRYSTALLISATION. --The heats of crystallisation, Q, of seven more members of the homologous series of normal monobasic fatty acids, obtained by W. E. Garner, F. C. Madden, and J. E. Rushbrooke, are to be found in the September issue of the *Journal of the Chemical Society*. With the exception of stearic acid, the data for all the even acids up to C_{20}, and all the odd acids except three, are now available. As the series of acids is ascended, marked alternation in the values of Q is shown, and this is ascribed to an alternation in the arrangement of the terminal groups in passing from one acid to the next. An alternation in the melting-points of both odd and even members exists, and the two melting-point curves converge and approach a maximum at 115°. No evidence of alternation was obtained for the specific heats of the acids in the liquid state.

RADIATION THEORY OF CHEMICAL ACTION. —In a memoir published in the *Rendiconto dell' Accademia delle Scienze Fisiche e Mathematiche della Società Reale di Napoli*, Fascicoli 4-8, April-August 1926, Prof. Francesco Giordani proposes a modification of the formula connecting reaction velocity, k, with radiation density, u_ν, proposed by Lewis:

$$k = \frac{\pi e^2}{3mh\nu} u_\nu N.$$

He supposes that it is necessary to take into account the number of vibrations in the molecule r, which he puts equal to the number of ordinary chemical valencies concerned in the reaction, and instead of u_ν he uses $u_\nu^{1/r}$. When the modified Planck expression for u_ν is substituted in the equation, raised to the power $1/r$, it is shown that the results are in fair agreement with experiments on the decomposition by heat of phosphine, nitrogen pentoxide, and ozone (bimolecular). The great deviations between calculation and experiment which have previously appeared are then avoided.

THE DETERMINATION OF γ BY THE METHOD OF CLEMENT AND DESORMES.- The determination of the ratio of the specific heats of a gas by Clement and Desormes' method may be made to depend on measurements of temperature and pressure differences resulting from an adiabatic expansion or contraction (Lummer and Pringsheim, Partington, etc.) The adiabatic change is obtained by momentarily connecting the gas, contained in a vessel under a slightly different pressure, with the atmosphere. It has been known to all previous workers that equilibrium is not established instantaneously, but in a time which depends on the shape and size of the orifice, the volume of the vessel and the pressure difference. In the *Proceedings of the Indian Association for the Cultivation of Science*, for August 15, 1926, G. Subrahmaniam and G. Gunnayia show how to calculate approximately the time necessary for the pressures to equalise, in terms of quantities found in the experiments. Their results indicate that the size of the aperture does not have any great effect when the temperature measurements are employed to calculate γ, but when the pressures are measured, overshooting takes place if the opening is too large. In fixing the lower limit for the size of the aperture the effect of radiation has to be considered.

The Nutrition of Cattle.

IN a previous article in our columns (NATURE, 1925, vol. 116, p. 175) an account was given of some aspects of the feeding of cattle, including the method of indirect calorimetry, by means of which the value of different foodstuffs for maintenance and production can be determined, opportunity being taken at the same time to consider the relationship between the protein of the diet and the milk. The values assigned to different foodstuffs in nutrition depend not only on the accuracy of the experimental data from which they are estimated, but also on the correctness of the principles of the method of calculation used; that finality has not been reached in either case appears from a number of papers which have recently been published dealing with the various methods and their difficulties, both of technique and of interpretation. Probably the most important general figure for a foodstuff is its net energy value, that is, the amount of energy contained in it which is available for maintenance and production after deducting the non-utilisable energy and that necessarily expended in the actual processes of utilisation of the remainder.

The net energy value can be determined *directly* by means of the animal calorimeter The heat given off by the animal is deducted from the energy value of the food as determined in the bomb calorimeter, the difference giving that available for the maintenance or increase of body weight, and for the production of milk. The method requires the use of complicated apparatus and a great attention to detail: to ensure accuracy, a number of corrections must be applied to the experimental results (M. Kriss, *Jour. Agric. Res.*, 1925, vol 30, p. 404), but with proper precautions the heat production can be satisfactorily estimated to within 1 per cent.

On the other hand, this estimation can be made *indirectly*, either by the use of the animal calorimeter again, but determining the oxygen consumption and the carbon dioxide production (instead of the heat emission) and calculating the latter from the amounts of protein, fat, and carbohydrate oxidised in the body, as determined from the respiratory exchange and the respiratory quotient, or, more simply, by deducting from the energy of the food the energy of the excreta plus that of the body tissue gained as determined from the nitrogen and carbon balances. This latter method is the one more generally used and gives results which compare well with the direct method (M. Kriss, *loc. cit.*, p. 393): its most serious source of error appears to be the loss of material, from the urine and fæces, presumably through fermentation, during drying, preliminary to the determination of the energy value of the excreta in the bomb calorimeter: this loss can be minimised by drying at a low temperature.

In using the second of the two indirect methods described above, the 'balance' method, a source of error may be introduced by irregularity of excretion; thus the fæces of a given period may not correspond accurately to that period, and this is especially the case when the diet is varied. R. W. Swift (*Journ. Dairy Science*, 1925, vol 8, p 270) has made a study of the weights of fæces in metabolism experiments of varying length with cows and bullocks, and has found that the chances are 31 to 1 that, with an eight-day collection period, the errors of the averages will not exceed 7 per cent. and 5 per cent. respectively: it is probably better to ignore the first few days on a new ration: hence the entire period should last about a week.

If an animal neither loses nor gains weight over an experimental period, the heat production will equal the available energy of the food: but only rarely does this occur; usually the calculated energy of the flesh and fat formed or lost from the body must be subtracted from or added to the energy of the ration, to give the maintenance requirement. It is possible to avoid the calculation of the energy of the body tissue gained or lost by feeding the animal on two differing sub-maintenance rations, and calculating from the lessened loss of energy from the body on the higher ration, the increased amount of energy which must still be added to the latter to prevent any loss from the body; at the same time an estimation can be made for the heat production of the body when no food whatever is given. By increasing the diet above a maintenance value it is possible to obtain a figure for the amount of food which must be added for each pound of body fat laid on, an extremely important calculation for the fattening of animals.

Two assumptions are made in these calculations, which have been used chiefly by Armsby and Kellner respectively, as is pointed out by J. Wilson (*Scient. Proc. Roy. Dublin Soc.*, 1925, vol. 18, pp. 77 and 117): first, that the maintenance requirement is the same whether food is being taken or not, or whether the ration is large or small, and secondly, that the maintenance requirement found with one type of food applies equally if the nature of the ration be changed, provided it has an equal calorific value. Wilson has made a critical examination of some of Kellner's and Armsby's results, from which he concludes that straw, for example, is less efficient than hay, as a ration, and that the food required by the bullock, whether idle or fattening, rises with the amount and kind of long fodder in the ration and also with the rate at which fat is being put on. Thus the maintenance requirement rises with an increase in the ration; in part this is due to the ensuing stimulation of metabolism which always occurs after food, so that the body lives less economically and a proportion of the energy of the food is wasted as useless heat. The increased heat production after a meal, especially one containing protein, is a well-known phenomenon. It is thus difficult to apply results obtained with one kind of food to an experiment in which another ration is given, or to assume that the energy value of a food will be the same at whatever level it is fed. Accurate results will be obtained only when the ration given is just sufficient for maintenance.

The force of these criticisms, however, is somewhat reduced by improvements in the methods of calculating results, including the adjustment of the daily heat production to a figure representing a standard day of twelve hours lying and twelve hours standing, as well as by improvements in technique. The latest method of calculation of the net energy values of feeding stuffs and some of the results obtained are given in a series of papers from the Institute of Animal Nutrition, Pennsylvania State College (M. Kriss, *Jour. Agric. Res.*, 1925, vol. 31, p. 469; E. B. Forbes and M. Kriss, *ibid.*, p. 1083; E. B. Forbes, J. A. Fries, and W. W. Braman, *ibid.*, p 987; D. C. Cochrane, J. A. Fries, and W. W. Braman, *ibid.*, p. 1055; E. B. Forbes, *Proc. Am. Soc. Animal Production*, 1924, p. 23, and *Science*, 1926, vol. 63, p. 311, and E B Forbes, J A. Fries, and M. Kriss, *Jour. Dairy Science*, 1926, vol. 9, p. 15). The animal is given different rations during a series of experimental periods: by subtracting the heat production of a period on a lower diet from that of one on a higher ration, the increased heat production due to the increase in the food is obtained. The net energy required for maintenance is the total heat production

in the period minus the total increase in this value due to the food, calculated from the average of the figures previously obtained. The total net energy of the ration is the *average* net energy for maintenance as found in the different experimental periods in which the particular food under consideration was used, plus the energy gained by the animal, which is determined by subtracting the total heat production from the metabolisable energy of the food.

By this method it is found that the results obtained in the different experimental periods usually agree fairly well, and it is easy to see and discard any abnormal set of figures. The authors are inclined to consider differences in maintenance requirements in different periods as due to experimental errors rather than to differences in the rations or in the plane of nutrition of the animal. On the other hand, from experiments on fasting animals it appears that energy is more efficiently utilised in sub-maintenance periods, so that consistent figures for net energy values of rations are more likely to be obtained when the plane of nutrition in the different periods does not vary too greatly, and thus that the results should be considered as applying accurately in other cases only when the animals are kept at a somewhat similar level of nutrition. A further point to which attention may be directed is the applicability of results obtained with a particular breed to animals of another breed or in a different country where the rations are almost certain to be different. F. J. Warth, L. Singh, and S. M. Husain (*Memoirs Dep. Agric. India*, 1926, vol. 8, p. 153) have established certain differences between their animals and those used in America in considering the requirements for milk production with Indian foodstuffs. These differences affect primarily the digestibility of the rations, due in part to their actual nature, but at the same time individual animals have their own characteristics.

In conclusion, it may be stated with confidence that there appears to be sufficient accurate knowledge of the efficiency of different rations for maintenance and production to enable the practical farmer to select from those available to him the most economical in meeting his requirements.

Marine Biology at Plymouth.

THE latest number of the *Journal of the Marine Biological Association* (N.S., vol. 14, No. 2, August 1926, 10s. net) is full of good things. Dr. Orton resumes the interrupted publication of his studies on the rate of growth of marine organisms with a paper on the cockle. The investigations were carried out mainly in an experimental box laid down in the estuary of the river Yealm, in which the growing cockles were exposed to practically natural conditions, and the results have been checked by observations on near-by cockle beds. Apart from the definite determination of growth-rate—a matter of some economic importance, though it may be expected that the growth-rate will vary in different localities—the main interest of the paper lies in the study of the growth rings on the shell. It appears that, in the main, the deeply marked rings do indicate the winter checks in growth, and may be used with caution to determine the age of the cockle. Dr. Orton has, however, made the interesting observation that the mere removal of the cockles from the box for an hour so for the purpose of examination suffices to cause the appearance of a "disturbance ring" on the shell. Specially well defined rings are induced by the technique adopted of marking the shells for identification purposes with a file. Such disturbance rings can also be induced in the mussel. Further, in mild winters the winter ring may become extended and spread out into several rings, so that accurate determination of the age by means of winter-rings is a matter of some difficulty, especially in the larger individuals. The paper would have been improved by the addition of a summary.

A second paper by Dr. Orton deals with the comparative effect of dilute but lethal solutions of T.N.T. on native and Portuguese oysters (*Ostrea edulis* and *Gryphea angulata*), and was carried out at the request of the Fisheries Department to clear up a point left undetermined in the course of Dr. Orton's elaborate study of the abnormal mortality among native oysters in 1920-21. It is said that the mortality did not affect the Portuguese oysters. Dr. Orton shows, however, that both species are about equally susceptible to T.N.T.

The next paper—a valuable study, by Dr. C. M. Yonge, of feeding and digestion in the oyster—also arises out of Dr. Orton's oyster-mortality investigations, and its genesis illustrates in a striking way how important it is that 'fundamental' or purely scientific studies should accompany, or better still precede, any investigations directed towards a practical or economic end. It became apparent from Dr. Orton's own work on the mortality of oysters that not nearly enough was known about the normal physiology of the oyster for any one to say what conditions were normal and what were indicative of disease or pathological disturbance. Dr. Orton wisely pointed the moral by recommending a special research into the anatomy and physiology of the oyster, and of this Dr. Yonge's paper gives us the first fruits.

The paper seems to us wholly admirable. Dr. Yonge is of the modern school in combining anatomy with physiology, in studying form and function together. Considerable space is given to a clear and well-illustrated account of the anatomy and histology of the digestive apparatus both in the adult and in the larval oyster, and to a description of the amazingly complex system of ciliary currents by which the oyster collects and sifts out the tiny planktonic organisms on which it feeds, rejecting all such as are too large for it to deal with, and leading the rest over the palps into the mouth, down into the stomach and the digestive diverticula (commonly known as the 'liver'). Other sections treat of assimilation, the digestive enzymes, the function of the crystalline style, and the storing of reserve products. Dr. Yonge finds that digestion is mainly intracellular—soluble matter and fine particles being ingested by the cells of the digestive diverticula, larger particles by the phagocytes present in all parts. This is demonstrated by ingenious feeding experiments with iron saccharate, with blood corpuscles of the dog-fish, with olive oil, and with the diatom Nitzschia. He rejects the theory of the Danish workers that the oyster is primarily a detritus feeder, and emphasises the importance of the smaller diatoms, peridinians, algal spores, and other microscopic vegetable matter.

It comes out clearly from Dr. Yonge's work, especially that on the enzymes present, that the oyster, like other lamellibranchs, is specially adapted for the digestion, assimilation and storage of carbohydrates. The rationale of fattening the oyster for market is, then, to supply it with plenty of microscopic vegetable food, as already indicated by Savage in a recent paper, and as realised empirically in some fattening ponds, particularly in France. It has been known for some time that the oyster stores its surplus nourishment mainly in the form of glycogen, which is no doubt

chiefly derived from the carbohydrates richly present in the diatoms and peridinians of its food. Dr. Yonge's elaborate paper represents a distinct advance in our knowledge of lamellibranch physiology, and cannot fail to be of great service both theoretically and practically.

The three papers so far considered take up about half the present number of the *Journal*, and the remaining papers can be only lightly touched upon. Mr. F. S. Russell continues his interesting studies on the vertical distribution of the macro-plankton, with papers on the diurnal changes in distribution of pelagic young fish and on the importance of light as a factor in determining the vertical distribution of plankton forms. From Dr. Atkins comes a third contribution to our knowledge of the phosphate content of sea-water in relation to the growth of algal plankton. Samples obtained from the English Channel, North Sea, the open Atlantic and Pacific confirm the author's views on the importance of phosphate as a limiting condition for production in the sea. Mr. C. F. Hickling gives some further details regarding the remarkable kind of luminescence discovered by him in the fish *Malacocephalus laevis*. Among two or three faunistic papers one may perhaps specially note one by Dr. Lebour giving a general survey of larval euphausiids, with a scheme for their identification. Such work is of very great service to plankton investigators, and it is to be hoped that Dr. Lebour will continue the good work and deal with other groups in the same way.

In conclusion, mention must be made of the ingenious 'vacuum grab' invented by Mr. O. D. Hunt, with the assistance of Dr. Bidder, and here described in detail. By means of this instrument samples of the bottom can be taken which retain the finest particles together with the micro fauna and microflora therein contained. E. S. R.

University and Educational Intelligence.

BIRMINGHAM.—At the meeting of the Council of the University held on November 3 the following appointments were made: Dr T. L. Hardy, assistant physician to the General Hospital, to be assistant to the chair of medicine; Dr. C. C. W. Maguire, physician for out-patients at Queen's Hospital, to be honorary demonstrator in the Department of Anatomy.

It was decided that the Court be asked to confer the title of emeritus professor upon Prof. O. J. Kauffmann, joint professor of medicine in the University from 1913 to 1926.

CAMBRIDGE.—Mr. T. W. Wormell, St John's College, has been appointed observer in meteorological physics at the Solar Physics Observatory. Mr. J. T. MacCurdy, University lecturer in psycho-pathology, and Mr H. C. B. Mynors, have been elected to fellowships at Corpus Christi College. The Adam Smith Prize has been awarded to G. T. Jones, Emmanuel College. The Engineering Department has been presented with portraits of Sir Alfred Ewing, the late Prof. Bertram Hopkinson and Prof. Inglis. The Henry Sidgwick Memorial lecture will be given at Newnham College on Nov. 13 at 5 P.M., by Sir William Bragg, who will take as his subject "The New Crystallography."

LONDON.—The following doctorates have been conferred: *D.Sc.* (*Economics*) on Mr. S. G. Panandikar (London School of Economics) for a thesis entitled "The Wealth and Welfare of the Bengal Delta"; *D.Sc.* (*Chemistry*) on Mr. G. W. Ellis for a thesis entitled "A Contribution to the Chemistry of Drying Oils, Parts i-iii. (containing a Study of the Autoxidation of Linseed Oil and a Theory on the Nature of the Autoxidation of Unsaturated Compounds)"; *D.Sc.* (*Veterinary Science*) on Mr. J. T. Edwards for a thesis entitled "The Chemotherapy of Surra (*Trypanosoma evansi* infections) of Horses and Cattle in India."

ST. ANDREWS.—On November 3 Dr. Fridtjof Nansen was installed as Rector of the University, after having been admitted to the honorary degree of Doctor of Laws. He delivered an inspiring address on the spirit of adventure, in the course of which he referred to his own experiences as an explorer and as a supporter of the League of Nations. The honorary degree of LL.D. was then conferred upon His Excellency Mons. P. B. Vogt, Norwegian Minister; Prof. Vilhelm F. K. Bjerknes, of the University of Oslo; Prof. Bjorn Helland-Hansen, of Bergen; Capt. Otto Neumann Sverdrup (Captain of the *Fram*); Prof. J. Norman Collie; Brig.-General the Hon. Charles Granville Bruce; Sir T. W. Edgeworth David; and (*in absentia*) the Right Hon. Viscount Cecil of Chelwood.

IT is stated in the *Chemiker Zeitung* that Dr. G. von Hevesy, professor of physical chemistry at the University of Freiburg in Baden, has been invited to succeed Prof. Bodenstein in the chair of physical chemistry at the Technische Hochschule at Hannover.

THE British Institute of Adult Education issued in September the first number of a half-yearly review entitled the *Journal of Adult Education*, published by Messrs. Constable and Co., Ltd., at 2s. 6d. The editors, Prof. J. Dover Wilson and Prof. A. E. Heath, are assisted by an advisory panel of thirty-one, whose names, well known in educational circles, appear on the cover. This first number is remarkable for the prominence given to the questions of what are and what should be the purposes of adult education. The questions are raised both explicitly in the more important articles, and indirectly by incompatibility of the ideals of some of the writers. They are dealt with most comprehensively by Prof. Robert Peers, the director of the important department of extra-mural education of University College, Nottingham, who classifies the various views concerning the aims of adult education under the three heads—development of the individual person, social service, and social change. A certain ambiguity is observable in the arguments owing to confusion between the aims of the students, the aims of the teachers, and the aims of those who organise and administer and finance the work. Education that aims primarily—not at the student's emancipation from the shackles of ignorance, but at the emancipation of 'workers' from the restraints incidental to a social system under which 'the means of life' are subjects of private ownership, the education on a Marxian basis, as given in the 'Labour' colleges, is described in one of the articles as 'independent' working-class education. This article, beginning with this curious use of the word 'independent' and ending with an appeal to class hatred by describing resistance to the subsidising of the mining industry as "the whole power of capitalism turned to defeating one particular section [of 'the workers'] by the use of the starvation weapon against women and children," shows that a wide circulation of the Journal is anticipated.

A PROJECT for founding a British Institute in Paris was launched at a meeting at the Mansion House,

8 in. long and 0·25 in. in diameter have been prepared by lowering a graphite tube full of the molten metal slowly through an electric tube furnace, so that freezing proceeds from the bottom upwards. The position of the crystal axes was determined by means of X-rays, and the rods extended in a tensile testing machine. The crystal axis of the specimen moved in the same direction as in aluminium during extension. As these metals have the same crystal structure as aluminium, it was concluded that distortion was similar in every case, and that gold, silver and copper crystals distort by slipping on a (111) plane in a (110) direction. The crystals all harden during the process of deformation, but when the shear stress is plotted against the extension, the form of the curves is different for each metal.

R. E. **Gibbs**: The polymorphism of silicon dioxide and the structure of tridymite. The structure of tridymite was similar to that of ice, *i.e.* D_{6h}^{4}, with four molecules per cell, in which $a=5·03$ and $c=8·02$. The framework can be considered as a close-packed arrangement of oxygen atoms of diameter about 2·6, whilst the silicon atoms occupy the spaces between four neighbouring oxygens. It is probable that the structures are ionic in nature, being variations of a two-to-one packing of oppositely charged ions. Possible modes of β-β transitions lead to the idea that these sluggish changes are characterised by a change of partners between neighbouring ions. On other hand, the α-β transition, at least in the case of quartz, is merely a small atomic rearrangement not sufficiently drastic to involve a change of neighbours. The α-states are probably created by distortions of the β-forms involving lower symmetry and possibly larger cells. α-tridymite is orthorhombic, having a cell $a=9·9$, $b=17·1$, $c=16·3$, in which the units must be polymerised groups $nSiO_2$, where n is larger than two and probably equal to eight. The existence of a third form α' of tridymite resembling the ordinary α-form was confirmed.

Twenty six papers were read by title only.

Royal Microscopical Society, October 20.—A. **Piney**: A method of silver impregnation of Zenker-fixed sections. The method is only a modification of Bielchowsky's technique and is designed to apply to tissues fixed in mercuric chloride solutions. The essential point is the removal of all traces of the mercuric salt, followed by removal of the iodine, which was employed for this purpose. The wax is removed from the section with xylol, and the section is then placed in 0·4 per cent. iodine in 80 per cent. spirit for 10 minutes. Some of the iodine is removed by soaking the section for 30 minutes in 70 per cent. alcohol, but the remainder is got rid of by immersion in 0·25 per cent. sodium thiosulphate dissolved in 50 per cent. alcohol (not in water as recommended by Heidenhain). The section is now washed in water for an hour, and then immersed in 0·25 per cent. potassium permanganate in water, swilled in distilled water, placed in 5 per cent. aqueous oxalic acid for 20 minutes, washed for 2 hours in running water, and then stained by the Bielchowsky method. Toning with 1 per cent. gold chloride and fixation with 5 per cent. hypo are an advantage, as is also counterstaining with Weigert's iron hæmatoxylin and van Gieson's solution. The method is particularly adapted for the demonstration of reticular fibrils in hæmatopoietic tissues.

PARIS.

Academy of Sciences, October 11.—V. **Grignard** and P. **Muret**: Pyrosulphuryl chloride. In the production of this substance by the reaction between sulphur trioxide and carbon tetrachloride there are difficulties in purification. Utilising the reaction between carbon tetrachloride and chlorsulphonic acid, the conditions have been studied with the view of obtaining a purer product. The decomposition resulting from rise of temperature has also been studied.—Henri **Jumelle**: New observations on tombak tobacco. The identification of the species is complicated by the fact that there are several tombak tobaccos. One tobacco sold under that name has proved to be *Nicotiana rustica*. It contains a high proportion of nicotine (6-12 per cent.) and may be of service as a source of nicotine for viticultural or horticultural purposes.—T. **Rado**: The calculation of the area of curved surfaces.—Paul **Flamant**: The continuity of the distributive transmutations and the extension of a transmutation defined for polynomials.—Paul **Dumanois**: The importance of the combustion yield in internal combustion engines. According to the theory of combustion and detonation developed by the author in previous communications, a mixture of petrol and methyl alcohol should give a higher efficiency than petrol alone. Experimental proof of this is now given: the fuel used contained 70 per cent. of methyl alcohol and gave an increase of 15 per cent. in efficiency over pure petrol.—Th. de **Donder**: The application of the quantification deduced from the Einsteinian gravific.—L. **Meunier** and G. **Rey**: The action of ultraviolet light upon wool. Under the action of sunlight or the mercury vapour lamp, the condition of the sulphur in the wool is changed; part is converted into sulphur dioxide, which is partially oxidised to sulphuric acid. These changes can be followed by an indicator such as methyl red. Reactions of the insolated wool with nitroprusside, quinone, alloxan and ninhydrin are also described.—W. J. **Richards**: The effect of α-rays on supersaturated solutions. It might be expected that α-particles would produce crystallisation in supersaturated solutions. Negative results were obtained with solutions in water of sodium sulphate, potassium sulphate, calcium chromate and lithium carbonate. Negative results were also obtained with aqueous sugar solutions and with fused salol.—Louis **Grenet**: The limiting states of alloys.—M. **Ballay**: The Ludwig-Soret phenomenon in alloys. The concentration changes produced in solutions unequally heated are shown experimentally to exist in alloys, and this phenomenon must be taken into account in a general discussion of the phenomena of segregation.—V. **Hasenfratz** and R. **Sutra**: Some derivatives of harmalol and harmol.—Marcel **Frère-jacque**: Vaillantite, an agent of sulphomethylation. Formation of a new active camphorsulphonic acid.—H. **Prophète**: Contribution to the study of the wax of flowers: rose wax. Study of its unsaponifiable matter.—Germain **Chalaud**: The first phase of the evolution of the gametophyte of *Fossombronia pusilla*.—Jean Jacques **Trillat**: The action of X-rays of long wave-length on micro-organisms. The case of *B. prodigiosus*. These researches showed the bactericidal influence of primary X-rays of long wave-length.—Auguste **Lumière** and Félix **Perrin**: A new class of hypnotics. The dialkylphenylacetamides. Dipropyl-, propylallyl-, and diallylphenylacetamide have been prepared and possess hypnotic properties, but the ratio of their active dose to the toxic dose is rather high.—**Javillier** and H. **Allaire**: Phosphorus ratios in the tissues.

ROME.

Royal National Academy of the Lincei: Communications received during the holidays.—G. **Fubini**: The theory of R surfaces and their transformations.—

Giorgio Dal **Piaz**: The discovery of a supposed vein of post-glacial volcanic rock in the neighbourhood of Bressanone (Upper Adige).—Giuseppe **Corbellini**: A class of variety characterised by means of parallelism.—V. **Hlavatý**: Local parameters in a Riemann variety.—J. **Soula**: Functions defined by Dirichlet's series.—Oscar **Zariski**: The development of an algebraic function in a circle containing several critical points.—Filippo **Burzio**: Order of magnitude of quantities relative to the second ballistic problem. A formula for ballistic nutation.—A. **Weinstein**: Liquid jets with given walls.—Bruto **Caldonazzo**: An extension of Bernoulli's theorem. This theorem, which is valid for the stationary motion of a perfect fluid, is extended to meet certain cases of variable motion.—Mentore **Maggini**: Interferometric measurements on the four large satellites of Jupiter. Observations on the changes of figure and on the axial inclinations of these satellites are described.—Vasco **Ronchi**: Further concerning "flying shadows." D'Arturo's criticisms of the author's conclusions are refuted.—Franco **Rasetti**: The Doppler effect in sensitised fluorescence.—G. **Wataghin**: The ballistic hypothesis and the Doppler effect. The two treatments as yet known of the Doppler effect both lead to results unfavourable to the ballistic theory of this effect.—G. **Natta** and F. **Schmid**: Oxides and hydroxides of cobalt (ii). The crystalline structure of the saline oxide of cobalt. The oxide Co_3O_4 crystallises in the monometric system and is isomorphous with magnetite. The size of the elementary cell of the crystalline lattice, which is of the spinel type, is 8·02 A.U. and contains eight molecules. The density is calculated to be 6·21, which lies among the somewhat discordant experimental values.—E. **Repossi** and V. **Gennaro**: The minerals of the serpentine of Piossasco (Piedmont). The mineral species so far identified in this serpentine are ilmenite, magnetite, calcite, aragonite, diopside, granite, vesuvianite, chlorite, titanite, perowskite, apatite, and, probably gavite.—Sabato **Visco**: The behaviour of the hepatic glycogen in fasting animals treated with insulin. The administration of insulin to fasting rabbits diminishes the loss in weight. The liver and spleen increase in weight, whereas the heart, kidneys, suprarenal capsules and lungs show slight and variable changes in weight. The amount of glycogen in the liver is increased very considerably by treating the fasting animal with insulin.

SYDNEY.

Linnean Society of New South Wales, August 25.—C. H. **Anderson**: A revision of certain Australian Rhenopodiaceæ. The paper embodies a critical examination of the two species, *Bassia tricornis* (Benth.) F.v.M. and *Bassia enchylænoides* F.v.M. A new genus is proposed to take in one of the species, and the other is transferred to the genus Kochia.—E. **Cheel**: Notes on *Melaleuca pubescens* Schauer and *M. Preissiana* Schauer. The author's view is that *M. pubescens* Schauer has priority, that the Victorian plants are merely forms of *M. pubescens*, and that the Western Australian plants known as "Ironwood" are glabrous forms of the same species.—Rev. H. M. R. **Rupp**: Description of a new species of Diuris from Barrington Tops, N.S.W. The species described as new is closest to *D. spathulata*, from which it differs in its venation, more prominent lateral lobes of the labellum, and in its short and thick column.—A. M. **Lea**: On some Australian Curculionidæ. The paper contains descriptions of two new genera and sixty-five new species, one of which belongs to Rhinomacer, a genus now first recorded as Australian.

SATURDAY, NOVEMBER 13.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Rev. E. M. Walker: The Study of History (2).

PHYSIOLOGICAL SOCIETY (at the London School of Medicine for Women), at 4.—R. T. Grant: An Observation on the Function of the Pericardium.—A. Levin: Fatigue, Retention of Action Current and Recovery, in Nerves of the Spider Crab.—T. Lewis and H. M. Marvin: Herpes Zoster and Antidromic Impulses.—R. W. Gerard, Prof. A. V. Hill, and Y. Zotterman: Energy Liberation of Nerve as a Function of Frequency of Stimulation.—R. W. Gerard: The Two Phases of Nerve Heat Production.—M. Lowenfeld, S. T. Widdows, M. Bond, and E. Taylor: Variations in Composition of Early Human Milk and Factors Influencing Them.—D. Woodman, E. E. Hewer, and M. L. Keene: Time of Appearance of Digestive Enzymes in the Human Fœtus.—W. C. Cullis, D. Rendel, and E. Dahl: Points in the Technique of the Ethyl Iodide Method.—Demonstrations by A. Levin: An Improved Device for Time-marking and Similar Purposes.—E. E. Hewer and M. F. L. Keene: Pineal and Choroid Plexus in the Human Fœtus.—G. Briscoe: Records of Different Types of Respiratory Movements.

MONDAY, NOVEMBER 15.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION (at British Medical Association, Tavistock Square), at 4.—Dr. A. Adler: The Cause and Prevention of Neurosis.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge), at 5.—J. A. Steers: The East Anglian Coast.

INSTITUTION OF ELECTRICAL ENGINEERS (Tees-Side Sub-Centre) (at Cleveland Technical Institute, Middlesbrough), at 7.—J. Rosen: Address.

INSTITUTION OF AUTOMOBILE ENGINEERS (Scottish Centre) (at Royal Technical College, Glasgow), at 7.30.—J. E. Southcombe: Recent Research on Friction and Lubrication.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—H. V. Lanchester: Bridges and Traffic.

ARISTOTELIAN SOCIETY (at University of London Club), at 8.—J. C. McKerrow: Evolution and Contingency.

ROYAL SOCIETY OF ARTS, at 8.—Prof. H. L. Callendar: Recent Experiments on the Properties of Steam and High Pressures (Howard Lectures) (1).

HUNTERIAN SOCIETY OF LONDON (in Cutlers' Hall, Warwick Lane, E.C.), at 8.45.—Sir Humphry Rolleston, Dr. G. Little, Dr. L. Williams, and others: Discussion on Medicine and the Press.

TUESDAY, NOVEMBER 16.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Dr. G. W. C. Kaye: The Acoustics of Public Buildings (Tyndall Lectures) (3).

ROYAL STATISTICAL SOCIETY (at Royal Society of Arts), at 5.15.—Viscount D'Abernon: German Currency: The Collapse and Recovery, 1920–1926 (Inaugural Address).

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. G. D. Hale Carpenter: The Biology of *Glossina palpalis* in connexion with Sleeping Sickness.

Nor can the evidence accumulated elsewhere be said to be more convincing. The work mostly quoted in favour of the existence of 'teleplasm' is Dr. von Schrenck-Notzing's "Materialisationsphänomene," which gives several hundred photographs of this mysterious substance. This work was of sufficient importance to lead to the study of its author's medium by the S.P.R. and by a Committee of the University of Paris. The official reports of both these bodies pronounced the phenomena observed to be quite inconclusive. Another attempt made by an academic body, this time the University of Vienna, to corroborate such phenomena, led last year to an equally pronounced failure. Thus Crookes's failure to convince the Royal Society may be said to have been the precursor of a consistent series of similar failures.

The tragic case of the late Dr. W. J. Crawford, of Belfast, is instructive. Here was a university lecturer of some distinction whose leaning towards mysticism made him an easy victim of a family of artisans with alleged mediumistic faculties. He devoted four years to their examination and endeavoured to duplicate and surpass the records of Crookes and Schrenck-Notzing. The 'invisible operators' who ruled the procedure led him on step by step until his records became the very travesty of scientific method, and gross imposition was presented in terms of his own psycho-physical guesses and speculations. When his career ended in suicide and an attempt was made to repeat his results, the repetition, which duly occurred, only served to reveal the *modus operandi* of the 'circle,' which was anything but spiritual. Such a *dénouement* is not, of course, unknown in purely physical science. Blondlot's *N*-rays were the subject of some fifty scientific papers, and his 'discovery' was recognised by the award of a substantial prize by the Paris Academy of Sciences. It is only natural that the caution wisely displayed by many physicists with regard to *N*-rays should be doubled and trebled when certain phenomena long discredited are presented in a new guise even on apparently unimpeachable authority.

Sir William Crookes in 1874 walked about in a well-lighted room with what he believed to be a 'spirit' on his arm, a 'spirit' resembling a girl of eighteen. No such amazing privilege has been vouchsafed to any man of scientific eminence since then. The phenomena obtained by scientifically trained observers have been poor in comparison with that high-water mark. This may be due to their 'unsympathetic' attitude, or it may be due to a wider knowledge of the chances of error and the means of deception. Investigators in search of ectoplasm have to be content with what looks like skin-bags or lengths of chiffon. As the control becomes stricter the results become poorer. When the control becomes rigid the phenomena cease altogether. That is the general rule, and it admits of only one interpretation.

The demands made upon the scientific investigator are nowhere more severe than in the cases of 'spirit photography' and the 'direct voice.' As the spirit 'extras' are not visible to the ordinary observer, we must suppose that they do not reflect ordinary light and are to that extent immaterial. Spiritualists usually meet this argument by saying that the effect on the photographic plate is not produced by light of any known wave-length but is a direct action on the plate itself. We must, therefore, assume that the invisible or disembodied artist can draw a likeness of a deceased friend of the sitter on the plate in such a way as to produce a correct negative. The difficulty of this feat is greatly increased if we remember that clairvoyants claim to see these spirit friends hovering about the sitters in the very attitudes shown on the photographs. Rather than face the innumerable difficulties in the way of a consistent theory conforming to the spiritualist view, most investigators will prefer to regard all so-called spirit photographs as examples of the almost numberless methods of deception which may be, and have been, practised in this most elusive department of spiritualist activities.

In the case of the 'direct voice,' we are confronted with even more formidable difficulties. There is nothing more 'spiritual' or less 'material' about a voice than there is about a brick wall, though the unscientific person may think otherwise. Where exactly does the material nature or structure of the direct voice begin? Do the spirits produce the necessary air waves direct at some focus in the air? One spiritualist view often met with is that the 'spirits' materialise a larynx and sufficient in the way of lungs and mouth cavities to produce the sounds heard. This does not make the matter any clearer. It is much easier to assume deception, more especially as fraud in this case is easy and 'convincing' and control extremely difficult, owing to the lack of orientation shown by most human ears in the dark. Here again the *onus probandi* must weigh heavily on those who claim that there is positive evidence.

The difficulties placed in the path of the observer all tend to make control more difficult and deception easier. Modern mediums work in total darkness or the dimmest of red light. The observer is not allowed to prescribe conditions. So long ago as 1880, Mr. Stainton Moses, an eminent spiritualist, said: "In 99 cases out of 100, people do *not* get what they want or expect. Test after test, cunningly devised, on which the investigator has set his mind, is put aside, and another substituted." Mediums may, by the rules of

the game, fail as often as they like and substitute other tests of their own devising. The patience displayed by expert investigators during some of their test sittings is astonishing. Hour after hour will go by without anything happening. The medium will fall asleep and wake up again. When anything does happen, if only the production of a rubber film (or something resembling it) from the mouth of the medium, it is eagerly scrutinised and carefully recorded.

Nobody can complain of unwillingness on the part of scientific men to investigate any phenomena offering a chance of extending the boundaries of knowledge, and the rewards, both material and social, of any such extension are very great. But after half a century of growing disappointment with spiritualistic phenomena, the number of qualified volunteers naturally shows signs of diminution. On the other hand, the flood of charlatans and impostors increases day by day. The 'new revelation' imported from the United States in 1852, with its combination of 'supernormal' telegraphy with Pentecostal gifts and Delphic oracles, has obtained almost undisputed sway over the mind of the masses thirsting for signs and wonders and determined at any price to believe.

It is for science to stem the tide of superstition and sift the true from the false. We are quite justified in assuming, with Sir Oliver Lodge, that man's future outlook on the universe will be very different from the orthodoxy of 1926. Such an evolution is bound to take place even on purely physical grounds, as indeed is shown by the prodigious changes in physical conceptions since 1895. But the fundamental principles of the scientific method will not change, and no set of phenomena which depends for its occurrence, not upon ascertainable laws, but upon the whim of invisible operators not amenable to a court of law, can appropriately form part of the subject matter of natural science.

In spite of all failures and discouragements, it is highly desirable that a competent body should exist for making out a *prima facie* case in favour of any alleged new phenomena of the class we are discussing. Such a body we have in the Society for Psychical Research, which has admirably fulfilled its functions in spite of material limitations such as do not hamper the wealthy 'colleges' of spiritualism. This Society has already done good work by its study of telepathy, hallucinations, and duplex personality. It includes people of the most diverse views, and can be relied upon to welcome any evidence of really unknown phenomena. It might possibly be associated usefully with the recently formed National Laboratory of Psychical Research, which is equipped with the means of studying psychical and related phenomena, but that should be easily arranged if desired. In the present state of this matter it is wisest and best for official science to wait for the recommendation of such a society before devoting any attention or labour to alleged 'supernormal' occurrences. The very use of the word 'supernormal' instead of 'abnormal' suggests that these occurrences belong to an order raised above the normal order of the universe (which would, of course, remove them from the province of science). That there may be such a supernormal order of things no philosopher can *a priori* deny, but the use of the word is too unpleasantly suggestive of a hieratic domination now happily overcome to be palatable to scientific men, and they will hesitate before installing the 'medium' in the high place from which, after much fighting and suffering, they have driven his ecclesiastical predecessor.

Education, Science and Mr. H. G. Wells.

The World of William Clissold: a Novel at a New Angle. By H. G. Wells. Vol. 1. Book the First: *The Frame of the Picture;* Book the Second: *The Story of the Clissolds—My Father and the Flow of Things.* Pp. 245. 7s. 6d. net. Vol. 2. Book the Third: *The Story of the Clissolds—Essence of Dickon;* Book the Fourth: *The Story of the Clissolds—Tangle of Desires.* Pp. 247-601. 7s. 6d. net. Vol. 3. Book the Fifth: *The Story of the Clissolds—The Next Phase;* Book the Sixth: *The Story of the Clissolds—Venus as Evening Star;* The Epilogue: Note by Sir Richard Clissold. Pp. 603-885. 7s. 6d. net. (London: Ernest Benn, Ltd., 1926.)

ALTHOUGH the critics have not been stirred by volumes 1 and 2 of William Clissold's achievement, there should be wigs on the green over volume 3, if it be not above them. Book V. is masterly in many ways—the less said of VI. the better, perhaps. No writer, other than the author, could have preferred the indictment he does against our public-school system and the ancient universities.

The attempt is made, in a preface, to justify the contention that the book is a novel: there is no novel in it: true it is, the story is told, ostensibly, by one William Clissold or through his brother Dickon but William is himself again, as he ever will be: from beginning to end, we are dealing with autobiography and early in the recital the writer gives himself away in saying—"Autobiography, provided that it be not too severely disciplined may be an almost inexhaustible occupation. Nothing is altogether irrelevant. Whatever interests me or has ever interested me is material." This, in a few clear words, is the book. It is a medical treatise--largely on social pathology.

The author is a photographer, working with a lens stopped down to a low aperture but of no great depth

of focus, giving very clear pictures of superficial appearances. A photographer neither analyses nor constructs—he must record what is before him. However much he may fake his picture in development, out in the open he must take what is offered him by Nature and, at most, can await a favourable light and so play with the shadows.

At the moment there is what amounts to little short of a conspiracy to represent science and religion as moving along the same path. They never can, unless and until we make a religion of our knowledge and recognise that, therefore, religion must be imperfect and ever correcting and shifting its boundaries. Science is ultimately the search after truth. Who can say what religion is? For every one the word has a different meaning. Our William, be it remarked, is a little fuzzy in his high lights. He can't be satisfied with what he has and may have and then leave it to the other fellow to have his turn, but hankers for more. He is so spoilt by frequent reprinting, that he must contemplate a new edition of himself, no doubt with special binding:

"To me it is far easier to suppose that this present unfolding of consciousness and will is only a birth and a beginning and that I am not merely myself but a participator in a Being that has been born but need not die."

Surely, he is here but seconding a vote of thanks to "that chap Oliver Lodge." Still, "belief in a living personal God—slight vestiges": we all have more or less as an ineradicable inheritance from primitive man.

The lapse into such anthropomorphism is proof how difficult it is for intelligence to prevail over convictions forced upon youth. The great problem before us soon in schools will be—how far we are entitled to go in retarding and repressing mental growth by forcing an 'established faith,' without explanation or qualification, upon children: whether parent and especially teacher be justified in misleading by baldly repeating assertions which have no authority other than tradition. The struggle is between knowledge and ignorance. Our William defines the position clearly and boldly:

"I do not know how Protestantism will end. But I think it will end. I think it will come to perfectly plain speaking and if it comes to perfectly plain speaking it will cease to be Christianity. There is now little left of the Orthodox Church except as a method of partisanship in the Balkans. The League of Nations may some day supersede that and then the only Christianity remaining upon earth will be the trained and safeguarded Roman Catholic Church. That is less penetrable, a world within a world, it shields scores of millions securely throughout their lives from the least glimpse of our modern vision."

Teachers of science, and examiners, are equally concerned. Over and over again, when advocating *the teaching of scientific method*, I have been told by my friends—"You must teach something definite: students ask for assurance and will not countenance any philosophic doubt": examiners, too, ask for positive answers. Tennyson's lines are not yet accepted even of science:

> There lives more faith in honest doubt,
> Believe me, than in half the creeds.

The attitude of all the schools is not merely unscientific but is one tending to systematise untruthfulness. Our William, at least, can think of better times:

"I can discover in all my world nothing enduring, neither in the hills nor in the sea, nor in laws and customs nor in the nature of man, nothing steadfast except for this—a certain growth of science, a certain increase of understanding, a certain accumulation of power. But there is that growth of science, there is that increase of understanding, there is that accumulation of power. I do not know why it should be so but so it is. It gathered its force slowly before man was. It goes on now with accumulating speed and widening scope and on it I build my working conception of the course of life. Man, unconscious at first, begins now, in an individual here and an individual there, to realise his possibilities and dream of the greatness of his destiny. A new phase of history is near its beginning. But it has not begun. Such science as we have brings us suggestions rather than direction."

William Clissold is not all religion, though considered under the conventional classification of *Wein, Weib* and *Gesang*, it has a limited range of subject. Wine is only once referred to—a single bottle of Château Margaux 1917, not a great vintage, produced at lunch by Sir Rupert Yorke. Still, this suffices to incite William's reflections upon Sir Rupert's sexual and religious outlook. It appears also to have led him to refrain from referring to certain questions he had intended to raise—the projected exchange of opinion would have been "as possible as with a pensive lion in the zoo." Pity it is perhaps that he has not met with more pensive lions in the course of his career and has not thereby been forced to concentrate upon some definite line of action.

After an over-full dose of *Weib*, we get music in the form of a study of futurism. Our William's swansong foreshadows a metamorphosis of mankind—new ways of living—one terrestrial anthill: this he regards as the necessary, the only possible, continuation of human history. He contemplates the organisation of a central police bureau to co-ordinate the protection of life, property and freedom throughout the world, without distinction of persons under an universally accepted code. In fact, the lions and lambs are all to lie down comfortably together. The coal strike was only begun when the book was issued. The history of Ireland, the

love lost between the States of Europe, the growing development during many years past of local self-government in Great Britain—such items are left out of account.

The men of large material influence are to reconstruct the world upon broader, happier and finer lines. Their first struggle is to be with the Press. Civilisation must be by newspapers. Open, candid, full and generous, these are the qualities the newspaper of the new life must possess. It must suppress nothing. It must bring to every mind capable of receiving it the new achievement of human and organising power, the victories of conscious change. The daily papers of educated people half a century ahead may be a tenth of the size and ten times the price of the present "wildly flapping caricatures of contemporary happenings." The Press apparently is to be the work of the men of affairs. Our William says, quite truly, the daily paper is a daily disappointment—but to how many? He has found but one newspaper that comforts his soul and that is NATURE, to which flattering reference is made. "Domestic bye-products," such as sons, will have to justify their sonship—there is to be a diminution of inheritance in property. The new social life will be aristocratic in the sense that it will have a decisive stratum of pre-eminent and leading individuals who will wield a relatively large part of the power and property of the community but it will be democratic in the sense, that it will open to every one with ability and energy to join that stratum and participate to the extent of his or her ability or energy. In the formal picture presented to us of the world republic, we shall be fully adult—a state to which few come now, doubtfully and each one alone:

"We shall put away childish things, childish extravagances of passion and nightmare fears. Our minds will live in a living world-literature and exercise in living art; our science will grow incessantly and our power increase. Our planet will become like a workshop in a pleasant garden and from it we shall look out with ever-diminishing fear upon our heritage of space and time amidst the stars. We shall be man in common and each one of us will develop his individuality to the utmost, no longer as a separated and conflicting being but as a part and contribution to one continuing whole."

Who shall say that our author is not an optimist and Holist?

The contemplated metamorphosis of mankind, our William contends at an early stage of his dream, demands a life based on broader and sounder common ideas, expressed in new terms and new artistic forms, accompanied by nervous and other physiological changes. This necessity to change and expand extends from man's soul to man's chemistry.

It is strange that a reader of NATURE and a pupil of the Royal College of Science should be so Lamarckian as to proffer such doctrine or believe that it can be realised within any period that is worth our consideration. The lesson of Tutankhamen's tomb seems to be lost upon him. Obviously, he has little knowledge of what is known in science. We have learnt sufficient of man's vital chemistry *to know*, that it proceeds along lines which are little short of fixed. This must be so. If open to variation away from our type, we should be all over the shop, to use a vulgarism. Still, the human mind is strangely variable—subject at all times to the caprice of chemical change, every function apparently controlled by a chemical secretion. The woman, at regular intervals, we know, is heavily drugged. Male desire, of which our William has much to say in Book VI., is probably of chemical origin, due to chemical changes induced by mental processes.

Coming down to sense, human control of the world, as our William says, has been a control in detail; there has been no comprehensive control—because there has been no comprehensive understanding. Hence his indictment of our educational system in Book V. It is worth noting, he makes the point, that the mind of youth is the primitive, medieval mind—conservative and reactionary:

"Few minds are mature enough and stout enough before thirty to achieve a genuine originality. The originality of the young is for the most part merely a childish reversal of established things. The independence of the young is commonly no more than a primitive resistance to instruction. The youthful revolutionary is merely insubordinate and his extremist radicalism an attempt to return to archaic conditions, to naturalism, indiscipline, waste and dirt. The youthful anti-revolutionary turns back to mystical loyalties and romance."

It is necessary to educate the young for the new order. Sections 14 and 15 on supersession of schoolmasters and an inquest on universities must be studied to be appreciated—almost every word is telling. On an experience of sixty years, I am prepared to vouch for the substantial accuracy of the indictment. Much that is said, I have said over and over again.

Present-day education is nothing short of a pretentious farce—taking into account the changed and fast-changing state of the world. It promotes inaction, where action is needed above all things. It degrades and only accidentally promotes intelligence. It is in the hands of a class of men who are eyeless to the needs of the times, of men who never will respond to the call that is now made upon the teacher. Yet parents and guardians smugly accept what is and make no attempt to improve the conditions. Even our William, being a man of words, only half sees what is, what might

and what should be. Education was begun in the monasteries, to serve clerical ends. We have long since got rid of monasteries—Henry VIII. did that for us. It were now time that we abolished the monastic in education. Only don't let us substitute co-education, the emasculating invention of the Evil One. The effect of the monasteries was of small account in comparison with that now being exercised by the survival of the system of training they instituted—it will yearly become a greater peril to us. Our William is explicit on this point:

> " . . . the last human beings in the world in whom you are likely to find a spark of creative energy or a touch of imaginative vigour are the masters and mistresses of upper middle-class schools . . . these schoolmasters and schoolmistresses, . . . to whom we entrust nearly all the sons and daughters of the owning and directing people of our world, are by necessity orthodox, conformist, genteel people of an infinite discretion and an invincible formality. Essentially they are a class of refugees from the novelties and strains of life. I do not see how, as a class, they can be anything else. . . . The whole crowd of upper-class youth has been picked over again and again before the schoolmasters come; the most vigorous and innovating men have gone in for diplomacy, the law, politics, the public services, science, literature, art, business, the hard adventure of life; and at last comes the residue. . . . Its [the school's] mentality is the mentality of residual men.
>
> " That is a neglected factor which has to be reckoned with in the history of the British Empire during the last hundred years. That is something the foreign observer has still to realise. A larger and larger proportion of its influential and directive men throughout this period have spent the most plastic years of their lives under the influence of the least lively, least enterprising, most restrictive, most conservative and intricately self-protective types it was possible to find. We have bred our governing class mentally, as the backward Essex farmer bred his pigs, from the individuals that were no good for the open market. The intelligent foreigner complains that the Englishman abroad has been growing duller and stiffer in every generation."
>
> . . . . .
>
> " The clue to the manifest change in character that Britain and its Empire have displayed during the last hundred years, the gradual lapses from a subtle and very real greatness and generosity to imitative imperialism and solemn puerility is to be found, if not precisely upon the playing fields of Eton, in the mental and moral quality of the men who staff the public schools."

A true bill. Italy, the one country where there is government, has no public schools. No other explanation is possible of the way in which the courage is gone out of us—of our loss of the art of government, the courage to govern, never more obvious than in the present coal strike—of the disappearance of the naturalist—of the decline of industry, *e.g.* the textile trade. The schools, to-day, it should be added, are greatly aided: golf and the motor-car serve to complete their insidious effect upon character.

Our William is nothing if not thorough—he would improve the public school and schoolmaster out of existence but recognises the need and desirability, under our present social condition, of schools of the preparatory class, largely staffed by women and not very big, where children up to fifteen could have a quasi-family life. (*N.B.*—The public school gone, these would be rid of the curse of the ' Common Entrance ' examination.) From fifteen onwards, the more directly a boy lives in contact with the real world, the better alike for the real world and himself. The reality of education for every one over fourteen, in a modern state, lies more and more outside any class-room; the fewer the school-made values a boy has, the juster will be his apprehension of reality. The new system will be one of special schools, studios and laboratories for arts, sciences, language and every sort of technical work. The style of work will be new.

All this is essentially sane. I saw the danger in early days and went so far as to express my opinion by saying, that I would not send my sons to a public school to save their lives and kept my word but was lucky in having at my door what was long, probably, the best day-school in London, if not in the country. I have also always held, that seventeen was the *very latest age* up to which a boy should be kept under monastic school conditions. I took my four boys away at that age and sent them to places of higher instruction, *where they were free to become men*. I have every cause to be satisfied: they may not be saints but neither are they serious sinners and the kick has not all been taken out of them.

The *Times*, on October 13, contained a most feeling obituary notice of Dr. E. A. Abbott, long well known as headmaster of the City of London School and a noted scholar. He is brought into comparison with F. W. Walker, the famous headmaster of St. Paul's School. We are told that Abbott, who relished Walker's half-cynical frankness of speech, used to relate how the latter showed him over his grand new school buildings at Hammersmith and how, when he (Abbott) expressed his admiration of everything and especially of the magnificent chemical laboratories, Walker replied: " Yes, they are all very well in their way; but, as we two are alone here, I may venture to say (lowering his voice to a confidential whisper) that you and I know that this sort of thing *is not education*."

Surely such an episode is disgraceful to both men. If ' this sort of thing ' were not education, why introduce it? If introduced, surely it was the headmaster's duty to see it made education. That two such men were able to scoff at a discipline that furnishes the key to

the comprehension of life is but proof of the hopeless narrowness and impenetrability of the classical and literary mind. Their attitude is that of most if not all our headmasters. 'Science,' we know, is a failure in schools—are the headmasters doing anything to improve the teaching, knowing as they must that to-day its dictates dominate the world?

Our William has something to say about science specifically but first let it be noted, that he extends his scepticism about schools to universities, particularly to "the universities for juveniles like Oxford, Cambridge, Harvard and Yale." We are all alive to the fact, that these are continuation boarding-schools, not free institutions as are the German universities. He is justified in his indictment, that there is a growing discontent with Oxford and Cambridge among those who have undergraduate sons—"sending their boys trustfully and hopefully to these over-rated centres, they find themselves confronted with pleasant, easy-going evasive young men up to nothing in particular and schooled out of faith, passion or ambition." I have said already, our William is an incomparable draughtsman. We must be prepared, he considers, to cut out this three or four-year holiday at Oxford or Cambridge and their American compeers from the lives of the young men we hope to see playing leading parts in the affairs of the world. So do I. We shall not get through with youths that are born tired, without method in their minds, such as we have to-day, who lapse into 'research' but make it an armchair occupation and put neither heart nor guts into the work.

To pass to specific science, our William's presentation of the Royal Society is of a piece with his appreciation of the universities. Perhaps it is worth while occasionally to see ourselves as others see us. He reports a meeting with his brother Dickon, at which the brother fingers his first paper in the *Phil. Trans.* The comments he makes are amusing and delightful parody.

"'Blastopore of the snail,' he objected. 'Fancy poking about at the blastopore of the snail! It's—indelicate. And cryo-hydrates! This chap Oliver Lodge seems to be all over them. Wonder what they are. Well, this is your affair, Billy. It's up to you to display the name of Clissold properly in these Philosophical Transactions. If that is the end of life. Not my pitch. Not in the least my pitch. I wouldn't try to see even a stethoscope through these Philosophical Transactions. No.'"

This is a confirmation, from outside, of the view I have often expressed, that the *Phil. Trans.* spell cremation, the *Proceedings* 'decent burial' of scientific discovery.

The brother, who has made his fortune out of advertising, then suggests giving the "dull old Philosophical Transactions" a real spirited Xmas number, a genuine advertisement display, with which "Temptation of St. Antony" won't be in the same field. The final opinion expressed by Dickon, to meet his brother's objection, that advertising would be vulgar, is again a noteworthy criticism:

"'If there's anything vulgar about modern advertising it's because it's been so concerned about pills and soap and pickles. Just a passing phase. A man or a class or a religion or—anything that will not advertise isn't fit to exist in the world. It means it doesn't really believe in itself. To want to exist and not to dare to exist is something beneath vulgarity. . . . That's why I have such a contempt for your rotten, shy, sit-in-the-corner-and-ask-the-dear-Prince-of-Wales-to-dinner-once-a-year-Royal Society. If the soap-boilers did no more for soap than your old Royal Society does for science,' said Dickon, 'nobody would wash.'"

Formerly, the opinion of the Society was often consulted in matters of importance to the State; now, the Department of Scientific and Industrial Research is more and more usurping this office. The individual original scientific worker, like the naturalist, may easily soon be ruled out of existence and an unimaginative being put in his place. We confine our activity to publishing work which is either largely premature and unfinished or even better left unpublished. Few attend the meetings and, at these, soft nothings are said and no one dare criticise. "We work submerged, we talk by no more than twos and threes," says our mentor. This is the way of the Society. It cannot be brought, it makes no attempt, to realise, how essential it is to organise the forces of science into a living body—what it could do if it formed itself into a great consultative scientific House of Peers. The only office it effectively serves is that of back-patting and bemedalling the supposed élite of the craft.

As our William truly remarks, "No great creative development can go on in modern social life beyond a certain point without a literature of explanation and criticism." We have no such literature: the result is that work is done and little use made of it. We keep no more than a casual profit-and-loss account and never seek systematically to balance our books. Our knowledge is never properly sifted and sorted and its values determined—no logical order is observed in filling in the blanks.

May it not be true that few would wash, if no more were done for soap than we do collectively for science? Is it policy to go on producing, paying insufficient attention to quality and demand, without taking proper steps to popularise and sell? Industry, to-day, we know is largely engaged in producing and forcing the sale of unnecessary goods: this is the manufacturers'

conspiracy. If we are not coming very near to producing goods and leaving them to rot, we are doing little to secure digestion of the food we provide. We finish nothing. To take an example. Cane sugar is now made, all but pure, in millions of tons and yet chemists cannot tell the manufacturer what it is—how its atomic bricks are built together. Children are put to such work, not experts: to-day, these are engaged in the study of poison gases.

Research work is fast being made an entirely selfish, narrow occupation, when not carried out for industrial purposes. A bureaucratic class of academic workers is fast growing up, fit for little more than drawing-room service, without practical outlook. We need a few Fords to introduce efficiency into the research machine —Mr. Ford is said to have a greater annual turnover of work-people than any other employer, which means that he takes the efficiency of the worker into account: our up-growing civil service, research system does not: the threatened result is that 'research' will become a merely parasitic occupation. The term will disappear from the field of practice.

We work submerged, says our William. We hand on our impressions and vague intentions only by the most fragmentary hints. In education nothing is done to record, preserve and utilise successful trials of method. Sanderson left no record of method behind him and to-day, apart from his buildings, Oundle has nothing to show of his influence—it has reverted to the primitive school type. His Home of Vision has no vision in it. One teacher succeeds another without ever considering his predecessor's methods. The Finsbury Technical College was proclaimed a success but its methods are on the dust heap.

Before attempting to form a world directorate, we need to run our own little shanty: to take notice of one another and be sympathetic and work together to make it really habitable for all. Not only leaders are needed but the apparatus also is not there. It is all very well to repeat Carlyle's saying, that the modern university is an university of books the books are not there. Even in leisure hours, you cannot live on the dull-as-ditch-water-doings of a no-sight family, with or without spoons. Writers of the day have no knowledge within them to use, thanks to their schooling. Here is our William's future opportunity: he is only fifty-nine and has time to turn over many new leaves. Let him write up to his professions, to show, if possible, how the new and necessary knowledge may be brought home to youth and made of some general avail. He has recognised his and our limitations, in his preface, in a single line, which is probably the most significant in the book, in saying of men of the type of "the devout Mr. Belloc, the aristocratic Duke of Northumberland, the political Mr. Ramsay MacDonald," that he can only comment upon such types. *Their ultimate processes are inconceivable to him.*

We are all cryptic beings and no one of us is open to the complete inspection of his fellow-man. We differ vastly in mentality. This is why Oxford is obdurate and will teach nothing that is needed by the world to-day. The word-slingers it trains throw from empty slings—at times perhaps a few very beautiful stones from the past but not the bullets of to-day. By a strange process, by securing control of the schools by men of its own type, it has made itself a community of one type of mentality, with but few escapes from its rigidity: the mechanism for the appreciation of modern things is not built into the type. We shall never improve our system of education and make it fit the needs of the times until we take into account, in the most liberal manner possible, the strange variability of the human mind. Society being composed of all sorts and conditions of men, to provide for all will always be very difficult, the less, however, the more we are alive to the differences and not too immodest in our individual opinions.

HENRY E. ARMSTRONG.

Our Bookshelf

A Practical Treatise on Outbreaks of Fire. By Sidney Gompertz Gamble. Pp. xii + 543. (London: Charles Griffin and Co., Ltd., 1926.) 30s. net.

THE author of this book held for twenty-six years the position of second in command of the London Fire Brigade, and prior to this had the experience of seventeen years as borough surveyor and chief officer of the fire brigade in a provincial town. The knowledge thus obtained and embodied in his book causes it to appeal strongly to members of fire brigades and to all concerned in minimising fire risks. The volume is divided into five parts dealing respectively with (1) natural science, legal and general matters; (2) fires and their causes, together with insurance; (3) means of suppression, material and personnel; (4) fire prevention and construction of buildings from the fireman's point of view; (5) miscellaneous matters. Besides providing a great deal of information with which the fireman in service ought to be acquainted, presented in a form which he can appreciate and use, the book contains much that is of interest to the layman. The section dealing with the causes of fires makes very interesting reading, and many of the various cases are illustrated by photographs; this section also deals in detail with dangerous trades, and discusses the precautions which should be observed in them. Another section contains much that will be of value to the officer whose duty it is to report on suspected cases of arson and incendiarism. Fully illustrated details of automatic and other systems of fire notification are included as well as sprinkler systems.

A feature of the book which assists in rendering it very readable is the historical notes freely scattered among the pages. The illustrations of fire appliances

from the earliest times down to those in present use are extremely good, and the historical account of the progress of the fire-engine is especially interesting. The principles on which modern pumps work are explained adequately, and multiple centrifugal pumps are included. Fire prevention and panic in places of public resort is a wide subject which concerns the whole community, and the author devotes a great deal of space to it. Such buildings are classified, and each type is treated separately. Remembering the wide experience which Mr. Gamble has had in London, his opinions must be taken as authoritative, and will be invaluable to surveyors under public bodies. We have nothing but praise for this book, and consider that the author has rendered service, not only to the members of his own profession, but also to the public, in presenting so much that is of value in such an acceptable form.

Ergebnisse der exakten Naturwissenschaften. Herausgegeben von der Schriftleitung der *Naturwissenschaften.* Fünfter Band. Pp. iii+329. (Berlin: Julius Springer, 1926.) 21 gold marks.

THIS collection of articles by leading continental men of science possesses a great amount of interest for students of physical science, both pure and applied. Thus, we have an article on planetary radiation by Prof. Schoenberg, which is followed by a comprehensive treatment of the measurement of photographs by Dr. Seliger, and by an article on dynamic meteorology by Prof. Wegener. Prof. Bjerrum gives a very interesting account of the electric forces between ions and their effects, and Prof. Pringsheim gives an account of work on the photo-electric effect in gases, in which he describes the recent work of Foote, Mohler, and Auger. The article on atomic disintegration, by Dr. Kirsch, gives a survey of the experimental results obtained in Cambridge and Vienna, and the author attempts to interpret these results in terms of the explosion theory advanced by Pettersson. The experimental proof of the statistical nature of the law of radioactive decay is treated in a further section, by Prof. Kohlrausch, who pays particular attention to the work of Frl. Bormann, which provides, in his opinion, the first conclusive experimental proof of the correctness of the fundamental assumption on which the law is based. The absorption of gases under the influence of electrical discharge and allied phenomena are considered in full in an article by Dr. Pietsch, to which are appended several pages of references. Finally, we have an excellent and up-to-date account of the Compton effect by Drs. Kallmann and Mark.

Edward Thring, Maker of Uppingham School, Headmaster 1853 to 1887. By W. F. Rawnsley. Pp. iv+103. (London: Kegan Paul and Co., Ltd., 1926.) 3*s.* 6*d.* net.

EDWARD THRING and Sanderson will rank as the two English headmasters of the last generation who left most personal mark upon their scholars and built up great schools on the foundations of small, ancient, and neglected grammar schools. Such reconstruction was a familiar feature of the last half-century, but Uppingham and Oundle will always recall the names of their re-founders. Thring's work was in one way more heroic than Sanderson's, because he did it in the teeth of an obstructive and unsympathetic body of governors, while Sanderson was supported by the generous and loyal help of his.

In this short account of Thring's career, Mr. Rawnsley gives a vivid picture of the man and explains his extraordinary personal influence. Thring had in a high degree that combination of humour, sharpness, sympathy, and devotion which makes the strongest appeal to the English boy. Numerous examples are given of all these and of his cardinal principle in education that every boy is good for something and that you must make him work by appealing to his individual interests. Thring's own interests lay mainly in music and literature, and one does not hear anything of science or history. In this respect he and Sanderson would seem to have been rather complementary to one another. Both stand out as worthy types of the individuality of the great headmaster.

F. S. M.

A Text-Book of Experimental Psychology: with Laboratory Exercises. By Dr. Charles S. Myers and F. C. Bartlett. Third edition. Part 2: Laboratory Exercises. Pp. viii + 121. (Cambridge: At the University Press, 1925.) 7*s.* net.

IT is satisfactory to note that this excellent text-book is now in its third edition. The student who has carefully worked through these exercises will have gained considerable practice in the very difficult art of psychological experiment. There is a fairly common belief that psychology can be evolved from the writers' inner consciousness without the limiting effects of an appeal to facts demanded by other branches of knowledge. Much futile discussion and many fantastic theories would be avoided if all exponents of psychology could have the discipline of working through this book.

There are four sections, designed to cover about a year. The first part deals with the technique of psychological experiment, the second with problems of the special senses, the third with perception and the higher thought processes, while the fourth is supplementary, giving additional experiments.

This revised reprint will be very useful.

Die Gattung Synedra in systematischer, zytologischer und ökologischer Beziehung. Von Dr. Konrad Gemeinhardt. (Pflanzenforschung, Heft 6.) Pp. iv+88+4 Tafeln. (Jena: Gustav Fischer, 1926.) 6 gold marks.

THIS monographic treatment of the abundant diatom genus Synedra will appeal chiefly to the specialist, but is not without points of general interest. The author supports a classification based on the features of the valves rather than on the characters of the chromatophores and throws out a suggestion that nuclear structure may afford a basis for distinguishing the larger groups of diatoms. No proper spindle is formed during nuclear division in Synedra, and a centrosome is lacking. In the considerable section devoted to ecological data it is made clear that all species of Synedra require water with a certain minimum lime-content. It is significant that, in the course of more than a year's continuous observation, no auxospore-formation was observed.

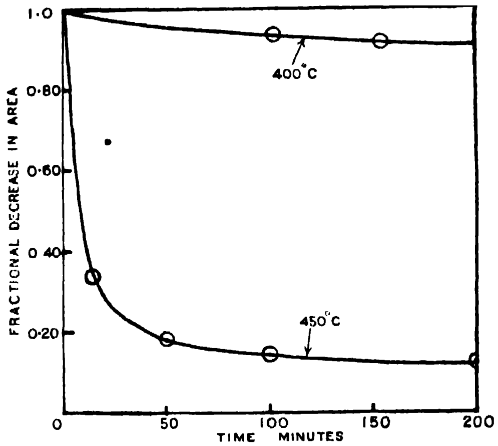
The Structure of Catalytically Active Copper.

THE nature of the change that occurs on the activation of a metallic catalyst by alternate oxidation and reduction, or by continued use, and the change that occurs during sintering, has been an open question (cf. *Proc. Roy. Soc.*, A, vol. 107, p. 277; vol. 110, p. 283). The solution of this problem



definitely would go far towards establishing the theory of centres of activity on an indisputable foundation, since it is necessary to show that both the area and the nature of the surface change (cf. the discussion by Hinshelwood, "Kinetics of Chemical Change in Gaseous Systems," Clarendon Press, p. 194).

Now the observations of Dunn (*Proc. Roy. Soc.*, A, vol. 111, p. 210) on the use of interference colours, in following quantitatively the growth of the oxide film on copper, give a method of estimating the linear rate of growth of the oxide covering the individual grain compared with that on 'inactive copper.' Palmer (*Proc. Roy. Soc.*, A, vol. 103, p. 444) showed that the conductivity of a mixed copper–copper oxide film was directly proportional to the copper content of the supported film, thus the rate of fall of the conductivity of the film is a measure of the mass of copper being oxidised in unit time, and a method is available for estimating the massive rate of growth of the oxide compared with that on 'inactive copper.'

Let a be the thickness of the oxide film, S represent the area of surface, and C be the electrical conductivity of the mixture of oxide and metal. Let the suffix 1 denote the values of these quantities for an activated or sintered catalyst, at time t after the commencement of the oxidation at constant temperature; and the suffix 2 represent the same variables either for the film before activation, or for the fully activated film before annealing.

Then

$$\frac{\left(\frac{da}{dt}\right)_1 \cdot S_1}{\left(\frac{da}{dt}\right)_2 \cdot S_2} = \frac{\left(\frac{dC}{dt}\right)_1}{\left(\frac{dC}{dt}\right)_2}. \qquad (1)$$

Thus S_1/S_2 can be evaluated, and we have a method of measuring the increase of area on activation, and the decrease of area on sintering.

The observations for the activation of a catalyst present experimental difficulties, owing to the irregular nature of the first reduction and oxidation in many cases; but they are of great theoretical interest and, so far, seem to indicate that the increase in area of the supported copper films on successive reduction is not large. The nature of the surface alters considerably, since the linear rate of oxidation increases markedly.

In the case of sintering, the observations can be made with accuracy; the nature of the surface is changed since the linear rate of oxidation falls, and the increase in surface area is marked. Continued exposure to high temperature does not cause the area to diminish indefinitely, but a definite limit is reached corresponding to each temperature. The effect of annealing a supported copper film at 450° C. and 400° C. is shown in the accompanying diagram (Fig. 1), the results being worked out by the method previously described.

The relative rate of increase of thickness of the oxide film slows down very considerably, as the time of sintering is increased. Dunn's conclusions (*loc. cit.*) that "the structure of a metal may be brought out owing to the variation of the oxidation rate of different crystal faces," and that "For a definite time of oxidation each crystal face will be characterised by a different colour," seem to provide indisputable evidence that, as well as the area change that occurs during activation and sintering, there is also an unmistakable change in the nature of the surface.

Magnetic Properties of Single Crystals of Nickel.

THE magnetic properties of single crystals of iron have been examined by Webster (*Proc. Roy. Soc.*, **107**, p. 497, and **109**, p. 570), Honda, Kaya, and Masuyama (NATURE, May 29, 1926), and more recently Gerlach (*Zeit. für. Phys.*, **38**, p. 828, 1926). Considerable differences have been shown to exist between the

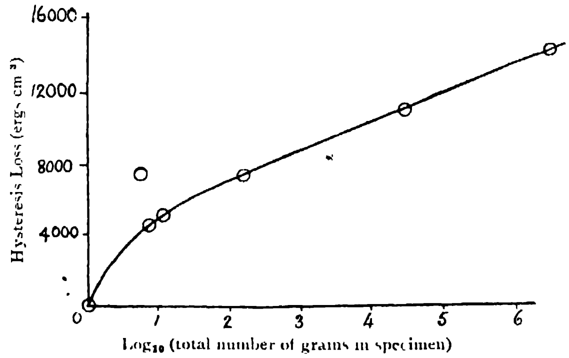

FIG. 1

magnetic properties of the polycrystalline metal and the single crystal.

We have recently succeeded in preparing crystals of nickel of several cubic centimetres in volume, from which specimens large enough for magnetic measurements can be obtained. The present note contains an account of a preliminary investigation on the variation of hysteresis loss with grain size. The specimens used were cylindrical rods of 20 mm. by 2 mm. diameter. The hysteresis loss, as in the case

of iron, decreases with the number of grains in the specimen, as shown in the accompanying graph (Fig. 1) and table.

Number of Grains in Specimen.	Hysteresis Loss (ergs/cm.^{3}).	Coercive Force (Gauss).
$2\cdot8 \times 10^6$	14,600	13
$2\cdot7 \times 10^4$	11,100	10
$6\cdot4 \times 10^2$	7,300	5
12	5,150	4·3
8	4,500	3·7
1	< 290	< ·5
7	7,600	5

The hysteresis loss for a single-crystal specimen was less than the experimental error, and was certainly less than 1/50 of that for ordinary nickel. The point off the curve was obtained with a specimen containing seven grains. In this particular case the etch pattern indicated that the grains were considerably distorted. For the specimens containing eight and twelve crystals respectively, the demagnetising factor was appreciably greater than for the other poly- and single-crystal rods of the same dimensions. In these two cases it is significant that most of the crystals occupied the whole cross-section of the rods. Gerlach's experimental results for iron indicate the presence of similar phenomena in that metal.

The intensity of magnetisation of the single crystal specimen in an effective field of 300 gauss was 565 units. Saturation was not complete in this field.

Further experiments on the magnetisation and magnetostriction along the different crystalline axes are in progress.

Invention as a Remedy for Unemployment.

THE very interesting analysis of the relationship of present patent law and patent procedure to invention and to the unemployment problem, which appeared in NATURE of September 18, should serve to stimulate clear and earnest thinking on a subject of great national importance.

A storm of indignant protest is always aroused if any one has the temerity to suggest that Great Britain is falling behind in the application of science to industry, or in the practical application to useful ends of newly discovered scientific truths. I am, nevertheless, of the opinion that, except perhaps in the allied fields of steam and marine engineering, it would be difficult indeed to prove that some such declension from our former pre-eminence has not taken place. It would be a wearisome task, and certainly provocative of controversy, to recite the evidence in support of this view, but an unprejudiced observer who considers, for example, the course of invention during recent years in such fields of useful activity as incandescent gas-lighting, electric traction, alternating-current engineering, or in the design of type-writing, addressing, and calculating machinery, will find it difficult to resist the conclusion suggested above.

That this failure to lead in the realm of commercial invention is not due to any diminution in the mental energy or native ingenuity of the race is abundantly evident from the splendid achievements of British scientific workers during the first quarter of the twentieth century.

It is probably true that since the death of Faraday the international reputation of British science has never stood higher than it does to-day.

I would in particular direct attention to the astonishing experimental skill and inventive ingenuity which have distinguished the work of our physicists. Without citing any names or making any detailed and, possibly, invidious comparisons, it may safely be claimed that in this respect no other nation has surpassed—if any have equalled—the freshness and power of attack exhibited by British workers.

Even in the realm of organic chemistry, in fields formerly almost abandoned to foreign labourers, the achievements of British investigators and inventors during the last eight or nine years constitute a truly wonderful record of steady progress in one of the most difficult of applied sciences. The same story of rapid and successful attack can be told in connexion with the manufacture in Great Britain of optical and heat-resisting glasses.

In all this there is abundant room for encouragement; for it makes clear the fact that where we are failing to lead in applied invention and applied scientific method, the failure is not due to lack of inventive ability.

It suggests that in countless instances invention is inhibited and inventors discouraged by the fact, still lamentably true, that the average Englishman possessing money—the man to whom new ideas are brought for development—is hopelessly at sea in respect of general scientific knowledge and general manufacturing processes. More often than not he is a gentleman, a man anxious to act fairly towards his fellows, and a man not unenterprising—quite willing, in fact, to risk money wherever he believes there is a reasonable chance of winning more—but the words the inventor uses and the drawings he exhibits are expressions in an unknown tongue.

The man of money remembers more of the Greek and Latin he laboriously learned at school than of the fragments of mechanics or chemistry he imbibed under the head of 'Science.' He turns the inventor down because he does not understand.

This inability does not prevail to anything like the same extent in the United States of America or in Germany. Generally speaking, in those countries the man who commands money knows at least enough of mechanics, or physics—knows enough about *things* as distinguished from *words*—to take a very intelligent interest in what an inventor has to say.

That makes all the difference.

A classical education may be the best possible preparation for any calling that succeeds it—I happen to think this is so—but the price Great Britain has paid, and is paying now, for the past almost total neglect of science in our public schools is incredibly big.

Until science, and 'knowledge of things,' take their proper place in our great schools, invention will continue to languish and inventors to cross the Atlantic.

Reform of the patent laws may certainly help the cause of invention, but alone it will not do nearly enough.

I would warmly advocate a more thorough and a wider official search, as in Germany and in the United States. I would also advocate the establishment of a British petty patent similar to the German *Gebrauchsmuster*, so as to eliminate the absurdity of giving the same kind of protection to a man who 'invents' a method of making some simple object

out of sheet-metal instead of casting it, as to the inventor of the steam turbine.

The issue of such patents as are suggested above is one of the least creditable branches of the Patent Office's activity during recent years.

The encouragement of real inventiveness will unquestionably diminish unemployment. Even in the case of 'process' and 'cheapening' patents, any temporary increase of unemployment thus created is more than balanced by increased production, and the consequent absorption of more and more men into employment. Generally speaking, the world is always hungry for goods, if the goods are useful and the price is right.

A Breeding Ground of the Nursehound (*Scyliorhinus stellaris*) in the Fal Estuary.

DURING recent years I have had considerable experience on the oyster-beds and adjacent grounds in the Fal Estuary, and as a result of observations made at various times I consider that the greater part of the Laminarian zone in that estuary forms an extensive and regular breeding ground for the nursehound (*Scyliorhinus stellaris* = *Scyllium catulus*). In the autumn of 1924 a few egg-cases containing embryos of this shark-like fish were dredged on Laminaria on the Falmouth North Bank, Carclase, and on other grounds in ½ to 1½ fathoms. (A chart of the grounds of this region is given in my report on a "Survey of the Fal Oyster Beds," 1926.) During the summer of 1926, egg-cases have been frequently taken on Laminaria at Turnaware Bar—which is situated about 1½ miles farther up the estuary than the grounds just mentioned—and young ones recently escaped from the egg-case have been seen at low water on this ground on several different occasions. Young nursehounds have also not infrequently been taken in oyster-dredges in autumn.

During the recent spring tides, the Laminarian zone at Brown Rose Bar—about 1 mile below Turnaware—was being examined for oysters, and, in an area of not more than 20 square yards, 8 egg-cases of the nursehound containing eggs or embryos, as well as a few empty purses, were found; probably others were on the ground and not seen. Two of these egg-cases had been laid within the last few days, and had the thong-like horny extensions of the corners of the case wrapped round the whole of the anastomosing roots of a bunch of old Laminaria stipes. In one instance the new egg-case had been attached to a group of stipes which also carried older egg-cases at a higher level. Four of the egg-cases contained embryos respectively about 12·5 cm. and 10 cm. long, both with internal gills, and two about 6·0 mm. long. It is interesting to note that Ford (*Jour. Mar. Biol. Assoc.*, vol. 12, p. 492, 1921) estimated that embryos would begin to have the gills covered at a length of about 10·0 cm. Thus the collection of egg-cases contained eggs or embryos of four different ages, and therefore of four different spawnings.

While examining one egg-purse in its natural position under water, two *Nassa reticulata*, sometimes called dog-whelks, were observed with their probosces inserted in a natural crack in the case, where the base of one corner thong arises from the body of the case. After observing the Nassæ for a few minutes, each was pulled off separately and at least half an inch of pink proboscis pulled out of the case. On opening the case, however, to see what damage had been done, there was found no trace of either yolk or embryo and only a remnant of albumen. As the purse was fixed in an upright position in the water, and the Nassæ were at the lower end, it was possible—but not probable—that they might have eaten the large amount of yolk generally found in the eggs, but on examining the other egg-cases, one similar in age to that attacked by the whelks was opened and also found to contain nothing but albumen, although the egg-case was intact and full of albumen.

It is clear, therefore, in this latter instance, that the nursehound had made an egg-case and had omitted—perhaps forgotten—to put an egg in it. The contents of both these purses were healthy in so far as they had no noxious smell. It is not improbable that Nassæ and similar forms may normally attack the embryos of the nursehound and its allies at the vulnerable natural slits in the egg-case (described by R. S. Clark, *Jour. M.B.A.*, vol. 12, p. 584, 1922).

It is well known that the nursehound breeds regularly in the gullies at Wembury Bay West, inside the Mewstone, near Plymouth, but there the egg-cases are usually attached to the strong, stockily growing sea-weed Cystoseira. It would seem, therefore, that so long as the nursehound can lay its egg-cases in fairly shallow water—on the south coast of England—the fish may use either Laminaria or Cystoseira and probably any other weed so long as it be strong and permanent enough. It is necessary that the weed used for attachment should remain *in situ* for nine months to a year, and perhaps longer, to enable the embryo to develop fully; and presumably the spawning fishes know that both Cystoseira and Laminaria are both strong enough and permanent enough even in a situation near low-water mark to serve their purpose; Cystoseira, from observation, grows certainly for more than one year, and is so firmly rooted that it is either difficult or impossible for a man to pull the weed off the rock. *Laminaria saccharina*, the species used by the nursehound, may shed its frond at the end of one summer's growth, but the stipes to which the egg-case is attached remains *in situ* and strong for a much longer period. The problem of how the nursehound found out that Laminaria and Cystoseira would suit its purpose is only one more of the millions of evolutionary problems awaiting explanation.

Application of the Drop Weight Method to the Determination of the Surface Tension of Colloidal Solutions.

IN connexion with some work by Henry N. Harkins and myself on the surface tension of certain colloidal solutions, it seemed essential to hold the drop used for the determination at almost full extension any desired length of time before it was allowed to fall. As usual, the drop was allowed to fall from a tip of horizontal circular cross-section into a stoppered weighing bottle (method of J. L. R. Morgan). The weighing bottle was immersed in a thermostat, and was kept dry on the outside by an enclosure of glass and brass, such as was used by Harkins and Brown. This is shown diagrammatically in Fig. 1. The new modification consisted in supporting the supply bottle entirely by the rod A, which was supported in turn by a microscope stand upheld by a heavy tripod which rested on a pier outside the thermostat. The rod was made so small that there was no contact with the inside of the tube C′. There should also be no contact between the stopper of the bottle E and the inverted capillary U tube upon which the tip D is

ground, since the adjustment of the level of the bottle E must transmit no vibrations to the hanging drop.

The form of the drop which hangs from the tip D depends both upon R/a and R/h. Here R is the radius of the tip, a is the square root of the capillary constant, and h may be designated as the 'pressure-height,' which is the difference in height between the bottom of the drop and the level the liquid in the bottle E would have provided the area of its meniscus were infinite.

The method was applied to pure liquids by Dr. Paul Gross, and it was found that the accuracy of the drop weight method is thereby increased considerably, so that the precision of the new method is to within a few hundredths of one per cent. To apply the method the cross-hair of the telescope of a cathetometer is adjusted by trial with the hanging drop, so that its level corresponds to the lowest level at which the bottom of the drop may be held without falling. To attain this level the height of the meniscus in E is adjusted by trial to the proper height by the use of the coarse and fine adjustments of the microscope stand. If the proper technique is used, the drop may be held at practically full extension for as many hours as may be desired. A study of the relation between the pressure-height and the stability of the hanging drop was carried out by Dr. Gross, and the results will be presented in a later more complete discussion of the improvements in the drop-weight method. The modifications introduced do not of necessity lengthen the time necessary for a determination of surface tension, since the greater certainty with which the proper conditions may be attained makes it possible to reduce the number of drops used, and in much work on colloidal solutions only one drop needs to be allowed to fall in the final determination.

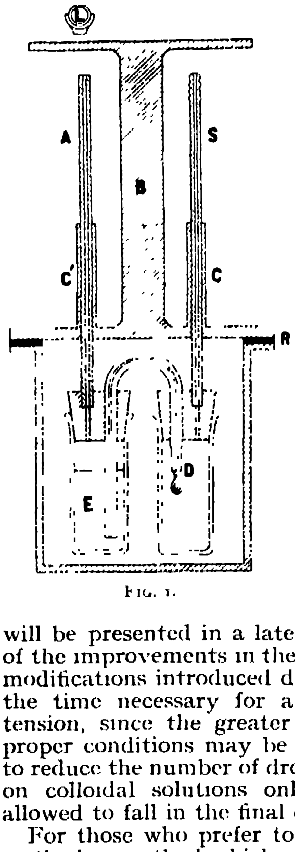

FIG. 1.

For those who prefer to use the less accurate ring method, a method which as commonly used has been in error by so much as ten per cent. or more, it may be mentioned that Dr. T. F. Young, Y. C. Cheng, and the present writer have recently determined experimentally the corrections for this method. The use of these corrections reduces the error to one per cent., and it is hoped that the work now under way will still further reduce this to one-tenth per cent.

Tertiary Man in Asia: the Chou Kou Tien Discovery.[1]

A RICH fossiliferous deposit at Chou Kou Tien, 70 li [about 40 kilometres] to the south-west of Peking, was first discovered in the summer of 1921 by Dr. J. G. Andersson and later surveyed and partially excavated by Dr. O. Zdansky. A preliminary report on the site was published by Dr. Andersson in March 1923 (*Mem. Geol. Surv. China*, Ser. A, No. 5, pp. 83-89), followed in October of that year by a brief description of his survey by Dr. Zdansky (*Bull. Geol. Surv. China*, No. 5, pp. 83-89). The material recovered from the Chou Kou Tien cave deposit has been prepared in Prof. Wiman's laboratory in Upsala and afterwards studied there by Dr. Zdansky. As a result of this research, Dr. Andersson has now announced that in addition to the mammalian groups already known from this site, there have also been identified representatives of the Cheiroptera, one cynopithecid, and finally two specimens of extraordinary interest, namely, one premolar and one molar tooth of a species which cannot otherwise be named than *Homo ? sp.*

Judging from the presence of a true horse and the absence of Hipparion, Dr. Andersson in his preliminary report considered that the Chou Kou Tien fauna was possibly of Upper Pliocene age, an opinion also expressed by Dr. Zdansky. It is possible, however, in the light of recent research, that the horizon represented by this site may be of Lower Pleistocene age. Whether it be of late Tertiary or of early Quaternary age, the outstanding fact remains that, for the first time on the Asiatic continent north of the Himalayas, archaic hominid fossil material has been recovered, accompanied by complete and certain geological data. The actual presence of early man in eastern Asia is therefore now no longer a matter of conjecture.

While a complete description of these very important specimens may shortly be expected in *Palæontologia Sinica*, the following brief notes may be of interest here. One of the teeth recovered is a right upper molar, probably the third, the relatively unworn crown of which presents characters appearing from the photographs to be essentially human. The posterior moiety of the crown is narrow and the roots appear to be fused. The other tooth is probably a lower anterior premolar, of which the crown only is preserved. The latter also is practically unworn, and appears in the photograph to be essentially bicuspid in character, a condition usually to be correlated with a reduction of the upper canine.

The Chou Kou Tien molar tooth, though unworn, would seem to resemble in general features the specimen purchased by Haberer in a Peking native drug shop and afterwards described in 1903 by Schlosser. The latter tooth was a left upper third molar having a very much worn crown, extensively fused lateral roots, and from the nature of its fossilisation considered by Schlosser to be in all probability Tertiary in age. It was provisionally designated as *Homo ? Anthropoide ?* It is of more than passing interest to recall that Schlosser, in concluding his description of the tooth, pointed out that future investigators might expect to find in China a new fossil anthropoid, Tertiary man or ancient Pleistocene man. The Chou Kou Tien discovery thus constitutes a striking confirmation of that prediction.

It is now evident that at the close of Tertiary or the beginning of Quaternary time man or a very closely related anthropoid actually did exist in eastern Asia. This knowledge is of fundamental importance in the field of prehistoric anthropology; for about this time also there lived in Java, Pithecanthropus; at Piltdown, Eoanthropus; and, but very shortly after, at Mauer, the man of Heidelberg. All these forms were thus practically contemporaneous with one another and occupied regions equally far removed respectively to the east, to the south-east, and to the west from the central Asiatic plateau which, it has

[1] Announcement of the Chou Kou Tien discovery was first made by Dr. J. G. Andersson on the occasion of a joint scientific meeting of the Geological Society of China, the Peking Natural History Society and the Peking Union Medical College held in Peking on October 22, 1926, in honour of H.R.H. the Crown Prince of Sweden.

been shown elsewhere, most probably coincides with their common dispersal centre. The Chou Kou Tien discovery therefore furnishes one more link in the already strong chain of evidence supporting the hypothesis of the central Asiatic origin of the Hominidæ.

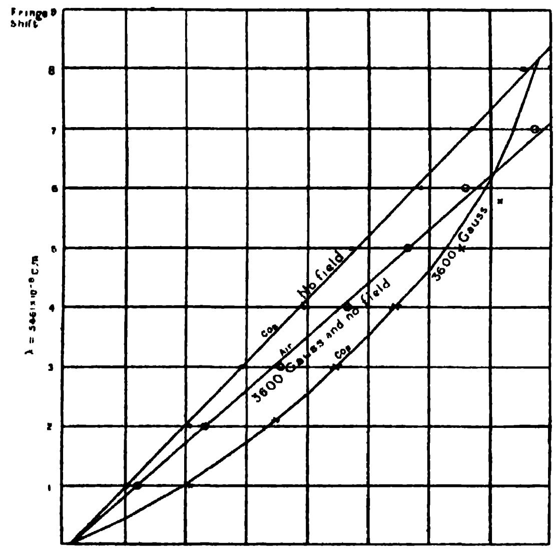
Action of Magnetic Fields on the Refractive Index of Carbon Dioxide Gas.

A. GLASER (*Ann d Physik*, 75.4, pages 459-488, and *Ann. d. Physik*, 78 4, 641-658), in determining the susceptibility of diamagnetic gases, noticed that, under a definite magnetic field, the susceptibility decreases as the pressure of the gas is decreased, approximately proportional to the pressure. For a certain pressure range, however, there is a deviation from the above law, and the law of variation, instead of being linear, follows approximately a parabolic law, and above and below this range the linear law has different characteristics.

Working to detect any relationship between the refractive index and pressure, Fraser (*Phil. Mag.*, April 1926, pp. 885-890), using the Jamin refractometer, failed to notice any change in the refractive index when the gas is subjected to a sudden magnetic field of about 184 gauss within a pressure range of 0·001 to 8 mm.

The present authors have noticed a decided change in the refractive index of pure dry carbon dioxide gas,



when subjected to a constant magnetic field of 3600 gauss, acting transversely to the direction of propagation of light and the pressure gradually increasing from 10 mm. to 400 mm. A Michelson type of interferometer was used for the purpose, and all parts were carefully selected to be non-magnetic. The graph (Fig. 1) shows the relation between the shift of fringes and the pressure variation within the range 10 mm. to 400 mm. for air and carbon dioxide. In the case of air, the magnetic field has no influence whatever on the refractive index, whereas with carbon dioxide the fringe shift nearly follows a parabolic path in the same region of pressure, as has been noted by Glaser. This shows a decided orientation of the molecules under the magnetic field, at least in the case of a dipolar gas of the type of carbon dioxide.

Experiments are in progress to determine the change with different temperatures and other dipolar gases.

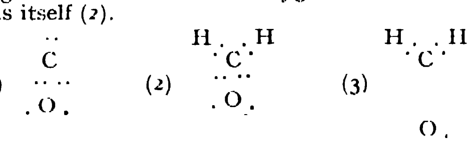
Electron Displacement *versus* Alternate Polarity in Aliphatic Compounds.

ADHERENTS of the theory of induced alternate polarity in carbon compounds consider in their deductions also the general electron displacement effect of Lewis's theory; some partisans of the latter theory, however, question the reality of the alternate effect, especially so far as open-chain compounds are concerned. (Cf. H. F. Lucas and co-workers, *J. Am. Chem. Soc.*, 46, 2475 (1924); 47, 1462 (1925).)

It seems to me that recent results of V. Henri and Sv. A. Schoú [*C. R. Acad. Sci. Paris*, 182, 1612 (1926)] afford strong evidence in favour of the alternate effect. Making use of spectroscopic data, these authors succeeded in determining the distances between the atoms in some simple organic molecule, in the gaseous state. They find for the distance between the carbon and oxygen atoms in carbon monoxide 1·02 Å.U., whereas the same distance in formaldehyde is found to be 0·9 Å.U. It is just such a *decrease* of the distance carbon to oxygen by the presence of the two hydrogen atoms, that would be expected on the basis of the alternate polarity theory.

Indeed, let us suppose for the sake of comparison that in carbon monoxide the four binding electrons are lying at equal distances from the nuclei of the two atoms (1). In formaldehyde, then, according to the alternate effect and considering the positivity of the hydrogen atoms, the carbon atom must become less positive, *i.e.* it attracts the electrons of its octet, and together with them the oxygen nucleus, nearer towards itself (2).



(1) (2) (3)

On the contrary, the general Lewis effect would require a displacement of the binding electrons towards the oxygen nucleus, and thus an *increase* of the distance between carbon and oxygen (3).

In phosgene, $COCl_2$, the reverse effects would be expected according to both theories on account of the negative chlorine atoms; the data for distances are, however, not yet available in this case.

If one assumes a triple bond in carbon monoxide (cf. Lewis, "Valence," 1923, p. 127), the above conclusions become doubtful, since it is not known how interatomic distances are influenced by the transition of bonds; only a direct comparison of the distances in formaldehyde and phosgene could afford conclusive evidence then.

Science and Psychical Research.

MY departure for New Zealand having been delayed for a month, perhaps I may be allowed a short reply to Sir Bryan Donkin's remarks in NATURE of Nov. 6. Sir Bryan and myself have come much closer in our views, apparently, but he still misunderstands some of the main points both in my original article and following letter. The term ' supernormal phenomena ' certainly includes both ' physical ' and ' mental ' phenomena of the type under discussion ; on that we are agreed. But Sir Bryan goes on : " In the mental part, however, are included practically all the various ' phenomena ' known generally under the term ' spiritualistic,' " or, later in his letter, ' ghostly.' It is here that I disagree. The genuine psychical researcher does not allow that these may be termed either, since both words connote a hypothetical explanation of the phenomena which we hold is not yet proven. Sir Bryan keeps trying to tie me down to an acceptance of the spiritistic hypothesis, whereas the whole of what I have written shows clearly that I am studying the evidence with an absolutely open mind. Another remark of his, " Seeing that the present discussion has been mainly concerned with these [*i.e.* the mental] phenomena," suggests that he cannot really have read carefully what I have written. Throughout, I have emphasised the importance of the *physical* phenomena, not the mental, and it was Sir Bryan himself who, by his narrowing of the field to the mental phenomena, attempted to deprive me of my chief argument.

As regards the subject of *trance*, Sir Bryan and I are alike in not knowing what it is. The only difference in our attitudes, I take it, is that I consider it a phenomenon worthy of scientific study, whereas Sir Bryan does not. I wonder whether Sir Bryan considers the phenomenon of *sleep* to be worthy of scientific study, or whether he would take the stand of the physicists who (mostly, but not all) maintain that the only phenomena which science may properly take account of are those which can be always repeated accurately under given experimental conditions. If I put Sir Bryan to bed and tell him to go to sleep, can he always do so ? Is sleep any the less a fit subject for scientific study because it cannot be produced to order in an experiment ? Trance, if anything, is more amenable to such procedure than is sleep It is therefore undoubtedly a fit subject for scientific study. My complaint is that those who have the necessary knowledge and training refuse to become interested in these things ; they seem to think that the year 1926 marks the culmination of human knowledge in some way, and that there is nothing more to learn about life except on the purely mechanistic side. My whole article was really a protest against this view.

R. J. TILLYARD.

The Athenæum,
Pall Mall, S.W.1.

Active Nitrogen.

FURTHER experiments have tended to confirm the work recently published by Dr. Rideal and myself upon the energy and nature of active nitrogen.

A study of the effect of the admission to the afterglow of a number of gases, elementary, compound, and mixed, shows that in no case so far examined does any chemical action resulting in the formation of definite compounds occur when the critical increment of the gas introduced exceeds *c.* 45,000-50,000 cal./gm. mol.

Experiments upon the action of active nitrogen upon the metals in the form of fine filaments show that catalytic decay takes place at their surfaces and in some cases (*e.g.* copper) is very marked. The efficiencies of the metals in this respect depend upon the stability of their nitrides. Calculations from the data obtained here again show that the energy of active nitrogen is *c.* 45,000 cal./gm. mol.

The decay of the afterglow has been measured by optical methods, and it has been found that the process is in all probability bimolecular with respect to the active nitrogen, but termolecular in reality since the total pressure appears to exert a marked influence, as suspected by Lord Rayleigh.

The line of reasoning adopted by Dr. Ludlam and Mr. Easson is sensibly the same as that of Saha and Sur. It is quite probable that an unstable compound such as N_2I_2 or a quasi-molecule of sorts is first formed when the iodine vapour is admitted to the afterglow, but is then broken up by collision with another molecule of active nitrogen, the energy liberated going to produce the line they mention. The nitrogen halides are notoriously unstable compounds and hence probably highly endothermic.

An alternative explanation is suggested by the presence of the β and γ bands in the spectrum of the afterglow. While the weight of evidence appears to be against their being really part of the true nitrogen afterglow bands, they invariably appear when the gas is purified in the usual manner. Since they extend at least so far as $\lambda 2154$, collisions between molecules of iodine and those of nitrogen or nitric oxide at this level may result in the appearance of the line in question.

This explanation could easily be tested by increasing the intensity of the β and γ bands, by the addition of oxygen, as in the recent experiments of Johnson and Jenkins (*Phil. Mag.* Sept. 1926) ; an increase in the strength of this iodine line should then follow. It is surely not at all legitimate to attempt an evaluation of the energy of active nitrogen from the spectral phenomena to be seen in the presence of such factors of totally unknown magnitude.

Cambridge, October 27.

Liveing's Fire-damp Indicator.

SOME years ago I made frequent use of Mr. Liveing's very ingenious instrument, referred to in NATURE of October 30, p. 626, and I found its indications to be both accurate and excellent. The only drawback to its use in those days was the shaking which accompanied the turning of the handle to produce the glow, as this made accurate observation of the percentage of fire-damp somewhat difficult.

Reflex Regulation of Posture.[1]

By Dr. F. M. R. WALSHE.

TO those interested in the physiology of the nervous system, the history of our knowledge of the neuro-muscular mechanisms underlying posture must form one of the most fascinating chapters in the records of the science, and it is but fitting that any account of it should be prefaced by an expression of homage to Sir Charles Sherrington, to whose labours we owe the entire foundation of that knowledge.

Sherrington's investigations, in the course of which muscle tonus has been revealed as a purposive reflex reaction and the basis of all postural activity on the part of the musculature, are now thoroughly embodied in physiological thought and do not require detailed reference. It is of interest, however, when we recall the vicissitudes through which the term 'tonus' and our conceptions of muscle tone have passed to refer briefly to the experimental preparation which in the hands of Sherrington, and later in those of Magnus of Utrecht, has provided the key to the elucidation of those intricate neuro-muscular processes which underlie reflex posture. I refer to the decerebrate preparation. Prior to its discovery and description the nature, and even the very existence, of muscle tonus were subjects of conflicting opinion and observation. Numerous investigators had sought for this peculiarly elusive form of muscular activity in the single muscles of cold-blooded animals, and such glimpses of it as had been gained were too restricted in extent and too fugitive for any clue to its nature to be apparent. "To glimpse at the aim of a reflex," as Sherrington has remarked, "is to gain hints for further experimentation on it . . . the larger the muscular field involved in the reflex effect, the plainer usually its purpose."

The decerebrate cat is an animal in which the brain stem has been severed in the region of the tentorium, the section putting out of action all that part of the brain, including the forebrain, which lies anterior to the posterior corpora quadrigemina. Such a preparation may be called a ponto-spinal animal. Following this procedure, there appears an abnormally heightened tonus selectively distributed in those muscles which maintain the animal in its habitual standing posture—in other words, in the group of 'antigravity muscles.' This hypertonus has been called 'decerebrate rigidity,' and its intensity and characteristic incidence throughout the skeletal musculature have made possible a minute analysis not alone of the origin and nature of muscle tone, but also of its significance. Decerebrate rigidity is reflex standing. It will be apparent, therefore, that the discovery of this preparation opened a new and most fruitful era in the physiology of the nervous system.

Briefly, we have in muscle tone an enduring reflex muscular contraction of low intensity, endowed with a quality of plasticity in virtue of which the muscle can maintain a steady tension at varying muscle lengths, and readily overset transiently by intercurrent reflex reactions of phasic or movement type. It is a proprioceptive reaction, the stimulus arising in the muscle engaged in the reflex and consisting of those variations in tension produced by the voluntary motor activities of the animal (Sherrington and Liddell). It is believed that the tonic contraction is of the same nature, and is a function of the same elements in the striated muscle fibre as that seen in the muscle engaged in movement (phasic contraction), its peculiar qualities depending on the fact that now the elements respond in rotation, groups of individual muscles giving asynchronous series of responses.

In that beautiful analysis of reflex reaction which Sherrington has embodied in his book, "The Integrative Action of the Nervous System," he has pointed out that the skeletal musculature is controlled by two great reflex systems, which in the intact animal are in turn controlled by the cerebral cortex. Each system influences its own groups of the musculature, employing them in characteristic fashion. One system, the phasic system, is concerned with short-lived muscular movements and the arcs involved are predominantly spinal. The flexion reflex is a typical example in the group. The other, or tonic, system with which we are now concerned maintains and regulates that steady tonus or tonic contraction which is the basis, the raw material, of posture. Between the two systems there is a close and harmonious relationship, or, in Hughlings Jackson's apt phrase, "a perfect co-operation of antagonism." Every movement starts from and ends in a posture, and even the most superficial observation of some voluntary purposive movement betrays the existence of these two elements. For the effective performance of some movement of a limb it is essential that the organism as a whole should be oriented with reference to gravity and other external forces. The minute experimental analysis of muscular movement confirms this impression and has revealed the activity of the two systems mentioned above.

The tonic reflex system includes the autogenous reaction in the muscle which we call muscle tone, and also a complex series of controlling reactions by means of which tone is adapted to follow up the numerous and diverse movements made by the intact animal.

These regulating tonic reactions arise in the otolith organs of the labyrinths, in proprioceptive nerve endings in the muscles and tendons throughout wide regions of the body, and also in the nerve endings in the body wall which subserve the sense of pressure.

In 1909, as he relates, Magnus chanced to be working with a decerebrate preparation and noticed when he turned the animal from the lateral into the supine position that the extensor hypertonus of its limbs underwent an appreciable increase with the adoption by the limb of an attitude of more complete extension. Further, when the head was so flexed upon the trunk that the line of the mouth made an angle of 45° above the horizontal, an additional increase was seen to set in after a latent period of several seconds. These modifications of tone, and afterwards of limb posture, persisted so long as the new position of the head which had given rise to them was maintained.

[1] Opening paper of a discussion on "Reflex Posture" before Section I (Physiology) of the British Association at Oxford, August 9.

Simultaneously and independently, Sherrington observed that with the animal in a fixed position, rotation of the head to one side caused a similar increase of extensor tonus in the two limbs of the side to which the snout pointed. Extirpation of the labyrinths left the reaction intact, but division of certain cervical posterior roots abolished it. It therefore arose in proprioceptors in the neck musculature.

These observations formed the starting-point of Magnus's great work upon reflex posture, and have resulted in the discovery and classification of an extremely complex series of tonic reactions, which in sum make up the nervous mechanism by which normal postural activity is attained. In addition, Magnus has revealed the existence of a group of phasic reactions arising in the semicircular canals, and these with the tonic reflexes under discussion constitute the whole reflex mechanism of normal co-ordinated muscular activity.

Magnus and de Kleijn found that by imposing variations in the position of the animal's head in relation to the horizontal plane of space certain constant modifications of limb tonus, and therefore limb posture, could be produced. Further, after bilateral labyrinth destruction, variations of head posture in relation to the trunk also elicited certain other constant tonic reactions. These two groups are the so-called tonic labyrinthine and neck reflexes and together make up a group of 'standing reflexes.' By appropriate manipulation of the head by the observer, the animal can be made to take up a wide range of attitudes, corresponding to those habitually adopted by the animal during life. They found, however, that although it could stand, the decerebrate animal, if overturned, lay like a log and had no power of reflex control over the posture of its head. It was clear, therefore, that there must exist in the intact animal other tonic reactions governing head posture. Transection of the brain stem immediately anterior to the mid-brain led to the discovery of these other reactions. The mid-brain animal, for so such a preparation is called, does not exhibit hypertonus, but tone of normal intensity. It can stand, walk, and jump, and if overturned at once actively reassumes the normal sitting posture. If thrown from a height it lands upon its feet. The reactions by which these results are obtained are purely reflex, and the animal is a reflex automaton.

Further analysis of the preparation's activities has revealed the existence of a group of labyrinthine, neck and body 'righting reflexes,' in virtue of which the animal is able to maintain its head right side up in the world. This righting of the head sets in train secondarily all the other reactions by which the trunk and limbs are in turn brought into line with the head. Slow motion kinematograph photographs of the cat falling through space reveal the successive tonic and semicircular canal reflexes described by Magnus and his collaborators. First the head is righted, the anterior and the posterior portions of the trunk follow in turn, and finally, in virtue of phasic semicircular canal reactions, the limbs are outstretched so as adequately to receive the body weight as the animal reaches the ground. The ease and accuracy with which each of the various tonic and phasic reactions separately analysed by Magnus can be followed in such photographs are the most convincing demonstration of the minute accuracy of his observations.

In apes there is added to these labyrinthine and proprioceptive reactions a group of retinal righting reflexes of tonic character.

The reflex arcs of the various reactions we have been considering lie entirely within the limits of spinal cord and brain stem and do not pass through the cerebellum or basal ganglia. There is laid down, then, in the central nervous axis of the animal a mechanism which makes possible all the phasic and postural activities of the intact animal. By an automatic mechanism the animal is kept right side up in the world.

It is to observations made at the bedside by the clinician that we must turn to determine whether or not the laws governing the regulation of posture in a wide range of animal forms—from guinea-pig to ape—hold also for man. The evidence accumulated during the past fifteen years goes conclusively to show that they do.

Warned by the difficulties which the pioneer investigators met with in their animal experiments, the clinician has sought for a form of hypertonus resembling experimentally produced decerebrate rigidity. The student of nervous diseases is familiar with several forms of tonic muscular contraction of considerable intensity, but all except one of these may readily be dismissed as bearing no resemblance to the condition in question. It might be thought that in man a condition of decerebration is not compatible with continued existence, and indeed complete bilateral decerebrate rigidity is one of the rarest observed phenomena. We have, however, in the hypertonus, or spasticity, of the residual hemiplegia left after a cerebral hæmorrhage or softening, a unilateral state of tonic muscular spasm in the limb muscles which is manifestly qualitatively identical with decerebrate rigidity. It arises as a proprioceptive reflex in the muscle concerned, and destruction of the muscle's afferent nerve supply abolishes it. It is plastic, and easily overturned by the same phasic reflexes as have this effect in the animal. It may persist undiminished for years. It has a selective incidence in the limb musculature: in the extensor, or antigravity, muscles of the legs, but in the flexors of the arms. This altered incidence in the upper limbs of man is related to the profoundly altered functions of the fore limbs in this erect animal, and the reasons for so thinking need not now concern us. Further, it has recently been shown that the tonic neck and labyrinthine reflexes of Magnus and de Kleijn may be present in these rigid and paralysed limbs, following the same rules which govern their occurrence and form in the decerebrate animal.

In addition it has been possible to recognise in a very familiar clinical phenomenon the existence of another group of tonic reflexes, arising in the proprioceptors of the normal limb and acting upon the paralysed limbs. It has long been known, and every hemiplegic subject soon discovers the fact for himself, that when with the normal arm the subject makes some forceful, tonically sustained, voluntary movement, the contralateral paralysed limb goes into strong tonic

spasm and takes up a new attitude, which is sustained for so long as the voluntary muscular act evoking it. The form, latency, and duration of this so-called 'associated movement' shows it to be a tonic reflex of the same type as those described by Magnus. Further, in favourable cases, a beautiful interaction between labyrinthine, neck and limb reactions may be observed if we combine changes in the position of the subject's head both in relation to space and to his trunk.

It is clear, in short, that the tonic reactions of Sherrington and of Magnus are present in the human subject. In a single personally observed case of complete decerebrate rigidity in the human subject, in which physiological 'decerebration' was performed by a tumour compressing the mid-brain, a perfect decerebrate rigidity with tonic neck reflexes and phasic flexion and crossed extension reflexes were obtainable.

These observations upon the subjects of disease and injury of the nervous system are of a double interest. They serve to correlate the work of the experimental physiologist with that of the clinical observer, they bring the human subject into line with animals lower in the scale. Further, they illustrate the value to the clinician of experimental physiology. For many years the labours of clinical neurologists have accumulated a vast mass of 'physical signs' of disease, which have been used empirically as aids to diagnosis; but so far as possessing other meaning was concerned they remained like the jumbled pieces of a mosaic. Thanks to the light received from the physiological laboratory, it is now possible to piece them together into a coherent and intelligible pattern, and they have become manifestations of a dissolution of nervous function, pregnant with physiological significance. Thus may the clinician not only derive information of inestimable value to him in his analysis of the phenomena of disease, but he may also, in a measure, repay some of his debt to the physiologist by carrying over the latter's animal observations to man.

Some Recent Advances in Astrophysics.[1]

By Prof. E. A. MILNE, F.R.S.

OF late years astronomers have become increasingly despairing as to what the stars are doing—in what direction they are evolving, how they produce the energy they radiate, whether (and if so why) some of them pulsate, how the stars are born and whether they die. At the same time astronomers have become increasingly confident as to what the stars are really like. It is proposed here to deal briefly with one province of this less speculative side of astrophysics, namely, that which is described, broadly speaking, as the subject of stellar temperatures and stellar spectra.

What are called the 'effective temperatures' of the stars have been determined by measurement of their colour, much in the same way as the temperature of a piece of red-hot iron may be estimated from its colour. With the piece of iron, we may measure either the total radiation leaving each square centimetre of its surface, or the ratio of the intensities of radiation for two different constituents of its spectrum. From either of these measurements we may infer the other. Both types of measurement are possible for the sun, and by the work of Abbot, Plaskett, and Fabry and Buisson, they have been shown to be in general agreement. For the stars in general, only the colour type of measurement is possible. It is true that of recent years the heat radiated by the stars has been measured directly, but such measures by themselves yield no more information than a determination of apparent magnitude. Colour-measures, however, by the use of Planck's law, yield the amount of radiation leaving each square centimetre of the star's surface—a quantity expressed parametrically by the effective temperature, or surface brightness.

The importance of this quantity lies in the fact that the total radiation leaving the surface per second is precisely the amount generated in the interior per second, assuming a quasi-steady state. Two examples of its employment in fundamental calculations may be mentioned. The amount of light from a star (a quantity given by the apparent magnitude) reaching the earth is equal to the product of the surface brightness into the solid angle subtended by the star. Hence a determination of surface brightness plus one of apparent magnitude is equivalent to a determination of the angular diameter of the star as seen in the sky from the earth. The confirmation of such estimates by the direct measurement of angular diameters at Mount Wilson by means of the Michelson interferometer affords a useful check on one of the steps in the reasoning, namely, the deduction of radiation per unit area per second from an observation of colour. The second example is that of the estimate of the densities of the components of a double star. The density-ratio of the components may be readily calculated in terms of the ratio of the surface brightnesses, the mass-ratio, and the difference of the apparent magnitudes. In this way it was inferred that the companion of Sirius must have a density some 60,000–70,000 times that of Sirius itself, and the verification of this by Adams at Mount Wilson, by measurements of the Einstein shift in the lines of the spectrum, has been one of the most sensational scientific events of the past year.

The effective temperature, however, is not the temperature of any particular portion of the star. The question arises, Is there any method of determining the actual temperature in the surface regions of a star, which alone we can directly observe? Have we a thermometer? The answer is in the affirmative. We can use the atoms volatilised in the atmosphere of a star as their own thermometer, by observing the absorption spectrum they produce.

The theory depends on the recent progress in atomic physics. It has long been known that the spectra of the great majority of stars fall into a single linear sequence, in which, as we pass by ascending effective temperatures from the red stars to the blue stars, some lines decrease in intensity, others increase, attain a maximum and decrease, others again only appear far on

[1] Substance of a lecture delivered before the Manchester Literary and Philosophical Society on October 19.

in the sequence. Such a linear array of spectra could scarcely be due to differences in chemical composition, and it was emphasised by Russell and others that in some way the ordered sequence of spectra must be related to the sequence in effective temperatures. The true explanation, however, was only discovered in 1920, by Saha.

It was Saha who first pointed out that at high temperatures the atoms composing stellar atmospheres must dissociate into ions and free electrons according to the same laws of thermodynamics used by chemists to calculate molecular dissociations. Given the ionisation potentials of the atoms, the degree of dissociation is a function of temperature and pressure—to be precise, the partial pressure of the free electrons—and for a given pressure the ionisation increases with the increasing temperature. Consequently, for each element we shall have first the spectrum of the neutral atom, then that of the once-ionised atom, followed in turn by that of the twice-ionised atom, and so on. At the highest temperatures the spectrum of the neutral atom should completely disappear, in general. Further, the absence of an element from a stellar spectrum does not necessarily mean the absence of the element from the stellar atmosphere. It may only mean that the lines it is capable of producing in its then stage of ionisation are outside the accessible range of spectrum.

It is necessary to distinguish the ultimate lines of an atom in any given stage of ionisation from the remaining lines. The ultimate lines are absorbed only by the atom or ion in its normal, or unexcited stage. The theory shows immediately that the ultimate lines of a neutral atom should steadily decrease in intensity with increasing temperature: the ultimate lines of an ionised atom should increase at first, slowly attain a maximum and then decrease as further ionisation ensues. Calcium provides an illustration of both types of lines.

Intermediate between successive stages of ionisation we have atoms in excited states, with corresponding absorption spectra. Only a minute fraction of the atoms are in any given excited state at any instant, but the fraction is a definite one given the temperature and pressure, on the assumption of thermodynamic equilibrium. Moreover, this fraction has a comparatively sharp maximum. It is easy to see that a maximum must occur. At lower temperatures, comparatively few of the atoms are excited. As the temperature increases the excited fraction of atoms in the given state of ionisation increases, but the total number of atoms in the given state decreases owing to the next stage of ionisation setting in, and ultimately all the atoms pass into the next stage of ionisation. The number of excited atoms is thus practically zero at both low and high temperatures. In between it must have a maximum.

Following the method of Saha, it has been found possible to calculate at what temperature such a maximum should occur. We then identify the maximum in the number of excited atoms with the observed maximum of the corresponding absorption lines in the stellar sequence. We thus arrive at a truly thermometric scale of stellar temperatures. The most recent and detailed comparisons of observed and theoretical maxima are those contained in the researches of Miss Payne, of the Harvard College Observatory, and the following is her table of temperatures.

Class.	Temperature.	Class.	Temperature.
K_5	3,000°	A_0	10,000°
K_0	4,000°	B_8	13,000°
G_0	5,000°	B_3	17,000°
F_0	7,500°	$B_{1\cdot5}$	18,000°
A_5	9,000°	B_0	20,000°

At present there still remains an empirical element in the temperature scale. It is necessary to assume a value for the pressure—the partial electron pressure—in stellar atmospheres, and to assume that the pressure is the same in all stars. The removal of this empiricism promises to open up a still more important line of work. A synthetic theory of the structure of a stellar atmosphere would not in fact deal with the pressure at any particular level. Starting with the value of gravity at the surface of the star, and the atomic absorption coefficients, it would proceed to calculate the distribution of atoms through the atmosphere, taking due account of the varying effects of selective radiation pressure on the individual atoms. Ultimate lines, for example, will give rise to much more intense radiation pressure than lines corresponding to excited states. Different classes of atoms will thus be at different horizons in the atmosphere, and so at different pressures. The nature of the spectrum itself controls the pressure, and so in turn the degree of ionisation. This double relatedness of spectra to ionisation, due to the intervention of radiation pressure, may lead after further study of stellar spectra not only to an improved temperature scale with the empiricism removed, but further to determinations of surface gravity and to astrophysical determinations of relative, perhaps even absolute, atomic absorption coefficients. The possibility of the latter type of determination serves to remind us that astrophysics contributes to atomic physics as well as borrows from it.

A further by-product of the theory is the determination of the relative abundances of the different elements in stellar atmospheres. Observations of maxima provide temperatures, and are independent of relative abundances: each maximum is a thing *per se*. But the places of first or last appearance of a line in the stellar sequence depend on the amount of the corresponding element available, and in the hands of Miss Payne have been used to estimate the relative abundances. It must suffice to state that the abundances bear a relation of rough similarity to the abundances of the same elements in the crust of the earth, with the exception of hydrogen and helium, the behaviour of which is anomalous.

It has already been mentioned that intensities of spectral lines are connected with the surface values of gravity. Empirical connexions of line-intensities with the absolute luminosities of the corresponding stars are now well known: they are another aspect of the same phenomenon. By a method originated by Kohlschütter, Adams and Joy, they are now used at many observatories to determine the parallaxes of stars spectroscopically. In conclusion, reference may be made to a similar method recently developed in the brilliant work of Ch'ing-Sung Yü at the Lick Observatory. He has investigated the continuous absorption spectrum associated with the limit of the Balmer series

of hydrogen. This spectrum is produced by the ionisation of hydrogen atoms: its intensity is a measure of the fraction of hydrogen atoms remaining un-ionised. Yü has found empirically that it is a function of colour-temperature and of absolute magnitude. The method eliminates one unsatisfactory feature in the method of Adams and Joy, namely, the use of different empirical reduction curves for stars of different types. Yü's photometric measures determine colour-temperature and hydrogen absorption from the same spectrogram, and from these two quantities the absolute magnitude may be inferred. It is too early to estimate the ultimate value of the method, but it is at once a new weapon for the determination of parallaxes by calibration on known stars, and a challenge to theoretical investigators.

Obituary.

PROF. W. J. HUSSEY.

PROF. W. J. HUSSEY died suddenly in London on Thursday, October 28. He reached England on October 23 with Mrs. Hussey and with Mr. and Mrs. Rossiter. They proposed to leave for the Cape on October 29, taking with them a large telescope of 27 inches aperture and 41 feet focus. This was to be installed near Bloemfontein, Prof. Hussey remaining until the building was completed and leaving Mr. Rossiter in charge to carry out an extensive programme of double star observations. Prof. Hussey had only lately recovered from an attack of pleurisy, but seemed fairly well on October 27, when he gave an address to the British Astronomical Association.

William Joseph Hussey was born at Mendon, Ohio, on August 10, 1862, and graduated B.S. of the University of Michigan in 1889. For some years he taught mathematics in the University of Michigan, and was acting director of the Detroit Observatory. In 1892 he was appointed assistant professor of astronomy at the Leland Stanford Junior University, afterwards succeeding to the chair. From Leland Stanford it was a natural transition to the post of assistant astronomer in the Lick Observatory, not many miles away.

Hussey's knowledge and enthusiasm were such as to enhance the high traditions of this famous observatory. Barnard and Burnham had left, and their places were filled by Aitken and Hussey. The first important work Hussey undertook was the re-observation and discussion of the double stars observed by Otto Struve. The results form vol. 5 of the Lick Observatory publications. Hussey measured many close and difficult double stars which were only within reach of the largest telescopes. Among them may be instanced δ Equulei, which has an elliptic orbit, and the two stars are only separable when near elongation. He followed this star closely and found it to have a period of 5·7 years, one of the shortest known, while previous observers had supposed the period to be about double this length. It may be interesting to note that he determined the parallax of this star by a combination of line of sight determinations of linear velocity with the determinations of angular movement resulting from double star measures.

In 1899 Hussey joined Aitken in a systematic examination of all stars between the pole and $-22°$ down to $9·0^m$ or $9·1^m$ to discover which of them were double. They worked on this programme from sunset to sunrise, and when Hussey left in 1906 to be professor of astronomy and director of the observatory of the University of Michigan, he had discovered so many as 1327 new double stars. Here he was engaged in spectroscopic work and in building and organising a new observatory. In 1911 the directorship of the observatory of La Plata was added to that of the University of Michigan. Before his resignation of this post in 1917, he had discovered 312 new southern double stars.

In 1902 Hussey was appointed to make telescopic tests of the suitability of sites in South California and Arizona for a solar observatory, and strongly advocated the selection of Mount Wilson. From 1917 he had in mind the possibility of the establishment of an observatory in the southern hemisphere specially for double star work. Three years ago he visited South Africa, and was very favourably impressed with the site of Bloemfontein. A personal friend from college days, Mr. Lamont, has recently provided funds for a telescope, designed and built under Hussey's direction, with an object-glass by Zeiss. This telescope was completed and was being taken to Bloemfontein at the time of Prof. Hussey's death. We understand that arrangements have been made to go forward with the establishment of this observatory, and that Mr. Rossiter left for South Africa on November 5. This, we may be sure, would have been in accordance with Prof. Hussey's wishes.

Prof. Hussey had many friends among English astronomers, who admired his gifts of industry and enterprise, and were always pleased when occasions like eclipse or other expeditions brought him to London and gave an opportunity of meeting him. He had been a foreign associate of the Royal Astronomical Society since 1903.

F. W. D.

WE regret to announce the following deaths:

Prof. F. M. Caird, emeritus professor of clinical surgery in the University of Edinburgh and a past president of the Royal College of Surgeons of Edinburgh, who worked as a student under Lister, on November 1, aged seventy-three years.

Dr. W Romaine Newbold, Seybert professor of moral philosophy in the University of Pennsylvania, who wrote on suggestibility, automatism and kindred phenomena, on September 26, aged sixty years

Dr Francis E. Nipher, emeritus professor of physics in Washington University, St. Louis, whose work covered aspects of gravitating nebulæ, wind pressure, and the electric discharge, on October 6, aged seventy-eight years.

Dr. Franz Pfaff, formerly professor of pharmacology and therapeutics at the Medical School of Harvard University, on September 26, aged sixty-six years.

Dr. C A. Waldo, emeritus professor of mathematics in Washington University, St. Louis, known for his work on warped surfaces, on October 1, aged seventy-four years.

News and Views.

On Saturday, November 27, the authorities of the town and cathedral of St. Albans will commemorate the six hundredth anniversary of the election of a prelate famous in the history of the Abbey—Richard of Wallingford, Abbot 1326–1335. This fact has interest for men of science and archæologists, for Wallingford was a scientific pioneer, as well as a distinguished abbot. At Oxford, where he was a student and doctor in the 'Hall' maintained by the leading Benedictine houses for the reception of promising youths from their local schools, he won fame as a mechanician and astronomer, almost as a magician. In this he shared the lot of 'Friar Bacon,' whose follower, though not immediate pupil, he was; it seems that that pioneer genius started what might have been a great school of science at the university. Wallingford was the author of scientific treatises, one of which, "The Rectangulus," survives in MS. to this day. Many of the scientific instruments he invented are preserved, either actually or as reproductions, in the Ashmolean Museum, and were the basis on which later men could work. His scientific *chef d'œuvre*, however, was the astronomical device 'Albion' ('all by one'), which showed "the action of the tides and the revolutions of the planets."

The above commemoration will be attended by Sir Frank Dyson (the Astronomer Royal), Prof. H. H. Turner, Dr. R. T. Gunther, and other scientific men (including representatives of the Clockmakers' Company), and will take the form of a service in the Abbey of St. Albans at 4 P.M., at which a wreath will be placed on Wallingford's tomb, and his prayers used. Later, there will be a gathering in the Town Hall, when papers will be read on Wallingford's work as man of science and abbot, and there will be a small exhibition of his scientific instruments. It is hoped that this will include the actual instrument 'Albion,' for it was acquired from the Royal Commissioners at the time of the dissolution of the abbey, by a local 'Squire,' and it has ever since been an heirloom in his family. The instruments will be explained by Dr. Gunther. The service and gathering are, naturally, public, and any one desiring more information on the matter should apply to the Hon. Secretary, Wallingford Commemoration, Kingsbury Knoll, Verulam Road, St. Albans.

According to a recent message of the Stockholm correspondent of the *Times*, the following awards of Nobel prizes have been made: The reserved prize for physics for 1925 between Prof. J. Franck of Gottingen and Prof. Hertz of Halle; the prize for physics for 1926 to Prof. Jean Perrin; the prize for chemistry for 1925 to Prof. Richard Zsigmondy, the prize for chemistry for 1926 to Prof. The Svedberg. Prof. Franck is professor of physics and director of the physical laboratory in the University of Göttingen and is the author of many papers on atomic structure, ionisation by collision, and related topics. Prof. Perrin is professor of physical chemistry at the Sorbonne; he is the author of a standard work on atomic chemistry which has passed through many editions and has been translated into French and German. He was elected a foreign member of the Royal Society in 1918. Profs. Zsigmondy and Svedberg are both best known for their work on the colloidal state. Prof. Zsigmondy is professor of inorganic chemistry in the University of Göttingen; he has worked largely on the gold sols, and his book on colloids and the ultra-microscope has been translated into English. A recent volume, "Das Kolloide Gold," by Prof. Zsigmondy and P. A. Thiessen, is the first of a new series of monographs in which the scattered work on the physics and chemistry of colloids is being brought together under Prof. Zsigmondy's guidance. Prof. Svedberg, professor of physical chemistry at the University of Upsala, has carried out numerous and fundamental researches on colloidal solutions of the suspensoid type and has made noteworthy contributions to our knowledge of the chemistry of photographic processes.

At a luncheon given on November 12 by the Imperial College of Tropical Agriculture to the Dominion Prime Ministers and representatives, Mr. Amery made the important announcement that 96,000*l*. out of the 100,000*l*. which Lord Milner set out to obtain as an endowment fund for the College has now been raised. Sir Arthur Shipley, who presided, pointed out the great need there is for agriculturists who have been thoroughly trained in tropical agriculture; men of this type are wanted everywhere, and it is this want that the Trinidad College is hoping gradually to satisfy One of the difficulties is that there is not at present a sufficient supply of schoolboys with any biological training. Sir Arthur deplored the fact that it is now possible for a student to take honours in a Natural Science Tripos at Cambridge without taking at least one biological subject. At the present moment the market for chemists and engineers is gravely overstocked, whereas there is an appalling dearth of entomologists and mycologists. This state of affairs the College is endeavouring to redress. Both Mr. Bruce, the Prime Minister of Australia, and Mr. Coates, the Prime Minister of New Zealand, stated that they took the greatest interest in the College, although neither was able to make any immediate promise to provide funds for its enlargement.

It is doubtless true that the number of fatal flying accidents to service flying officers this year—more than seventy to date—large as it is, is in diminishing ratio to the number of hours flown as compared with previous years since the War. It is probably true also that many of the accidents which occur are due to errors of judgment on the part of the pilots. The number of accidents is sufficiently large, however, to occasion concern and to re-emphasise the need for more and more research in connexion with the design and construction of aircraft, and obviously for the exercise of more care in the selection of pilots and more care in their training. Whether the private aircraft construction companies should be granted subsidies with which to carry out their own research programmes, the suggestion made by Mr. Handley Page

in his letter published in the *Times* on November 12, or whether it would be better for the Royal Aircraft Establishment to undertake aircraft construction as well as design, is a debatable question. It is obvious that Great Britain, however favourably it compares with other countries as regards accidents, has still to carry out much research work before a type of aircraft is evolved which will combine stability with manœuvring capacity. There is still much work to be done in connexion with the elimination of the possibility of fire on 'crashing,' and other safety precautions There is little doubt that every aeroplane accident whether it is a service machine or a commercia machine involved, shakes the confidence of potentia passengers in the safety of air travel and reacts unfavourably against the development of commercial air services.

ON November 23, the centenary occurs of the death of Johann Elert Bode, the famous German astronomer. Born at a time when scientific studies in Germany were recovering from the set-back brought about by the disastrous Thirty Years' War, Bode was the first to diffuse a general taste for astronomy among his fellow-countrymen. He was the Lalande of Germany, and his name is known to every one as the author of "Bode's Law." That law, it is true, is to be found in the writings of Titius, Wolf, and others, but it was Bode who first directed attention to it. His world-wide reputation, however, rested on other grounds. The son of a schoolmaster, and born in Hamburg, January 19, 1747, Bode at the age of twenty-one years published a popular treatise on astronomy and an essay on the transit of Venus of 1769. Three years later Frederick the Great made him astronomer to the Berlin Academy of Sciences, in which position he did much to stimulate astronomical studies. His well-known "Astronomische Jahrbücher" were commenced in 1774; two years later he published an essay on the constitution of the sun, and in 1778 made known the law bearing his name. He closely followed Herschel's newly discovered planet, and it was he who named it Uranus when Herschel would have called it Georgium Sidus. His "Uranographia," or Great Celestial Atlas, appeared in 1807 and contained observations of about 17,000 stars. Long regarded as the head of German astronomers, he was younger than Mayer, but among his contemporaries were such as Harding, Gauss, Schumacher, Struve, and Encke.

THE opinion among engineers of the value of a training in the scientific principles of the profession has altered greatly during the past twenty years, and there are few, even among the older school of engineers, who do not now recognise the advantages of such a training. But although few subjects have been more widely discussed, there are still wide differences of opinion as to how, when, and where such a training is best obtained, and as to exactly what it should include. Should it be obtained at a technical school in evening classes, or in a full-time course at a university? Should it precede, be carried on simultaneously with, or follow a course of practical training in works or office? Should the university attempt anything in the nature of practical training? How long should the period of practical training last? In a paper read at a meeting of the North-East Coast Institution of Engineers and Shipbuilders on October 29, Principal Sir Theodore Morison, of Armstrong College, Newcastle, suggested the formation of a committee of the Institution with the view of giving an authoritative answer to these and other cognate questions.

THE outcome of Sir Theodore Morison's suggestion will be of interest, and we look forward to a report of the discussion of the paper. Numerous committees of engineers have considered the subject in the past in Great Britain and other countries, without by any means exhausting its possibilities. Since the report of the committee of the Institution of Civil Engineers on engineering education some years ago, the scope of engineering has in many respects changed, and the ideal scheme of fifteen years ago is not of necessity best fitted to satisfy to-day's requirements. Such a committee has recently been considering the subject in the United States of America. Perhaps the most interesting part of its report is the general insistence on the importance of cultural subjects, and of a thorough grounding in the general physical principles of engineering. The idea of specialising until a late period of the course, and even then of too pronounced specialisation, is in general deprecated. We are of the opinion that this is a very sound view. We believe that the majority of the engineering schools of the universities of Great Britain do aim at giving this sound fundamental training. At the same time, provision should be made at certain selected universities for highly specialised courses of post-graduate standing. At the moment, this would appear to be the weakest part of the university training of engineers in England. Such a committee as the one suggested might well consider what courses of this nature might most usefully be instituted.

IT seems probable that in the immediate future the development of electricity supply in Ireland will rapidly increase. At present it is more backward in this respect than any country in Europe. The consumption in Northern Ireland is 43 units per head of the population, and in the Free State only 16 units per head. This compares with a consumption of 2500 units in Norway, 900 in Switzerland, and 140 in Britain. In his presidential address to the Irish section of the Institution of Electrical Engineers, Mr. Kettle, the city electrical engineer to Dublin, took a favourable view of the future of electricity supply in Ireland. He said that the Shannon scheme is not mainly a 'power' scheme. It is more a 'transmission' scheme comparable to the Swiss Central Board arrangement and the British Government scheme. He admitted, however, that the promoters of the Shannon scheme seem to anticipate that it will be a commercial success from its commencement—an altogether too sanguine view to adopt. The Free State has anticipated the ordinary course of events

by about ten years, but having put its hand to the plough it cannot turn back. The country has been definitely committed to the scheme, and the fullest co-operation with other schemes is necessary in order to make it a success. A second Shannon Power Bill is apparently expected in the near future and it will probably deal with the supply and control of the entire electricity supply of the Irish Free State. A transmission scheme has been outlined for Northern Ireland, but the authorities there appear to be disposed to proceed more gradually than those of the Free State. There is not much difference between the two schemes except that one would use coal and the other water power. Mr. Kettle thinks that both networks should be so designed that they can be combined to form an all-Ireland scheme at a future date.

THE story of Clerk Maxwell has hitherto been mainly confined to biographical details of his life and general career. As, however, it is now nearly fifty years since he died, it is possible to see how much his work has influenced the development not only of physics but also of applied engineering. In particular, every radio expert claims him as one of the great pioneers of electrical communication because of the invaluable help his electromagnetic theory of light has been in the development of their art. In the October issue of *Electrical Communication* Mr. Rollo Appleyard begins a series of articles on the pioneers of electrical communication by an eloquent eulogy of Maxwell. In 1856 Maxwell accepted a professorship at Aberdeen. In 1860 he became a professor at King's College, London, and in 1871 he became professor of experimental physics at the Cavendish Laboratory, Cambridge. It has to be remembered that from 1851 to 1865 very rapid progress had been made in submarine telegraphy, and many data in connexion with electrical phenomena had been collected which Maxwell had to interpret from the theoretical point of view. His great paper on the "Dynamical Theory of the Electromagnetic Field" was published in 1865. On this paper the electrician has built his practical theory of the working of the alternating current transformer and much of the modern theory of electrical communication. Maxwell admitted electricity to the rank of a physical quantity, but he warned us against assuming too hastily that it was either matter or a form of energy. He considered that it was proved that electricity could not be annihilated and that it could not be created. He has left us a memory of individual thought and achievement which has rarely been rivalled in the history of the world.

PROF. A. P. LAURIE delivered a lecture to the students of the Royal Academy, London, on Wednesday, November 10, on "The Theory of Colour and its Application to Painting." Modern pictures in oil vary frequently and lower considerably in tone in the course of years. One cause of this is the yellowing of the oil, and an investigation was undertaken to see whether some other cause was not also present. Pigments may be regarded as translucent particles of varying refractive index, and the light received from their surface will consist partly of light reflected from the first surface struck by the ray of light, and partly by light transmitted through the pigment, and then reflected. The first reflection will consist principally of white light. The ratio between the reflected and the transmitted ray varies according to a somewhat complex formula with the difference between the refractive index of the medium in which the pigment is ground and that of the pigment itself. Thus, if the refractive index of a linseed-oil film increases with age, the result will be gradually to lower the tone of the pigment ground in it. Experiments have shown that in nine months the change is sufficient to affect the opacity of white lead and the tint of cadmium yellow. A rough table was then prepared of the principal bright pigments used by artists, these pigments being arranged in the order of transparency by examination in media of higher and higher refractive index and also in their spectrum order, so as to enable artists to pick out those least affected by the two changes taking place in linseed oil. These experiments throw new light on the methods of oil painting in the fifteenth and sixteenth centuries; the painters of that time were evidently experimentally aware of both of these properties of linseed oil and based their technique upon these facts with the view of keeping up the colour key of their pictures.

THE thirteenth Thomas Hawksley Lecture was delivered at the Institution of Mechanical Engineers on November 5 by Prof. E. G. Coker, the subject chosen by the lecturer being "Elasticity and Plasticity." After a brief historical introduction, Prof. Coker described the advances which have been made in recent years in the science and technique of photo-elasticity. An interesting feature of this part of the lecture was the description of the apparatus now used for measuring the applied load, which depends upon the elastic deformation of a steel ring loaded diametrally. Photo-elastic methods are employed to determine the most suitable form of ring, and a mechanical multiplying device fixed within the ring serves to record visually the diametral extensions. Prof. Coker then outlined the mathematical theory of photo-elasticity, in regard to the determination of the principal stresses both by direct measurement of the lateral strains, and by Filon's development of Clerk Maxwell's method of integration along the lines of principal stress, using as an illustration of the latter the dovetailed joint used for steam turbine blades. Dealing next with the subject of elastic breakdown, Prof. Coker described the various attempts which have been made to discover a law governing failure under all systems of stress, and referred particularly to those involving combinations of the single criteria proposed by Rankine, St. Venant, and Guest, and to the strain energy theory of Haigh and its modification by von Mises. A most interesting portion of the lecture was devoted to the subject of plasticity, the researches of Prandtl, Hencky, and Nadai being brought under review, particularly in their application to the phenomena associated with the pressure of a die in a steel plate. The manner in which the soap film method used by

Griffiths and Taylor for the determination of stress distribution in torsion can be extended to the case of plastic strain was described, and the lecture concluded with a review of the present state of knowledge regarding the application of optical methods to the determination of plastic stresses.

MR. P. A. BUXTON, of the London School of Tropical Medicine, to whose researches in the New Hebrides reference was made in the article on West African Development which appeared in NATURE of November 6, writes to correct a rather important misapprehension of his conclusions regarding the relation between malaria and abortion. In commenting on the omission in Mr. Ormsby Gore's report of any reference to Mr. Buxton's important memoir on "The Depopulation of the New Hebrides," the statement was made that "it seems fairly well established from the recent researches of Mr. Buxton in Melanesia that malaria is one of the principal determining causes of abortion and still-births" This was based on the statements on page 425, vol. 19, *Trans. Roy. Soc. Trop. Med. Hyg.*, to the effect that "abortion is common in all the islands of Melanesia"; the probability "that methods of obtaining abortion, which have been known [to the natives] from time immemorial, have been used more and more frequently within the last half-century," partly due to increasing monogamy, the outcome of the white missionary's zeal; and the supposition "that unprovoked abortion is common in the New Hebrides, owing to the malaria, and therefore any procedure which is adopted to produce abortion will occasionally be followed by the desired result, even if it is intrinsically harmless." Too much has been read into this last statement, for Mr. Buxton writes: "My conclusions may be summarised thus: malaria and the practice of abortion (not abortion caused by malaria) are both concerned in the disappearance of these peoples. But I have never showed, or tried to show, that malaria caused enough abortions to make it a factor in the depopulation, and it seems improbable that this is so, for the depopulation is an event of the last century and the malaria is an indigenous disease.'

REFERRING to our note in the issue of November 13, p. 708, on the distances at which the 'concentration shoot' off Portland on October 30 was heard, Prof. A. E. Boycott writes stating that the firing was heard very clearly in the open near Aldenham, Hertfordshire, about 125 miles from Portland, and was mistaken at first for thunder There was a fairly strong north wind blowing. Dr. R. T. Gunther, 5 Folly Bridge, Oxford, states that the firing was distinctly heard on the towing-path near Oxford and it also caused the windows of his house to rattle. Oxford is about 110 miles from Portland.

IN the issue of *Science* for October 1 there is a short but interesting contribution from Dr. Edgar F. Smith on Priestley's life in America, whence he withdrew in 1794 from the animosity to which his religious views had given rise in England. Priestley's daily life in his adopted home is briefly described, and his manifold activities summarised. Persecution followed him across the Atlantic, mainly on account of the anonymous attacks on him which are stated to have been written by William Cobbett, "an Englishman whose pen, dipped in gall, spared the venerable scientist in no wise." He was, however, a friend of American divines. Priestley's advanced views on education are compared with those of Herbert Spencer, and the article is a sympathetic account of a man who has not, perhaps, had the credit paid to him which is his due.

IT is announced in *Science* that the John Fritz Gold Medal of the American Societies of Civil, Mining and Metallurgical, Mechanical and Electrical Engineers for 1927 has been awarded to Elmer Ambrose Sperry, of New York, for the development of the gyrocompass and the application of the gyroscope to the stabilisation of ships and aeroplanes.

AT the annual general meeting of the Cambridge Philosophical Society, the following officers were elected for the session 1926-27: *President*, Dr. H. Lamb; *Vice-Presidents*, Mr. G. Udny Yule, Prof. J. T. Wilson, Prof. A. Hutchinson; *Treasurer*, Mr. F. A. Potts; *Secretaries*, Mr. F. P. White, Mr. R. H. Fowler, Mr. H. Munro Fox; *New Members of Council*, Prof. T. M. Lowry, Dr. H. Jeffreys, Dr. F. J. W. Roughton, Mr. F. T. Brooks.

IT is now announced that the Proceedings of the Optical Convention, 1926, held at the Imperial College of Science and Technology, South Kensington, on April 12 17 last, will be ready in the first week of December. The book is in two cloth-bound and fully illustrated quarto volumes, each of more than 500 pages, and contains the presidential address and the papers read at the Convention, with a full report of the discussions thereon. The address of the Secretary of the Optical Convention is 1 Lowther Gardens, Exhibition Road, London, S.W.7.

A NATIONAL Coal Products, Chemical, and Engineering Exhibition, arranged by the Manchester Section of the Society of Chemical Industry with the assistance of Provincial Exhibitions, Ltd., was opened at the City Hall, Manchester, on November 16 and will remain open until November 27. Scientific exhibits have been obtained from the fuel departments of the universities of the north of England, from the Fuel Research Board, and from the Lancashire and Cheshire Coal Research Association, and there are models, diagrams, and photographs of special interest to those engaged in the mining and utilisation of coal. In connexion with the Exhibition, a Conference on Tar will be held on November 26; three sessions have been arranged, the chairmen of which are Prof. A. Smithells, chairman of the Fuel Section of the Society of Chemical Industry; Mr. T. Glover, president of the Institution of Gas Engineers; and Mr. E. Escott Wood, president of the Coke Oven Managers' Association.

THE Smithsonian Institution of Washington announces the dispatch of a botanical exploring expedition to Colombia under the leadership of Mr. E. P. Killip. Starting from Cartagena, the expedition will follow the valley of the Magdalena River to

Puerto Vilches and then cross over to Bucaramanga and Pamplona near the Venezuelan frontier. The expedition forms part of the programme decided on in 1917 by the Smithsonian Institution, the New York Botanical Garden, and the University of Harvard, for the systematic exploration of the four north-western states of South America, and continues the work begun in 1922 by Mr. Killip in the country around Buenaventura.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Two laboratory assistants at the Low Temperature Research Station, Cambridge—The Superintendent, Low Temperature Research Station, Downing Street, Cambridge (November 27). An assistant in mycology in the Pathological Laboratory, Harpenden, of the Ministry of Agriculture and Fisheries—The Secretary to the Ministry, 10 Whitehall Place, S.W.1 (November 29). A lecturer in chemistry at Armstrong College, Newcastle-upon-Tyne—The Registrar (December 1). Chemists, physical chemists and physicists for work under the Research Association of British Paint, Colour and Varnish Manufacturers—The Director of the Association, 8 St. Martin's Place, W.C.2 (December 2). An assistant lecturer in organic chemistry in the University of Leeds—The Registrar (December 6). A demonstrator in mathematics at the Royal College of Science, South Kensington—The Secretary, Imperial College of Science and Technology, South Kensington, S.W.7 (December 7). A professor of anatomy in the University of Lucknow—The Registrar (December 31). A principal of the Denbighshire Technical Institute—The Secretary and Director of Education, Education Offices, Ruthin (December 31). A lapidary (male) for the Department of Mines, Ottawa, Canada—The Secretary, Civil Service Commission, Ottawa, Canada (January 6). A professor of physiology in the University of the Witwatersrand, Johannesburg—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (January 31). A principal of the University College of Wales, Aberystwyth—General Secretary of the College (January 31). A lecturer in geography at the Bedford Training College—The Principal, The Crescent, Bedford. A lecturer in mathematics in the Gordon College, Khartoum—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1 (marked "Lecturer").

Our Astronomical Column.

COMET COMAS SOLA.—This comet is 1926 *f*, being the sixth to be detected during the year; but four of the six, also Neujmin's Comet, 1926 *g*, were periodic comets observed on their return to perihelion. Mr. G. Merton has photographed the new comet on two nights, and Mr B M. Peek sends the following notes on its physical appearance With a 12-inch mirror, power 200, the diameter of the nebulosity is 1′ using averted vision. Direct vision shows a coma of 15″ diameter, and a stellar nucleus of 12 mag, the total light being fully 11 mag.

Herr Ebell has deduced the following orbit, which is still uncertain owing to the distance of the comet and its slow motion:

T	1927, May 14·333 U.T.
	62° 48′
Ω	57 15
i	24 57
log *q*	0·24405

EPHEMERIS FOR 0^h U.T.

	R.A.	N. Decl.	log *r*.	log Δ.
Nov 21	40^m 25^s	7° 36′	0·4437	0·2614
29	32 25	8 19	0·4326	0·2548
Dec 7	25 6	9 11	0·4213	0·2518
15	19 8	10 13	0·4097	0·2528

The comet is well placed for observation, being on the meridian before midnight. It is likely to become an easy telescopic object during December.

MODERN ASTRONOMY.—The July issue of *Natural History*, the journal of the American Museum of Natural History (vol. 26, No. 4), is an attractive number devoted entirely to astronomy. Prof. S. A. Mitchell (Director of Leander M'Cormick Observatory) writes on total solar eclipses, of which he has seen six, involving journeys of 50,000 miles in all. The three latest American eclipses of 1918, 1923, 1925 are described in great detail. That of 1923 had the best weather prospects, but the least successful results. Beautiful coloured reproductions of these three eclipses, by Mr. Howard Russell Butler, are given. He describes his method of working in the second article. He notes that there are three factors of colour—brightness or value, prismatic hue, saturation. He makes rapid outline sketches, indicating in shorthand the values of these factors for each region, and works the picture up from these, using photographs to improve the outlines. He also reproduces a coloured picture of a lunar crater lit by a low sun. The sunlit portion is nearly white, with various faint tints. The part in shadow, lit by the sunlit walls and by the earth, varies from greenish brown to brown. The gibbous earth is shown, the ocean being blue, polar regions and solar reflection white, clouds and land light brown; the sky is dead black and star-studded.

Prof. G. E. Hale writes on solar tornadoes. He gives some beautiful spectroheliograms of prominences, filaments, and vortices, describing the paddle apparatus he has invented for imitating the latter. He mentions the curious change in polarity of sunspots at the beginning of new cycles, but points out that the change is not shared by the high-level hydrogen vortices, which seem to follow the same law of rotation as terrestrial storms. Incidentally, he refers to stars using their energy to build up the atom from electrons and protons. Inasmuch as other physicists are relying on the stars deriving their energy from the atom, to explain the immense duration of their life as suns, there would seem to be need of co-ordination, so that astronomers may not be liable to the accusation of forgetting the conservation of energy, and trying both to "eat their cake and have it."

W. J. Luyten writes on "island universes." He takes the recently adopted distances (ranging from a million light years) as fully established, and studies their size, etc., on this basis. He dates the "era of island universes" from Lord Rosse's discovery in 1845 of the great spiral nebula in Canes Venatici; but surely Sir William Herschel is entitled to the pioneer honours. Many of his estimates of the size and distance of these objects were of the same order as those adopted to-day.

Research Items.

ILLEGITIMACY AND RACIAL INVASIONS IN BRITAIN.—Dr. John Brownlee has published in *Man* for October an interesting note on the distribution of frequency in illegitimacy in the north of England and Scotland, and its relation to and bearing upon the evidence for racial migration. In the north of England there is a sufficiently close correspondence between the distribution of the round barrow and that of illegitimacy to suggest that this custom was introduced at the beginning of the Bronze Age, and that the invasion of Angles was not sufficient to do more than introduce a new racial element into this part of the country without modifying the custom Information on illegitimacy in Scotland has been studied in more detail. The range of variation is much greater, the highest percentage of illegitimacy occurring in Aberdeenshire and in the southern districts of Scotland, especially Dumfries and Galloway. The Aberdeenshire district contains a larger proportion of broad-headed persons than any other part of Scotland; but the broad-headed population of the Aberdeenshire tombs is more closely allied to the type of central Europe than is that of Yorkshire and southern England. The percentage of illegitimate to legitimate births is 12 to 15, a rate comparable with that of central Europe. In Dumfries and Galloway there is no broad-headed association, the population being the most narrow-headed in Scotland; but here a close association with a certain type of hill-fort appears. This type of fort belongs to some period about the beginning of the Christian era. In the Norse settlements, Orkney, Shetland, and the western islands, the illegitimacy rate is low, but there are pockets in the north, chiefly adjacent to the coast, where the rate is high.

FOSSIL APES AND MAN.—In the recent issue of the *Bulletin of the Geological Society of China* (Vol. 4, No. 2) Dr. Davidson Black reviews our present knowledge of the distribution of the primates, living and extinct, with special reference to the ancient geography of Asia and its bearing on the ancestry of man. He accepts the principles enunciated by Dr. W. D. Matthew in his well-known essay on "Climate and Evolution" published in 1915, and refers to them repeatedly in his discussion of the subject. He especially emphasises the fact that at any one time the most advanced members of a group of animals must be nearest the original centre of its dispersal, while its lowest or most conservative members are farthest from this centre. Dr. Black then shows on a series of maps the present distribution of the several groups of primates, with the few known records of their extinct representatives. Central Asia, north of the Himalayas, is thus suggested as the region in which they successively originated and from which they were dispersed. Finally, Dr. Black shows the distribution of the known fossils on six maps which represent the continental lands of the successive Tertiary periods, according to Dr. A. W. Grabau. A discussion of these maps leads to the same conclusion, and Dr. Black looks most hopefully to an exploration of the Tertiary sediments in the southern foothills of the Tian-Shan mountains for the discovery of remains of the immediate ancestors of man. Both geologists and anthropologists will await the result with great interest.

FERTILITY IN THE COMMON MULE.—Dr. E. Warren (*Ann. Natal Mus.*, vol. 5, pt. 3, 1926) records an interesting case of fertility in a mule about the authenticity of which there appears to be no doubt. The mule is the result of a cross between a jack donkey and a dark chestnut mare, and was in foal to a hackney stallion. It was eight years' old when it first foaled and is believed to be in foal again. It produced abundant milk and suckled its foal in a perfectly normal manner. Dr. Warren describes the sire, the mule dam, and the foal in some detail with special reference to the degree of likeness of the latter to each parent. He finds that the extent of the prepotency of the parents, and the dominance of the characters, with respect to features which are diagnostic of the two species, horse and ass, vary within wide limits and range from nearly complete dominance to perfect blending.

AUSTRALIAN BIRDS.—The second edition of the official check-list of the birds of Australia has now been issued by the Royal Australian Ornithologists' Union. It has been published only after considerable deliberations on questions of nomenclature by a representative committee of Australian ornithologists and adheres fully to the code of the International Commission. The list gives for each bird the accepted generic, subgeneric, specific, and vernacular name, the range in Australia and beyond, references to the original use of the accepted name and to the standard works of Gould, Mathews, and other workers on Australian birds. A very useful appendix gives the derivations, pronunciations, and origin of all the scientific names used. The work appears to have been very thoroughly and completely done, and, as it has been compiled after due consultation with Mr. G. M. Mathews, who has worked intensively in this field of late years, the list may be regarded as authoritative. As such, it will prove invaluable to ornithologists generally and to museums in particular.

PLANT GROWTH IN THE SEA.—The third number of the *Journal of the International Council for the Exploration of the Sea*, edited by Dr. E. S. Russell and published in Copenhagen in August, keeps up the high standard of interest and utility of the first two numbers. The present issue contains an article on chemical factors concerned in plant growth by W. R. G. Atkins, and original papers by P. Jespersen, Oscar Sund, and C. H. Roberts, whose observations on the rate of absorption of atmospheric oxygen through thin films of fuel oils show how rapidly this may occur, and indicate that oil pollution does not markedly slow down the oxygenation of sea water, although it may be directly harmful to marine animals, since all the oils tested were found to be toxic to fish. In the first article, Atkins correlates a large amount of information concerning chemical factors, most of which has been obtained during the past ten years, as may be seen from the bibliography of more than fifty references. The information has not been brought together previously, and compilations of this kind are much wanted. A point of general interest which has arisen from these researches is the great fertility of the sea; from changes in alkalinity and hydrogen ion concentration it is calculated that the suspended vegetable organisms in the open water of the English Channel every summer use sufficient carbon dioxide in photosynthesis to produce 3 grams of dextrose from every cubic metre of water, or 250 metric tons of dextrose over an area of 1 square kilometre. This corresponds to the annual production of 1400 metric tons wet weight of vegetable plankton organisms per square kilometre in this district, a value which is confirmed by the amount of phosphate utilised annually.

Starch Formation in the Presence of Different Salt Ratios.—The real complexity presented to the investigator by 'calciphobe' and 'calciphile' vegetation is probably well indicated by some recent experiments by Dr. V. S. Iljin upon starch synthesis in the presence of salts of calcium and sodium (*Bulletin de l'École supérieure d'Agronomie*, Brno, 1925.) Leaves of plants were immersed in weak solutions of maltose or glucose in the presence of varying concentrations of chlorides of sodium or calcium, and the concentration noted which brought starch formation to a standstill. Plants growing on soils of high calcium content still continued to form starch in the presence of high calcium concentration; on the other hand, even low concentrations of sodium salt prevented synthesis. Halophytes, on the other hand, continued to form starch in concentrations of sodium up to 0·35-0·5 *M*. Some species reacted in this respect at definite salt concentrations quite irrespective of the nature of the soil on which they were previously growing, whilst other species behaved quite differently when taken from soils rich or poor in calcium. Iljin concludes that we may not speak of 'phily' or 'phoby,' but only of the degree of tolerance of the plant to the injurious action of some salt. A plant particularly resistant to such injurious action may be placed at a considerable advantage in the struggle for existence in a soil in which the salt in question is present in a relatively high concentration.

Inheritance of Melanism in Lepidoptera.—Heslop-Harrison (*Journ. of Genetics*, 17, 1, 1926) continues the description and discussion of his remarkable experiments upon the inheritance of wing colour and pattern in the lepidopteran genus Tephrosia. He finds that, in interspecific crosses between *T. crepuscularia* × *T. bistortata*, melanism, introduced by the latter, remains, as it does within the limits of a species, a Mendelian recessive; that the progeny carrying two female characters (♀♀) out of a *bistortata* (female) × *crepuscularia* (male) mating are non-viable; that in back-crosses between *bistortata* (♀♀) and the two possible of the F_1 generation carrying two male characters (♂♂), one half of the ♀♀ dies; and that in the reciprocal *crepuscularia* (♀) × *bistortata* (♂♂) crosses, the sex-ratio among the offspring is undisturbed.

The Infection of Tree Roots by *Armillaria mellea*.—This root rot is one of the most serious of tree parasites and is usually assumed to enter through a wound. Considerable interest therefore attaches to the observation of S. M. Zeller (*Phytopathology*, 16, 479-484, July 1926), who gives grounds for thinking that if an infected root runs across a healthy root, even when both are of considerable age, infection gradually spreads to the healthy from the diseased root, layers of dead flakes being sloughed off the surface of the healthy root as new cork layers are formed in the bark parenchyma. With prune trees, evidence has also been obtained of the entry of the fungus through the little collar around the base of the emergence of a branch root, presumably as the result of the rupture of the bark parenchyma of the parent root during the emergence of the lateral.

The Possible Identity of different Mosaic Diseases.—An important paper upon this subject by M. N. Walker appears in *Phytopathology* (16, 431-458, July 1926). Cross inoculation with the mosaic diseases of cucumber, tomato, and physalis confirms other accounts as to the difference in behaviour of the virus in the expressed juices of these plants; thus tomato and physalis juice withstand ageing, drying, dilution, etc., whilst the virus of cucumber juices is much less resistant to such treatment as drying. On the other hand, the disease on tomato produced by injecting with cucumber mosaic shows the usual properties of tomato mosaic, and, conversely, the disease on cucumber obtained after inoculation from either physalis or tomato shows the usual great susceptibility of the extracted virus in cucumber juice. The conclusion would appear to be that the infective principle in each case was the same, and the differences in the properties of the extracted virus are to be attributed to the properties of the juice of the host plant.

A Tertiary Inter-basaltic Flora from Western America.—Dr. F. H. Knowlton has studied the fossil flora of the beds of clay and shale, named the Latah formation and found in Washington and Idaho (*U.S. Geol. Survey Prof. Paper* 140-*A*, 1926). These beds were formed by the obstruction of the drainage due to the advance of the great lava flows of the Columbian plateau, and are in places overlain by a later series of flows. The plants are unusually well preserved and are of interest as affording evidence bearing on the age of the lavas. Ninety-five forms are recognised, of which 51 are regarded as species new to science, 25 as species found in other areas, and 18 are not named specifically. As a whole, the flora is very modern in appearance, the oaks, elms, maples, and poplars being similar to certain living forms. Taxodium was one of the most abundant forms, and a Sequoia is also common, while Ginkgo is represented by a few specimens. Most of the new species are founded on remains of leaves, but a considerable number of remains of reproductive structures are present, some of which have not been specifically identified. The floras are regarded as showing affinities with those already described from beds of Miocene age. The diatoms of the deposit are described by Dr. A. Mann, who describes 11 new species and some interesting twin forms.

New Theories of the Mother-Rock of Californian Petroleum.—In any oilfield the point of chief theoretical interest is the original source of the oil and the character of the organic matter whence it was derived. Since 1907 the generally accepted theory ascribed the bulk of Californian oil to Miocene diatomaceous shales, and the example has been used repeatedly to illustrate an almost ideal mother-rock, and further an advancement of the hypothesis of marine organic origin of petroleum. With the development of the great oilfields of the Los Angeles Basin, however, there has latterly been some doubt raised as to the validity of the diatomaceous shale theory; in fact, in one case, that of Santa Fé Springs, it would seem to be established definitely that the oil originated in younger formations, namely, the clay-shales of the Fernando group (Pliocene), since the deepest well, drilled to 7215 feet, was not abandoned until it was 2500 feet below the top of the rich oil-bearing sands, the last 1000 feet being barren beds; at the bottom of the well some fossiliferous Fernando beds were proved, thus showing that the Miocene (Puente) shales had not been reached. It is reasonably argued that the great thickness of barren beds present in the lower part of the Fernando formation inhibits the theory of a Miocene mother-rock for the Santa Fé Springs oil, since, had this older horizon been competent in this respect, the Fernando sands would have been successively richer in depth. The fact that Santa Fé Springs has been one of the largest oil-producing fields in the world (for many months in 1923 it was giving a daily production of more than

42,000 tons of oil), is further significant. Recent papers of G. C. Gester, J. E. Eaton, G. E. Cunningham, and T. F. Stipp in *Bulletins of the American Association of Petroleum Geologists* have done much to create the doubt of alleged oil-source in this region, in fact throughout California; but with the appearance of W. A. English's *Bulletin* (*No. 768*) on the Puente Hills Region (which includes part of the Los Angeles Basin), recently to hand from the United States Geological Survey, the alternative theory receives official support, and it is clear that we must prepare to modify considerably our faith in diatom-shales as ideal mother-rocks. Foraminifera, not Diatomacea, are the prominent organisms of the Fernando beds, especially of the oil-measures.

COEFFICIENTS OF EXPANSION AT LOW TEMPERATURES.—An accurate knowledge of the coefficients of expansion of solids at low temperature is necessary for testing theories of the solid state, and R. M. Buffington and W. M. Latimer have obtained expansion data for aluminium, copper, silver, rock salt, quartz parallel to the optical axis, and pyrex glass between 90° and 315° K. The Fizeau interference method was used, and a full description of the investigation is published in the *Journal of the American Chemical Society* for September. The coefficients of expansion of the crystalline solids, which change slightly more rapidly than do the specific heats, approach zero at low temperatures, in agreement with the prediction of Nernst. It was possible, from the data on aluminium, copper, and silver, to introduce terms depending on the constraints between the atoms into the equation for the entropy of solids, and the entropies of six monatomic solid metals are shown to be satisfactorily represented by the new equation.

PHOTOGRAPHY AT LOW PRESSURES.—The May issue of the *Memoirs of the Kyoto College of Science* contains a paper by Osamu Masaki on the effects of low pressure on the sensitivity of the photographic plate. Two pieces cut from the same plate were enclosed in two compartments in a glass-fronted brass box. The pressure in one of the compartments could be reduced to that of 0·005 cm. of mercury. The box was placed behind a rotating Hurter and Driffield wheel, the openings in which exposed strips of the plates for times in the ratio 1, 2, 4, 8, 16, etc. to the light of a 50-watt incandescent electric lamp of milky glass placed a metre away. The density of the film after development for 3 minutes was measured by means of a photoelectric cell and electrometer. In almost all cases the plates were more sensitive under reduced pressure, the effect being greater for slow than for fast plates. The reduction of pressure also reduced the tendency to fog. The greater part of these effects appears to be due to the drying of the emulsion, but some part is played by the removal of occluded gases under the reduced pressure.

VELOCITIES OF DIFFUSION IN GELS.—The *Science Reports of the Tôhoku Imperial University* for July 1926 contain a paper by M. Watanabé on the relation between the diffusion velocity and the concentration of the diffusing substance. The equation $K = m\log C + n$, in which K is the value of $d/\sqrt{t}$ at the beginning of diffusion (d being the distance of the diffusion in time t), C the original concentration of the diffusing substance, and m and n constants, was found to hold at the beginning of diffusion of a salt from solution into a gel containing a reacting substance. O. von Fürth and F. Bubanovic consider that the equation holds if $K = \log d/\sqrt{t}$. For a limited range of concentrations it is clear that both formulæ apply, and Watanabé shows that this is due to the diffusion of the substances dissolved in the gel, which renders the results inaccurate. When a colloidal reactant was used the formula $d/\sqrt{t} = m\log C + n$, was found to apply over a wide range of concentration, while Fürth and Bubanovic's expression is limited to a few concentrations. In a further paper in this journal the formula is applied to the results of experiments on the diffusion of mixtures of copper and zinc sulphate solutions.

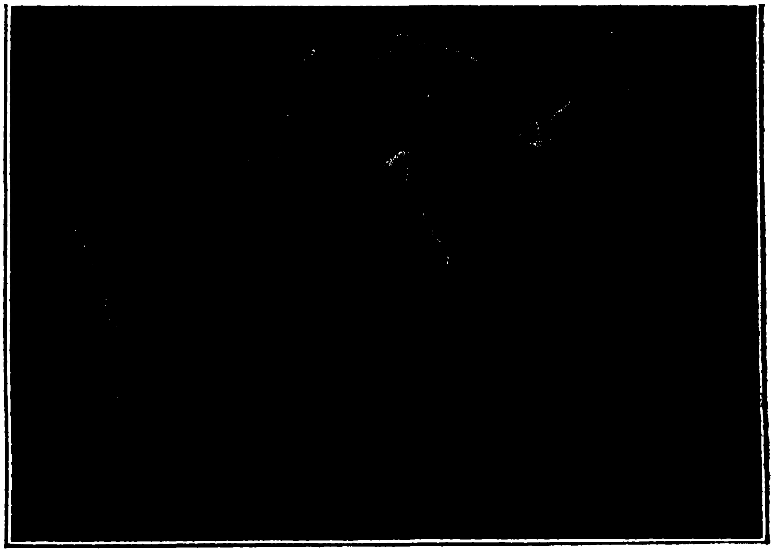
THE RATE OF REACTION OF NITRIC OXIDE AND OXYGEN.—H. B. Baker has shown that carefully purified and dried nitric oxide and oxygen do not react; but under ordinary conditions combination takes place rapidly, and W. A. Patrick and R. L. Hasche have studied the effect of increased glass surface on the reaction velocity. In the *Journal of the American Chemical Society* for September, Hasche describes further experiments in which the influence of a paraffin-coated reaction chamber, and moisture, sulphur dioxide, and nitrogen tetroxide have been measured. It was found that moisture increased the speed of combination, and the decrease in velocity caused by the paraffin surface is thought to be due to a decrease in the amount of moisture. In the absence of water vapour, a period of induction of about 10 sec. was noticed at initial partial pressures of less than 14 mm. The effect of sulphur dioxide and nitrogen tetroxide was negligible.

HEAT LOSS AND FRICTIONAL RESISTANCE IN AIR CURRENTS.—The relation between the heat lost by a hot surface when cooled by a current of air passing over it, and the frictional resistance experienced by the surface, has been subjected to investigation by many research workers. So early as 1874 Osborne Reynolds examined this question. That such a relation may exist appears clear from the fact that both the frictional resistance and the heat transference occur in association with the passage of momentum in the air in the neighbourhood of the surface. A further contribution to this subject has appeared in the Aeronautical Research Committee Report, R. and M. No. 1004 (H.M. Stationery Office, 1s. net). In this paper Miss D. Marshall has recorded two distinct series of tests. In the first place a short heated section of pipe, 5 in. in diameter, was cooled by a current of air forced through it, the heat transmitted being estimated from the rising temperature of the air. In the second test, thin rings of nickel heated electrically were supported in a wind channel, the transmitted heat being measured from the energy supplied to the ring. In this latter case the effect of artificially roughening the surface of one of the rings was specially investigated. In common with previous experiments, a considerable discrepancy is found to exist between the observed heat transmission and that calculated from the measured surface friction, a difference of 20 per cent. being found in the case of the smooth rings. In the case of the roughened rings, however, fairly close agreement is found over a considerable range of speed. Thus it will appear that the effect of surface roughness is much greater than would be anticipated, the dimensions and form of the irregularities constituting quite an important factor. The investigation must prove of considerable interest in its bearing on the surface friction of thin plates in the neighbourhood of the leading edge, for these results are in fairly good agreement with the law of surface friction deduced by Blasius from Prandtl's theory of the boundary layer. This agreement extends both to the law of variation of frictional resistance with speeds and the actual value of the forces.

Progressive Lightning.

DR. N. ERNEST DORSEY (*Jour. Franklin Inst.*, **201**, pp. 485-496, April 1926) in America, and Dr. G. C. Simpson (*Proc. Roy. Soc.*, A, vol. 111, No. 757, May 1926) in England, have recently published papers in which they have discussed from theoretical considerations the start and progress of a lightning flash, and in a recent number of NATURE (August 7, p. 190) these two authors discuss the question again, and even if they do not arrive at opposite conclusions they, nevertheless, are not by any means in accord.

So long ago as 1900 I made some apparatus with a view to obtain by experimental means, if possible, some evidence as to the progressive character of the lightning flash; but before dealing with this I think it well to refer the two authors to a paper by Dr. H. H. Hoffert (*Proc. Phys. Soc.*, **10**, 1890, pp. 176-179) which appears to me to bear on the subject, and which I think they have overlooked. Dr. Hoffert desired to test an assertion which I had made in a discussion on a paper by Mr. Whipple (NATURE, May 16, p. 71, 1889), to the effect that very often the lightning flash was multiple; two, three, or many more succeeding one another very rapidly along exactly the same path, which I thought was obvious to every one, but the truth of which, nevertheless, was not readily accepted. He therefore exposed a camera during a very heavy thunderstorm in the direction in which the frequent flashes were seen, and kept it waggling rapidly to and fro. So far as he knew, he exposed the plate to a single flash only. In the first place he obtained a triple photograph of the flash he had seen, the three images being widely separated. They are all identical in form, bea.ing out fully what I had said, but the photograph showed much more than this, and it is these other points that bear, so I think, on the later theoretical discussion. I have three prints which Dr. Hoffert gave me at the time, which are entirely untouched.



The print accompanying the paper is exceedingly faithful and true for the purpose of illustration, and there is a skeleton diagram with reference to which Dr. Hoffert gave a very full discussion of all that is shown. The point of greatest interest in connexion with the controversy above mentioned is the almost certain conclusion that a flash within the cloud and terminating (or starting ? C.V.B.) at a point from which the main flash started preceded this by a very evident interval. The other point of interest is that this region remained luminous all that time and until the third main flash had occurred; also that the more marked angles in the main flash, which may have been foreshortened portions directed towards the camera, also remained luminous in the intervals between the three main flashes. These were more in the upper part of the flash from which branches directed towards the ground emanated, and the branches were far more conspicuous in the first of the three main flashes. The lower part was devoid of branches and of continuous luminosity. Reproduced herewith is one of Dr. Hoffert's prints (Fig. 1), but I doubt if the more delicate features can be reproduced. It would be better added to Dr. Simpson's collection if it interests him.

Before describing my apparatus of 1890 I should like to refer to an observation which I made about the year 1876, as in a life's observation of lightning the phenomenon then accompanying every flash is one which I have seen on no other occasion. It may have some bearing on the conclusions of the two authors. A storm one evening in the autumn had passed directly over the village of Wing in Rutland and moved away to the north, leaving a clear starlit sky above the thundercloud, with the stars of the Great Bear in their lowest position far above. When the storm was distant about ten miles and more, for every flash seen in the rain cloud and below, and simultaneous with it, there were one or more very slender flashes of typical lightning form from the cloud upwards and many times as long as the usual kind of lightning below. According to my recollection, these reached one-third or perhaps half-way towards the stars of the Great Bear, and in one instance there were seven of these flashes going simultaneously into the clear sky.

Coming now to the year 1900, I wished to obtain some experimental evidence, if possible, of the progress of the lightning flash. The impression that there is a downward direction in a flash is very common, and occasionally observers believe one has an upward direction. Without paying too much attention to impressions of this kind, and yet not ignoring them altogether, I desired to make a conclusive test, and to get any information possible as to the beginning or to the progressive character of the flash. The scheme was to use a pair of identical camera lenses (specially selected for stereoscopic photography) and to mount these on a disc which could be rotated by hand through gearing at any desired speed. In the apparatus I then made I could drive them at any speed up to about forty turns a second. The lenses were four inches apart, centre to centre; the two images of a lightning flash would then be carried in opposite directions at any speed up to about forty feet per second, and if the flash in each part of its length should be 'instantaneous' a difference in time between the two ends of the flash of about $\frac{1}{10000}$ second would be observable. If, for example,

the flash were a vertical line and the lenses at the moment were one above the other, one image would be tilted in one direction while the other would be tilted in the other direction, and the more so the greater the duration. If the lightning were not at any part 'instantaneous,' by which I mean if it lasted long enough for its image to be broadened —that is, $\frac{1}{40000}$ second or more—the two images would fade away, but on opposite sides, and the sharp side would still be available for comparison. If the lenses should happen to be on the same level, then one image would be lengthened and the other shortened, and measurements between well-defined kinks would show this. Similarly for other positions of the lenses there should be both tilting in opposite directions and change of length. If the duration of the illumination at each point in the flash should be sufficiently short the stereoscopic method of observation seemed to promise to be most convenient. For this purpose it would be necessary to cut a print, taken from the 10×8 backed plate used to receive the images, into two parts, and to slide the two parts so as to bring the two images to stereoscopic distance, and so that the motion due to the lenses was parallel to the line joining the eyes. If then they were maintained strictly parallel to their former positions, the effect of the movement due to the lenses, if apparent, would be to make the stereoscopic image appear to leave the plane of the paper; and owing to the extreme delicacy of the stereoscopic sense, this might be as valuable a test as a micrometric one and much more convenient.

I made this apparatus in 1900, and carried it about with me, for example, to the British Association meeting at Glasgow the following year, and only once obtained a moderately good view of a few flashes, but the developed plates showed nothing at all! Though I have had this now for twenty-six years, I still have not succeeded in obtaining any photograph. It had been my intention to go on until I did get a result before describing the method, but as I now have no window in London with a good sky view, and in my present house at St. Marybourne in Hampshire, while I have all the sky there is, I have no 'compact' storms such as we so often have in London. For twelve years I have not seen a storm in which the lightning is fairly frequent and in one direction, which is what I mean by 'compact,' and therefore if any results of interest are ever to be obtained in this way they must be by some one else. If Dr. Simpson thinks the method worth following, the apparatus with the 10×8 double back, which it is made to take, is freely at his disposal.

In the case of a multiple flash on the same track the different pairs of images would be at altogether different azimuths, and the wheel of lenses might well have made more than one turn between each. They would therefore in no way clash when examined. There might, however, be a marked difference between the first and succeeding flashes if the first showed any sign of progressive character due to the operations discussed by Drs. Dorsey and Simpson. The first flash has certainly left the whole track conducting, and succeeding flashes therefore might well fail to show any such progression.

There is one more experiment which I have wished to make with this apparatus. This is to fire a rocket towards or into a thundercloud when it is getting ripe for another flash. The ordinary display rocket would do perhaps, especially if its head were removed and its stick lightened. I should, however, prefer to make suitable rockets on purpose with perhaps an extra calibre of composition over the spindle and no head. Such a rocket would go at an immense speed to twice the usual height if undisturbed by lightning on the way, leaving a conducting trail of potash smoke and ions of every kind. A six-oz. rocket ($\frac{7}{8}$ inch) or a half-pound (1 inch) would be the most convenient to use. The pound rocket ($1\frac{1}{4}$ inch) is more difficult to make, but it would be very persuasive, while a 3 lb. rocket ($1\frac{3}{4}$ inch), the largest within my experience, is too much of an undertaking and too dangerous in its descent to be lightly selected.

If a photograph were obtained with the revolving lenses of a flash striking a rocket a good way up, the rocket itself might be expected to be the place of origin of the flash, and this position would be obvious on the plate, as below this the lightning would no doubt follow the rocket trail.

Rocket-directed lightning also would be good for spectrum examination, as a prismatic camera could be employed with certainty as to time and direction. There might be some indication of potassium in the spectrum below the rocket, and a great splash of potassium at that place if the lightning got inside and fired the remaining charge all at once.

To fire such a rocket, the only safe plan would be to pull a string lying on the ground and leading to a striker at the rocket. No slow match would work at the desired instant, and electric communication by wire would be too dangerous. I am unable to make the rocket experiment as I am in a village of thatched houses.

C. V. BOYS.

The Detection of Icebergs.

THOUGH navigation in iceberg-infested waters has been recognised from early times to be fraught with special dangers, it is only comparatively recently that attempts have been made to apply scientific methods to the detection of these floating dangers to navigation. Early whalers and explorers in Arctic and Antarctic waters met and surmounted these dangers without such assistance, but the present circumstances of sea travel in waters occasionally subject to invasion by icebergs are so different as to render special precautions necessary. Some of these circumstances are the increasing size and speed of passenger vessels, the replacement of wooden hulls by steel, and the need, in the face of competition from rival steamship companies, to complete the voyages within scheduled times. The small ice 'growler,' floating almost submerged, is not only the most difficult to detect, but is also almost as dangerous an obstruction to modern steel ships as the iceberg of large dimensions, which is likely to be more readily perceived even in a fog.

The apprehension of the need for early warning of the approach of the ice has been especially lively since the *Titanic* disaster in 1912. This disaster led directly to the formation of the International Ice Patrol, which now maintains a continuous patrol during the ice season in the dangerous area of the North Atlantic. This organisation is maintained by the United States, the countries chiefly concerned contributing to the cost in proportion to their shipping tonnage. At present the chief duties of the Ice Patrol are: The continuous location of ice endangering the shipping lanes, and dissemination of relevant information to vessels approaching the danger area; oceanographical

work associated therewith; the investigation of various devices and aids to the location of casual icebergs, and of the waters of polar origin in which they are found.

The early experiments of Profs. Barnes and L. V. King on the detection of icebergs by temperature differences in the neighbouring sea water, which were carried out with the assistance of the Canadian Government, seem to have been unsuccessful, since we find that attention is now being concentrated on underwater echo methods of detection similar to those used for echo sounding. These methods formed the subject of a recent illuminating article in NATURE, May 9, 1925, p. 689. In the 1925 season an echo sounder of U.S. Navy type was tried by the Ice Patrol, and it was established that weak echoes could be obtained from a large iceberg in favourable circumstances at a maximum range of 2500 yards, the echoes being, however, first reflected from the bottom of the sea. 'Growlers' and very small bergs did not reflect well under normal conditions.

In the meantime, it is encouraging to note that the Canadian Government and the Research Council of Canada have afforded Prof. Boyle and his co-workers the financial and material assistance which has enabled them to institute a series of fundamental investigations[1] on the properties of ultrasonic (high-frequency) sound waves in water. Some tests have also been carried out at sea. The investigations included the measurement of the energy in an ultrasonic sound beam in water by means of a torsion pendulum, together with the measurement of the energy reflected from various materials, such as steel, various types of rock, and ice immersed in the water. The lateral distribution of energy in the sound beam has also been determined in this way. One of the most striking experiments has been the production of stationary waves in a small tank, which were made evident by the pattern formed on a tray by the dust of coal cinders which had fallen slowly through the acoustic energy field above. This method of rendering visible the interference pattern due to the combination of direct and reflected beams has been utilised to check the values of the coefficient of reflection from different substances by decreasing the energy output of the transmitter until a definite pattern just failed to form in the case of each reflector.

The experiments showed that ice was, of the materials tried, the worst reflector of sound. This, indeed, was expected from the fact that the products (density × velocity of sound) for ice and water differ little from one another. The circumstance that ice in its natural condition contains a considerable amount of included air in the form of bubbles held under pressure will, however, tend to make the detection of icebergs by echo methods less unpromising than might be judged from calculations on the basis of the data relating to pure ice, while the variations in temperature and salinity in the water surrounding a melting berg must also be taken into consideration.

The final report details the results of some practical trials to determine the range of iceberg detection at sea by the use of a high-frequency sound transmitter fitted on the s.s. *Montcalm*, a vessel maintained by the Department of Marine and Fisheries of Canada. It was anticipated that the small transmitters used would enable echoes to be obtained from rocks at a range of about 1000 yards, and this estimate was found to be justified. Echoes from a medium-sized iceberg were detected at a range of only 250 yards, but echoes due to multiple reflections between the berg and the ship were observed in other cases at a distance of 150 yards. In spite of this statement, it is clear that a very accurate measurement of time interval between echoes must be made before the explanation of the cause of the multiple echoes can be accepted. It is stated that the tests, which were carried out in shallow water, showed that echoes from the bottom and surface of the sea were a source of disturbance up to and beyond the time of arrival of the echoes from the iceberg.

The results obtained by Prof. Boyle are promising in that more powerful transmitting apparatus has already been constructed by him. Whether a reasonable increase in power will permit detection of the smaller icebergs and 'growlers,' which must be considered the most dangerous types of ice, can only be decided by further practical experiments at sea. In view of the attitude already displayed by the Canadian Government and by the Research Council of Canada, there is room for little doubt that Prof. Boyle will be enabled to continue his investigations to a point which will decide whether the directional high-frequency, or the relatively non-directional low-frequency, sound beam is better adapted for the detection of floating ice. The Total Solar Eclipse of January 14, 1926.

A JOINT meeting of the Royal Society and Royal Astronomical Society was held at Burlington House, London, on Thursday, November 11, to discuss the results obtained by the British eclipse expedition to Sumatra in January of this year. The Astronomer Royal opened the discussion with an account of the coronal pictures obtained by various eclipse expeditions in the past sent out from the Royal Observatory, Greenwich. In addition to the well-known changes of form with the solar cycle, he pointed out the close connexion of certain prominences with arches in the corona, and also certain changes detected as taking place during an eclipse, as seen from a comparison of plates taken at widely distant stations.

Mr. C. R. Davidson gave an account of the instrumental arrangements made for the Sumatra observations (see NATURE, February 27, p. 306), and of the chief results obtained from it. A study of the objective-prism spectra obtained by Col. J. Waley Cohen with a camera of 38-foot focal length, and by Dr. F. W. Aston with a 19-foot camera, gives the heights to which the different elements can be traced, the observed heights being in general accordance with previous results. The coronal rings show evidence of intensification in the neighbourhood of several prominences; the brightening does not quite coincide either in position or in form with the prominences, but some close relation seems to be indicated. The plates taken with the Grove-Hills flint slit-spectroscope do not go beyond the oxygen triplet at λ 7772. The dicyanin stain failed to work satisfactorily under the conditions of heat and damp prevalent in Benkulen. The wave-lengths of the two coronal lines in the green and the red were determined as 5303.4, 6374.1 I.A.U. The flash spectrum obtained by Mr. Davidson with the Grove-Hills quartz slit-spectroscope extends down to λ 3066. The lines have been measured and

grouped in series, where the data are available. In the coronal spectrum obtained with the same instrument, the lines from a high prominence, which also appear on the plate, gave an excellent scale for the coronal wave-lengths. These have been determined as 3387·95, 3454·11, 3601·03, 3642·87, 3800·77, 3986·82, and 4086·30 I.Å.U. The relative brightness of the lines of the corona differs from the values found in previous eclipses, but it is easily apparent that the lines themselves differ in the distribution of intensity with height above the sun's limb.

Mr. Stratton gave an account of the photometric work which has been done, by the kind permission of Prof. L. S. Ornstein, by Dr. Minnaert and himself on the ultra-violet slit-spectra with the aid of the Moll spectro-micro-photometer at the physical laboratory at Utrecht. The trustworthiness of the actual measures of intensity of the lines have been tested by examining certain multiplets which have been found to have relative intensities in close accordance with their proper values. The intensity of the K line has been measured at eight different heights and a satisfactory accord found over a range 30,000 km. to 100,000 km of height with the theoretical value calculated by Mr. P. A Taylor from Prof. E. A. Milne's theory of the chromosphere. The coronal lines also have been measured for intensity at different heights, and curves plotted connecting the intensity with the height. The lines were divided into three well-marked groups; the extreme groups confirmed the results found some years ago by Sir Norman Lockyer through a study of variations in the coronal rings from different sources. Attempts have been made from a study of line intensities to determine the temperature of the sun at different levels. In the Balmer series an application of Schrödinger's formula has given a temperature which decreases as the height above the sun's limb decreases. The temperatures deduced cannot be accepted, but what the observations gave was a measure of the weakening at lower levels in the chromosphere of the lines in the Balmer series corresponding to the atoms with the larger orbits. This weakening was to be expected from the increased ultra-violet radiation from the sun streaming through these lower layers; its extent has now been measured. Balmer lines from Hδ (6) to H 29 have been used in this work. The hydrogen continuous spectrum which extends towards the violet from the head of the Balmer series has also been examined. From this a measure of the temperature (the distribution of the velocities of the electrons) was possible. The value thus found, 1700° K. at 8000 km. height, is too low, as checked by a cross-determination from the relative intensities of certain ionised titanium lines at that same level and in the low level of the flash spectrum. One further result of interest in the photometric work is a study of the continuous spectrum in the low corona or high prominence at a height of 20,000 km. In agreement with the result obtained by Deslandres in 1893, this continuous spectrum when compared with that of a black body gave a lower temperature than the sun's temperature. The result is consistent with Ludendorff's recent work on the distribution of intensity in the continuous spectrum of the corona, which he finds to be unaltered from that of the sun. But Ludendorff's results come from much higher layers and are consistent with the light being scattered by electrons. The suggestion is that at the lower layers concerned the light is, partly at least, affected by Rayleigh scattering from atoms.

Prof. Ornstein raised the point whether a formula due to Miss Bleekers which fits many laboratory spectra need be rejected because when applied to the Balmer series it gives a negative temperature. This is very little different in reality from the extremely low temperatures given by the Schrödinger formula. Both formulæ make it clear that some disturbing factor is affecting the relative intensities of the lines, which clearly do not correspond to thermodynamical equilibrium. He welcomed the co-operation in this work of physicist and astrophysicist.

Dr. Minnaert dealt with the problem of comparing intensities at different wave-lengths and urged the necessity of extending our knowledge of a trustworthy curve of the intensity of the solar radiation for different wave-lengths. Abbot has not used sufficient resolving power to meet present requirements of spectrophotometers, and H. H. Plaskett's work needs to be extended more towards the ultra-violet. It is desirable that astrophysicists living in suitable climates should make further measures by photographic methods, if full value is to be obtained from future eclipse records.

The president of the Royal Society, Sir Ernest Rutherford, expressed his appreciation of Mr. Davidson's beautiful photograph of the Balmer series and of the kind co-operation of the Dutch scientific workers in reaping the fruit of the eclipse expedition, their own expedition having failed through bad weather conditions. It is the first time that intensity measures have been made on eclipse spectra; and the possibility of this has been due to the work of Prof. Ornstein and his colleagues at Utrecht.

Prof. Newall expressed great pleasure at hearing from the Astronomer Royal that Mr. Wesley's drawings of the corona are to be reproduced, and added his view that Mr. Davidson's ultra-violet spectra are the best yet achieved in eclipse work. He, too, welcomed the co-operation with the Dutch physicists and astrophysicists.

Prof. Fowler expressed admiration for the photographs, and pointed out with what refinement the adjustments must have been made. The photographs seen that day were remarkable for the large size of the solar image, and they should add considerably to our knowledge. He was interested to hear about the suggested relation between the coronal intensity and the prominences, as there is no evidence for it in earlier eclipses. The increased accuracy of the wave-lengths of the coronal lines should help in the further investigation of their source What is now required is higher resolution and more powerful instruments. Longer exposure is necessary, and this could be obtained by working on the edge of the belt of totality or even outside it.

Prof. Milne pointed out that the theories being tested at this eclipse are all of very recent growth. Prof Ornstein must feel gratified that his contribution is bearing fruit so soon. It is possible that some of the theories of solar physics will need to be revised. He was much interested in Mr. Taylor's results. It is clear that radiation pressure must play its full part in supporting the atoms at high levels if the chromosphere reaches the heights indicated. The low temperatures found at the lower levels of the sun only indicate that the fraction of the more highly excited atoms there is less than it would have been if the atmosphere had been in thermodynamical equilibrium. If the distribution of intensity in the continuous spectrum is due to atomic scattering, then it looks as though the prominence must consist of a mass of material thrown out with a comparatively high density.

Mr. R. H Fowler suggested that it is the laws of a perfect gas that are failing at lower levels rather than those of thermodynamical equilibrium. He had made a rough numerical estimate of the falling off of

intensity of lines of the higher quantum numbers and compared it with Urey's correcting factor. That will account partly for the result expressed in terms of the parameter, T, as indicating a lower temperature.

Prof. Lindemann supported the view that the future of eclipse work lies with photometry rather than with the determination of wave-lengths. In discussing the continuous light, the possibility of light-scattering in the instrument should be borne in mind. He would like to see a negative temperature gradient in the sun, such as might fit the demands of convective equilibrium.

Dopes and Detonation.

WE have received a copy of the Air Ministry Reports and Memoranda, No. 1013, by H. L. Callendar, R. O. King, and C. J. Sims, published by H.M. Stationery Office. The primary object of the investigation which is described was the determination of the physical actions that delay or prevent detonation in the cylinder of an internal combustion engine.

The addition to petrol of non-detonating fuels, such as benzene, has long been familiar as a means of checking the onset of 'pinking' in a high-compression engine. In the case of benzene a large addition is required; alcohol and toluene are more effective than benzene by about 50 per cent., though they still appear to act mainly by dilution of the original fuel.

There are, however, other classes of substances, many times more effective than toluene, the action of which cannot be explained by dilution. Thus, in the case of lead ethide, the addition of 0·25 per cent. by volume is nearly as effective as 100 per cent. of toluene. Nickel carbonyl shows a similar order of effectiveness.

The action of such 'dopes' must evidently depend on some specific property requiring further investigation. It has been shown that the heavier paraffins, on account of their high critical temperatures combined with low critical pressures, are exceptionally liable to persist in the form of nuclear drops, which serve as foci of simultaneous ignition by compression owing to their low ignition temperature. The marked effect of pressure in promoting detonation is explained by the rapid increase of nuclear condensation with increased density of charge. The action of a dope in delaying detonation is to 'infect' the nuclear drops in such a way as to delay their ignition. The fact that these drops form a small percentage of the whole mixture helps to explain the possibility of a relatively small quantity of the dope being effective. It has been shown that lead ethyl and nickel carbonyl, two of the most effective metallic dopes, when mixed with petrol residues, decompose rapidly at temperatures above 200° C., depositing a film of metal on the surface of the liquid. This metallic film would tend to protect the nuclear drops from oxidation, and would help to keep down their temperature by reflecting radiation.

Organic dopes, such as methylaniline and xylidine, have the advantage that much higher compression ratios can be employed than in the case of metallic dopes without risk of fouling the engine with deleterious deposits. On the other hand, much larger quantities are required than in the case of lead ethide. Organic dopes probably act mainly by the dilution of the nuclear drops, which results in a rise in the ignition temperature; but the chemical reactions which may occur are very complicated and require further investigation.

University and Educational Intelligence.

CAMBRIDGE.—Honorary degrees are to be offered to the Maharajadhiraja Bahadur of Burdwan, the Right Hon. W. L. Mackenzie King (Prime Minister of the Dominion of Canada), the Right Hon. J. G. Coates (Prime Minister of the Dominion of New Zealand), and to Mr. W. T. Cosgrave (President of the Executive Council of the Irish Free State).

Amongst those elected to the Council of the Senate are Sir H. K. Anderson, Dr. T. C. Fitzpatrick, Prof. A. C. Seward, Mr. T. Knox Shaw, and Mr. F. J. M. Stratton. Mr. R. E. Priestley, Clare College, assistant registrary, has been elected secretary of the general board of the faculties, a body that is to be elected for the first time on November 30.

Mr. W. H. Florey, lately John Lucas Walker Student and Rockefeller Research Fellow, has been elected to a fellowship at Gonville and Caius College.

MANCHESTER.—The Council has made the following appointments: Dr. William Susman, to be lecturer in morbid anatomy and histology; Mr. C. J. Polson, to be assistant lecturer in chemical pathology; Mr. A. M. Downie, to be assistant lecturer in bacteriology; Dr. F. A. Mason, to be lecturer in tinctorial chemistry and dyestuffs; Mr. Arthur Riley, to be assistant lecturer in textile engineering; Mr. F. W. Bailey, lecturer in papermaking.

Dr. Ivar Waller has been awarded an honorary research fellowship in physics.

Dr. James A. Bowie has been appointed Director of the Department of Industrial Administration in the Manchester College of Technology. After the War, Dr. Bowie was appointed lecturer at the College, where he devoted his attention to industrial relations with special reference to problems of wages, profit-sharing, and copartnership.

THE Universities of South Africa form the subject of an article by Prof. H. Clement Notcutt, of the University of Stellenbosch, in the October number of the *University Bulletin* (issued by the Association of University Teachers). It is pointed out that whereas the Act of Parliament which brought the Union into existence provided that the English and Dutch languages should both be "official," Afrikaans, which differs from the Dutch of Holland both in vocabulary and in syntax and is the home language of a large part of the inhabitants of Dutch descent, has recently been given by Parliament the same status. Consequently there are now three official languages. In the schools, English and Afrikaans are taught with the intention that all children of European descent growing up in the country shall have an adequate knowledge of both languages, but there is an ever-present danger of their failing to acquire the power of using either with that exactness which is necessary for clear thinking. Prof. Notcutt might have added that the prestige won for Afrikaans has reacted unfavourably on the position of Dutch, and a movement inspired largely by enthusiasm for maintaining the Netherlands connexion and cherishing the traditions handed down from the original Dutch settlers is in fact tending to estrangement, for the Dutchmen of Holland cannot, generally speaking, find time to learn Afrikaans, nor can the Afrikanders spare for Dutch so much time as they could before Afrikaans became a literary and official language. It is estimated that a higher proportion of the *white* population is attending college or university than in Great Britain or any of the other British Dominions. A noteworthy characteristic of South African university students is their devotion to sports, in which respect they resemble the students of Oxford and Cambridge rather than those of the other English universities.

Contemporary Birthdays.

November 20, 1851. Prof. John Merle Coulter.
November 21, 1866. Sir John Carruthers Beattie.
November 22, 1868. Sir Thomas H. Holland, K.C.S.I., K.C.I.E., F.R.S.
November 22, 1875. Prof. L. N. G. Filon, F.R.S.
November 23, 1864. Dr. P. Chalmers Mitchell, F.R.S.
November 26, 1851. Prof. J. Cossar Ewart, F.R.S.

Prof. COULTER, botanist, was born at Ningpo, China, and he was educated at Hanover College, U.S.A. Early in his career, when only twenty-one years of age, he was botanist with the United States Geological Survey in expedition work in the Rocky Mountains. Afterwards he returned to his old college, becoming professor of natural sciences; next he accepted the chair of biology in Wabash College. President, and professor of botany in Indiana University from 1891 until 1893, he has been, since 1896, professor and head of the department of botany in the University of Chicago. He is a member of the National Academy of Sciences, Washington and of the National Research Council; and a foreign member of the Linnean Society of London.

Sir J. C. BEATTIE, a graduate of the University of Edinburgh, studied also at Berlin and elsewhere abroad. Professor of physics in the South African College, Cape Town, from 1897 until 1918, he is now vice-chancellor and principal of the University of Cape Town. In 1909 (collaborating with Prof. J. T. Morrison) he brought to successful issue a magnetic survey of South Africa.

Sir THOMAS HOLLAND, Rector of the Imperial College of Science and Technology, received his scientific training at the Royal College of Science, South Kensington. He joined the Geological Survey of India in 1890, and was appointed professor of geology and mineralogy in the Presidency College, Calcutta, in 1893. From 1903 until 1909 he was director of the Geological Survey of India. Returning to England he became professor of geology and mineralogy in the University of Manchester, occupying the post for nine years. The Geological Society of London awarded him its Bigsby medal in 1913 in recognition of eminent services rendered to geology, more especially during his tenure of office in India. Sir Thomas is chairman of council of the Royal Society of Arts.

Prof. FILON has been Goldsmid professor of applied mathematics and mechanics in the University of London since 1912. Born at St. Cloud, France, he was educated at University College, London, and his energies, in the past and present, have centred there.

Dr. CHALMERS MITCHELL was born at Dunfermline. He graduated at the University of Aberdeen and Christ Church, Oxford, studying as well at Berlin and Leipzig. Since 1903 he has been secretary of the Zoological Society of London. Dr. Mitchell has made notable contributions to biological science, and has in addition promoted wide interest in scientific progress generally by numerous articles and other works.

Prof. J. COSSAR EWART was born at Penicuik, Midlothian, and graduated at the University of Edinburgh. Sometime occupant of the chair of natural history in the University of Aberdeen, he returned to Edinburgh in 1882, becoming Regius professor of natural history. Prof. Ewart has specially studied fishery questions; whilst he has written many critical memoirs on the development of the horse and on animal heredity.

Societies and Academies.

LONDON.

The Physical Society, October 22.—**Ernest Wilson**: The corrosion products and mechanical properties of certain light aluminium alloys, as affected by atmospheric exposure. Experiments have been made upon the electrical conductivities, the corrosion products and tensile properties of high purity aluminium, and certain light aluminium alloys, which have been exposed to London atmosphere for a period of twenty-four years. The elements concerned are copper, nickel, manganese, and zinc in varying amounts up to a few per cent. There is also a note on the corrosion products of high conductivity copper.—**M. C. Johnson**: The distribution of intensity in a positive ray spectral line (Part 2). The distribution of velocity among the particles contributing to the 'moving' spectrum is compared with the distribution of velocity in positive rays measured by the electromagnetic method and with some investigations of Betschinsky and Döpel. The appearance of the many-lined spectrum of hydrogen in the positive rays, and the ratio of intensity of the 'moving' and 'resting' spectra is also considered. The inverse square law of probability of electron capture, and some consequences of the work of Wien and Rüchardt, are the most likely controlling factors in the several phenomena.

Optical Society, October 28.—**R. Kingslake**: The analysis of an interferogram. It has been frequently suggested that it should be possible to analyse mathematically the interferometer pattern produced by a lens, in order to obtain a measure of the aberrations from the coefficients of the terms in the various orders of x and y. x and y are here the co-ordinates of a point on the interferogram, the optical path difference of which relative to the central ray of the lens is known at once by counting the fringes. Results obtained by this method do not agree well with those obtained under identical conditions by the oblique Hartmann test. **T. Smith**: The stationary value of axially symmetric functions (Part 2). Alternative methods to those described in Part 1 of constructing a series representing the stationary value of a given function are developed and applied to evaluate all the terms not involving powers and products of the coefficients of the function higher than the eleventh. The formula in its optical applications enables the first 451 monorythmic aberrations of a symmetrical optical instrument to be determined.

Mineralogical Society, November 2.—**L. J. Spencer**: (1) Schultenite, a new mineral from South-West Africa. The colourless platy crystals from Tsumeb are monoclinic ($a:b:c = 0{\cdot}8643:1:0{\cdot}7181$, $\beta = 84^\circ\ 36'$ and gave on analysis by E. D. Mountain the formula $PbHAsO_4$. They are identical with crystals prepared artificially by the late Baron A. de Schulten in 1904 (see NATURE, Sept. 18, 1926, p. 411). (2) Aramayoite, a new mineral from Bolivia. This was found in 1925 in a silver-tin vein in the Animas mine at Chocaya. It shows a confused aggregate of cleavage plates with iron-black colour and brilliant metallic lustre. In addition to the perfect basal cleavage there are also good cleavages following a steep tetragonal pyramid. The mineral is pseudotetragonal. Analyses by T. B. McGhie and by E. D. Mountain give the formula $Ag(Sb, Bi)S_2$.—**K. Yardley**: (1) X-ray examination of aramayoite. Some photographs taken with the beam perpendicular to the perfect basal cleavage (001) show no symmetry; powder photographs also show that the tetragonal symmetry

apparently indicated by the cleavages does not actually exist. Ionisation spectrometer data reveal the triclinic nature of the mineral and give a complete crystallographic description: $a=5.672$ Å.U., $b=5.688$, $c=5.623$; $\alpha=86°\ 55'$, $\beta=90°\ 53'$, $\gamma=93°\ 18'$. The structure is pseudo-tetragonal with two molecules of Ag(Sb, Bi)S_2 in a minimum cell. (2) The structure of baddeleyite and of prepared ZrO_2. The natural form of ZrO_2 is monoclinic with four molecules in the unit cell. Ionisation spectrometer measurements on a single crystal and powder photographs both indicate a distorted CaF_2 arrangement of the ions. The structures of three specimens of the mineral from entirely different sources are practically identical, except for slight variations of spacing due to the presence of impurity. Powder photographs of prepared zirconia from two distinct sources are almost identical with those of baddeleyite and show that prepared zirconia is also monoclinic and not (as previously stated) tetragonal.—W. **Binks**: The crystalline structure of zircon. X-ray examination of zircon shows the structure of zircon to correspond to the space group D_{4h}^{19}. The unit cell containing eight molecules $ZrSiO_4$ has dimensions $a=9.30$, $c=5.93$ Å.U. The silicon and zirconium atoms form two interpenetrating face-centred lattices, and the oxygen atoms are arranged tetrahedrally around the silicon atoms. The structure has some resemblances to that of anhydrite ($CaSO_4$).

Society of Public Analysts, November 3.—W. R. **Schoeller** and C. **Jahn**: Investigations into the analytical chemistry of tantalum, niobium, and their mineral associates (vi.) The precipitation of the earth acids by sodium compounds. When tantalic oxide is fused with potassium carbonate and the solution of the mass treated with sodium chloride, 4 : 3 sodium tantalate is precipitated. Niobic oxide treated in the same manner yields 7 : 6 sodium niobate. The precipitates are dense, crystalline powders. Sodium tantalate and niobate are decomposed by dilute acid. The quantity of the latter is proportional to that of the alkali in the precipitates. This reaction was applied to the indirect volumetric determination of the earth acids in the mixed sodium salts, but the end-point could not be ascertained with sufficient sharpness with colour indicators.—A. E. **Parkes**: A simple method of testing for sulphites in foods. The food (if not a liquid) is mixed with water and placed with fragments of marble and dilute (about $2N$) hydrochloric acid in a conical flask, closed with a rubber stopper bearing a small thistle funnel bent twice and having a small bulb on each limb. The funnel contains a few drops of dilute ($0.01N$) iodine solution and dilute barium chloride solution. After evolution of carbon dioxide has ceased, the flask is heated, and, in the presence of a sulphite, the colour of the iodine in the funnel is discharged and the liquid becomes opalescent (barium sulphate). The test may be made approximately quantitative.—J. W. **Haigh Johnson**: A critical review of the methods of analysing waters, sewages and effluents, with suggestions for their improvement. Present methods yield results which are often inconsistent. Recent modifications in sewage treatment have greatly increased the amount of nitrogen oxidation products. Comparing the Wanklyn, Kjeldahl, acid chemical, and biological processes, the first is too vague, whilst the acid chemical test yields only a fifth of the result obtained biologically. A method of combining the Wanklyn test and the alkaline oxidation method is described, and suggestions are made for improving the Kjeldahl test and for the biological determination of absorbed oxygen.

PARIS.

Academy of Sciences, October 18.—G. **Bigourdan**: The equations of diverse origins, which may affect the pendulum corrections C_p adopted at the Bureau International de l'Heure (B.I.H.), year 1925.—Marin **Molliard**: The dimorphism determined in the gall of *Mikiola Fagi* by a secondary parasite. Some oak galls from the forest of Fontainebleau were observed to differ in shape and other characteristics from the normal gall, and this has been shown to be due to another parasite, identified by Ch. Ferrière as *Secodes coactus*. Similar galls have since been observed in abundance in other parts of France, Normandy, Brittany, Savoy.—Charles **Richet** and **Oxner**: The accommodation of salt-water fish to supersaturated waters. A study of the effect on *Sargus Rondeleti* of a gradual increase in the proportion of sodium chloride in the water. This fish could support a salinity 37 per cent. above the normal, but a diminution to 18 per cent. below the normal caused death. J. **Costantin**: The variability of living beings according to prehistoric man.—Ch. **Depéret**: The neolithic layer of Glozel (Allier). Some doubt has been thrown on the authenticity of the objects found at Glozel: the author's own excavations and observations confirm the view of Morlet that the find is authentic, and of extreme importance.—Léon **Guillet** and Albert **Portevin**: The influence of the chemical composition of alloys on the possibility of making castings.—E. **Bataillon** and Tchou **Su**: Activation and rectification in the parthogenesis of the echinides by hypertonic solutions alone.—Paul **Alexandroff**: The dimension of closed *ensembles*.—Léon **Pomey**: Partial differential equations and linear integro-differential equations with an infinity of variables.—Leonida **Tonelli**: The double series of Fourier.—G. **Cerf**: The characteristics of partial differential equations of the first order.—André **Roussel**: Certain isoperimetric problems.—H. **Galbrun**: The propagation of a sound wave in the atmosphere.—A. **Toussaint** and E. **Carafoli**: The theory of supporting wings.—A. **Dauvillier**: The discovery of the characteristic O and N series of low frequency. Spectrographic joining of the X-rays and the extreme ultra-violet. Utilising a thorium filament prepared by M. de Boer, good spectra have been obtained with 25 milliamperes at 2800 volts. These show the pure low frequency spectrum of thorium, consisting of the characteristic N and O radiations. The line 121 Å.U. approaches the optical spectra obtained by Millikan in the extreme ultra-violet (limit of aluminium, 136 Å.U.).—H. **Pilon** and A. **Laborde**. The immersion of metals in homogeneous media opaque to the X-rays. Improvement of radiographic methods. The method suggested consists in immersing the metallic body in a homogeneous saline solution the absorption co-efficient of which, for the X-rays used, is nearly that of the metal. Some suitable solutions are given: for aluminium a 35 per cent. solution of barium chloride, for iron, barium iodide (159 gm. in 100 c.c. of solution), for copper, the same barium iodide solution. Under these conditions discontinuity in the metal is very clearly shown.—Jean **Bouldoires**: The transformations undergone by aluminium bronzes. Results are given of a thermal analysis, measurements of resistance and micrographic study of aluminium bronzes submitted to varying heat treatment.—Georges **Delbart**: The magnetic permeability of cold-drawn steels.—Emile **André** and Mlle. Th. **François**: The saturated fatty alcohols of the oil of the sperm whale and of *blanc de baleine*.—Guy **Emschwiller**: The action of magnesium on methylene iodide. The reaction (in ether) is vigorous and takes place

a brilliant analysis of the phenomena of line spectra. Many of those who read papers before the sections of the British Association may feel aggrieved that the substance of their contributions is neglected, while considerable importance is attached to their incidental analogies. Then again, there is the large class of contributors whose papers are ignored altogether in the newspapers, and this is frequently attributed to the reporter's preference for the contributions of scientific workers of well-established reputation, or for those of distinguished laymen.

It is obvious there must be selection. A modest estimate of the average daily output during the Oxford meeting would be sixty papers. To do bare justice to them all, the newspapers would need to devote at least thirty columns daily to science news, and this would involve the employment of a staff of scientific experts for each newspaper, unless all editors were prepared to present to their readers exactly the same copy. But if the public demand for science news were sufficiently great to warrant such wholesale circulation, it is clear that it would also be sufficient to justify the publication of a science daily newspaper.

In existing circumstances, editors will select those items of news which they think will appeal to their particular public. But any author of a paper can help them materially in this process of selection if he will take the trouble to prepare for the official programme of the Association, a summary which is not only written in language intelligible to the average well-educated member of the community, but also calculated to awaken interest either from the newness of its facts or the novelty of their presentation. It is useful if, in addition, one or two copies of his complete paper are available in advance to the reporters in the Press Bureau, as this widens the scope of selection of individual reporters. Attention to such matters as these will usually safeguard an author against misrepresentation of his facts, theories, and opinions. The title given to a paper is also important in this connexion. "The Hygroscopic Relations of Colloidal Fibres" conveys all that is necessary to members of Section A, but is not likely to interest a reporter with limited space and time at his command, who sees, moreover, that there are a dozen other papers with far more attractive titles to be delivered the same day. He is only human in preferring to look to papers on "Intelligence in Rats," the "Psychology of Patriotism," or "The Public Schools and National Life" for his copy.

It is not suggested that scientific workers should aim at providing reporters with 'stunts,' or that the importance of scientific investigations be judged by their immediate value as copy for newspapers or topics of conversation. But it is clearly worth while to present the results of investigation in any one branch of science and theories based upon them, in a form which will enable every scientific worker, as well as the specialist, to appreciate them. Since the general public is also interested in science, there seems every reason why it should be provided with the best of science, and every assistance given to reporters—the channels of communication between science and the public—in the difficult task of selection and presentation. Serious scientific workers are themselves partly to blame for having the patient work of years dismissed in three or four unintelligible lines. They have put a new weapon in the hands of humanity; they have insensibly imposed upon it a new mental outlook; upon them devolves the responsibility of enabling all members of the community to understand the functions, aims, and methods of science, and the essence of the scientific spirit, its fearlessness in facing facts, its determination to resist prejudice, and its constant researches to test the validity of theories or the universality of laws.

If scientific workers will not seriously apply themselves to the task of securing greater and better publicity for their work, other than that which they obtain in the scientific and technical press, and reports of proceedings of learned societies and institutions, they must not complain of the manner of the publicity. They must be prepared for valuable utterances and suggestive discussions to be neglected in favour of th trivial and fantastic contributions made to the proceed ings by our scientific entertainers- the terms in whic the *Saturday Review* described the press reports of tl Oxford meeting of the British Association. Yet there is now less justification for this criticism than formerly, since recently the Press, taken as a whole, has progressively improved its performance in separating the grain from the chaff. Many of the principal newspapers now have at their disposal the services of journalists who are also scientific writers of distinction. Tl daily reports of the Oxford meeting in the principa London and provincial journals were fuller than eve before, and considering the circumstances in which they were compiled, remarkably fair and accurate. Naturally, newspapers like the *Times* can devote more columns to the proceedings than those in the class typified by the *Daily Express* and the *Daily News*, but little exception could be taken to the reports as a whole. They flattered the intelligence of their readers. Moreover, many of these journals maintained a running fire of comment in leading articles on the more important papers delivered, a striking commentary on the interest in science which the meeting provokes.

There is little doubt that this interest could be sustained. The *Daily Express* published recently a series of articles by eminent scientific workers. Most

of the serious weekly periodicals devote some space to scientific subjects. The day cannot be far distant when the editors of the *Observer* and the *Sunday Times* will make a science page as regular a feature of their papers as their literature, music, and dramatic art pages. It is not improbable that the demand for scientific information is great enough to justify the publication of a science daily newspaper, or at least a sound and popular science weekly, written in a form calculated to appeal to a wider public than NATURE. There are daily and weekly journals devoted to finance, and these are not read solely by professional financiers.

The steps which might be taken by scientific workers to satisfy the public demand for knowledge of their work have already been the subject of comment in these columns. Reference has also been made to what has been done in the United States, by scientific workers themselves, to deal with a like situation. It is obvious that where there is a demand it will be satisfied by somebody. If the scientific community in Great Britain wishes to safeguard itself against the kind of misrepresentation of its endeavours which masquerades in the guise of 'popular science,' if it wishes to safeguard those members of the public interested in science progress against exploitation by enterprising advertisement agencies, there is no time to be lost. The opportunity to give the best of science to the nation exists. Do scientific workers possess the will and energy to take advantage of the present favourable situation?

The Electricity Bill.

THE Electricity Bill, after passing its third reading in the House of Commons, is now being considered in the Upper House. As there were twenty-six pages of amendments to be discussed and the bill is of a highly technical nature, the task was no easy one, but it started auspiciously. In the committee stage the bill was discussed from almost every point of view, and so it is unlikely that any serious flaw has been overlooked. Many politicians think that this bill makes a long step in the direction of nationalisation. In the opinion of the Government, however, it will stop nationalisation. It is pointed out that the electric supply industry is on a quite different footing from other industries. In every district of Great Britain electric supply is a monopoly. It is urged, therefore, that the industry should not be deprived of the great benefit that would ensue when co-operation and centralisation replace individual effort. The need for passing the bill at once is imperative, as several schemes for developing electrical supply are being held up pending the new legislation.

The amendment adopted by the Government making it obligatory instead of permissible for the Electricity Board to advance free of interest such sums as might be necessary to enable authorised undertakers or owners to alter their frequency, will probably meet the chief objection of many opponents of the bill.

It will be remembered that the origin of the bill was the desire expressed by many engineers to increase the interconnexion of networks of electricity supply in Great Britain. The primary object of the bill was to increase the efficiency of the supply. It will probably follow that an increase in the retail supply and a lowering in the price of electricity will take place concurrently. In Canada and the United States there are huge supply networks covering many thousands of square miles. The Pacific Gas and South Californian Edison Companies network covers 120,000 square miles and links up 130 stations, which is more than double the area covered by the Government scheme.

The Electricity Commissioners have pointed out that 56 per cent. of the capital of electricity undertakings is locked up in spare plant. If complete interconnexion were established, this could be reduced very considerably. This is one of the principal gains which the promoters of the bill hope to secure. In due time considerable savings will doubtless be effected, and care has been taken to ensure that the consumer will benefit largely by them.

In our opinion this scheme will be a boon to both the country and the industry, provided that no undue delay ensues before it is put into operation. A really forward policy need not involve large expenditure. The Electricity Commissioners' Reports prove conclusively that many of the electricity networks in Great Britain are inadequate and were very expensive to construct. In some cases the cost per unit of maximum demand is about twenty times as great as that of the most efficient stations. The multiplicity and variety of the systems of supply in London, although largely due to early electrical legislation which established two competing companies in each local area, is not creditable to electrical engineers. Figures have proved the great economies that could be effected without even the necessity of scrapping plant the efficiency of which is only fair. A first step in the direction of improvement has been the standardisation of the pressure of supply. Whenever new schemes have been sanctioned or systems changed from direct current to alternating current, or even in those cases where direct current is being retained, the pressure of supply is now 230 volts.

We are glad to see that progress is being made by electrical manufacturers in the direction of cheaper

systems of distribution in rural districts. Every one, who has travelled on the continent knows the extensive use that has been made of overhead electrical distribution, particularly in connexion with railways. Whether they spoil the view of the landscape or not, there can be no question but that the use of poles, whether of wood or iron lattice work, is a great boon to the various countries concerned. We hope that the collieries and iron and steel works in Great Britain which do not generate their own electricity will be able to secure a bulk supply at low rates when this bill is passed. We also hope that those firms which can generate from waste heat more than sufficient power to meet their own needs will benefit by being able to sell their excess power to the Electricity Board.

The Mystery of Money.

Wealth, Virtual Wealth, and Debt: the Solution of the Economic Paradox. By Prof. Frederick Soddy. Pp. 320. (London: G. Allen and Unwin, Ltd., 1926.) 10*s.* 6*d.* net

IN childhood many things are hidden from us, but we use money to buy our first sweets at an age which is rarely within the recollection of mature thought. So we take money for granted. We learn by experience that it procures the things we want, and that usually seems to be all we want to know about it. Its origin, its functions, the explanation of the ebb and flow of its command over goods, with an accompanying maldistribution of unearned gain and undeserved loss, are, if not entirely unknown phenomena, at least recondite subjects which are best left alone.

Prof. Soddy is, however, a more adventurous spirit. After achieving a position of distinction in his own sphere which would satisfy the ambition of most men, he has become intrigued with the elusive problem of money. So we have "an attempt, rarely made nowadays, by a specialist in one field of knowledge to solve the problems in another."

Prof. Soddy has produced a volume which contains at one and the same time a penetrating analysis of the ultimate realities of modern banking science and a new theory of money which, despite his assertion that the solution which he brings is "the most ordinary incontrovertible commonsense requiring nothing more than that to prove it," will be rejected by every student of economics.

In the preface the reader is encouraged to read the conclusions in the last chapter before he commences on the arguments in the book. He could economise his time still further by skipping the very interesting but irrelevant matter in the first 100 pages, because it is not until Chapter vi. that the author comes to grips with his first concept of wealth. In this chapter, which bears the heading of "The Two Categories of Wealth," the first section has the sub-title of "The Nature and Definition of Absolute Wealth," and we have to assume, in the absence of any clear indication, that his definition lies in the concluding words, which read: "Wealth as a form, product, or result of a draft upon the flow of available energy consists of the special forms, products, or results which empower and enable human life." After careful study we doubt whether this definition will jump readily to the minds of "all serious readers sincerely anxious to understand the causes of modern unrest." The theme, however, is further developed and two main categories of wealth distinguished. The first includes commodities "which retain part of the energy expended in their production, as an internal store, which, in the consumption of these commodities, is released to serve the purposes of life." The second category includes commodities of which "the energy is expended in overcoming dead resistance, in changing the form or nature of the materials worked upon, and does not remain in the materials as an essential to their use." As examples in the first category we are given food, fuel, explosives, etc., and in the second, clothes, houses, furniture, tools, plant, roads, vehicles, and ships. The difference lies in the relative perishability of those in the first category contrasted with the relative permanence of those in the second. So we reach the distinction, familiar to the economist, between consumers' goods and producers' goods— a distinction which Marshall characterises as "vague and perhaps not of much practical use" ("Principles," II., III., 1).

The meaning of the new term "Virtual Wealth" is not made easy. Prof. Soddy tells us that "the important thing is that this Virtual Wealth does not exist." 'Money,' although nowhere defined, apparently includes gold and silver coins, bank notes and cheques; we assume the latter term to mean all bank balances. Gold in the form of bullion is part of the national wealth; in the form of coins in circulation it is condemned as representing a waste of the community's labour. The system of bank balances is described as a power conferred upon the owners of those balances "not to possess but to be owed wealth." From this it is deduced that money is not wealth, but evidence that the owner of the money has not received the wealth to which he is entitled—wealth which he can demand at his convenience. It follows that "in a community, of necessity, the aggregate money, irrespective of its amount, represents the aggregate value of the wealth which the community prefers to be owed on these terms rather than to own. This negative quantity of wealth I term the *Virtual Wealth* of the community, because the community is obliged . . . to act as though it

possessed this much more wealth than it actually does possess."

The trained student, to say nothing of the ordinary reader, will not find the argument very lucid, especially when he reads, on a later page, that "Virtual Wealth has, in fact, very little to do with the quantity of money." The author does not seem to realise that both in their private and business lives people retain floating balances of money (in the house, office, or bank) because it is a convenience to do so. The custom rests upon an economic basis; balances so kept perform a useful service. But the real object of Prof. Soddy's attack is the creation of bank money, which proceeds from the mechanism of banking operating through the extension of credit resting upon a gold basis. With an increase in 'cash balances' of 100*l.* and a cash ratio of 15 per cent., it is possible, he notes, to create deposits to the extent of 666*l.* 13*s.* 4*d.*, this liability being balanced on the assets side by the 100*l.* of original cash plus 566*l.* 13*s.* 4*d.* of advances. In this manner additional purchasing power is created, and Prof. Soddy says that if the total advances tend steadily to increase, people are undoubtedly "empowered by the banks to acquire wealth temporarily from the community to which they were not entitled and for which the whole community paid."

The author asserts that the financial device of the cheque for economising the use of currency means that a complete and unsuspected alteration has come over the nature of money. It may be complete, but it is surely going too far to imply that it is unsuspected by any one familiar with monetary science. In the ordinary course the growth of credit is small and gradual. It is controlled in all communities using the gold standard by that standard. Viewed impartially, the cheque system joined with the expansion of credit has been a blessing and not a curse. On the other hand, the multiplication of credit by the banking system during the War years, and immediately afterwards through the increase in the cash basis provided by the withdrawal of gold from circulation and the substitution therefor of Treasury notes, did bring into being a mass of purchasing power which was acquired from the community as a whole through the depreciation in sterling. In one word, we had inflation, and undoubtedly inflation was profitable not only to manufacturers, merchants, and traders, but also to the bankers. Views may differ as to the necessity of this operation, but few will now be found to hope that it is possible, as Prof. Soddy would wish, to put the clock back.

Prof. Soddy contends that "something of the order of two thousand million pounds have been created by the banks," which at 5 per cent. brings them in a revenue of a hundred million. His remedy is that the State should "buy back in the open market £M2000 of War Loan with genuine new money to replace that created by the banks." It is not clear how this money is to be issued. In one place we are told it is unnecessary to issue this quantity of Treasury notes and put them in circulation; three pages later we learn that this new money has in future to be held by the banks. Debtors to the banks in respect of present advances must, under this scheme, either sell their securities or find some one who has fresh money to lend them in order that they may repay the banks, which in future are to be required to lend only genuine deposits and are to be forbidden to extend credit upon the principle of keeping only in their tills a safe proportion of deposits.

The precise manner in which these proposals are to be executed is not specified. If contact and trust can be established between repaid National Debt holders and debtors to the banks so that the former lend to the latter sufficient to repay the banks, this part of the scheme might work in theory. The hypothesis, unfortunately, rests upon unexpounded assumptions which will not bear a moment's examination. The new money would unquestionably be paid into the banks, to the credit of the repaid National Debt holders as depositors. Now the banks are in future to keep pound for pound against deposits. We are at a loss to understand how they can do so and still "lend money at interest as before." If they keep cash pound for pound against deposits, they can earn no interest, and the whole credit structure, with all the assistance it renders to industry, will be brought to the ground. Further, how are the debt holders who are to be penalised by the redemption of their stock in new currency to be selected? If impartially, then the innumerable changes that have taken place in the ownership of debt holdings necessitate nothing less than a capital levy. In truth, Prof. Soddy's real plea is for the nationalisation of banking. But just as he shirks the issue of a capital levy, so he omits to carry his other proposals to their logical conclusion.

In the latter half of his book the author concentrates on the problems of the monetary factor in relation to production, and argues in favour of a stable price level controlled through the medium of a national statistical office. Control of currency is, however, to be in the hands of the State. As production increases, new money is to be printed and issued to the consuming public, by meeting Government expenditure therewith instead of by taxation. We are told that the correct quantity of money is that which is sufficient at the stable level of prices to purchase the total stocks of finished wealth in and outside the industrial system. No attention is given to the special circumstances of

Great Britain as an exporting country. We are left wondering how we are to have a stable price level—presumably upon a gold basis—kept in proper relation to the price levels of other countries upon a like basis, if the export trades optimistically expand their output despite the absence of foreign buyers at the prices current, and if floods of new currency are issued by the State *pari passu* with the optimism of the producer.

While we have every sympathy with the difficulties that Prof. Soddy has found in the full comprehension of our present monetary system, we fear that his remedies would involve evils and difficulties far worse than those from which we at present suffer.

W. H. COATES.

Venereal Disease.

Proceedings of the Imperial Social Hygiene Congress, Wembly, Oct. 1925. Pp. iv+301. (British Social Hygiene Council, Carteret St., London, S.W.1.) 4s.

THE report of the Imperial Hygiene Congress deals exclusively with venereal diseases. Formerly all diseases were regarded as 'trials,' or as 'punishments for sin.' To-day only venereal diseases are so regarded, and only by the least civilised. It is known that they are caused by microbes, and that microbes do not discriminate between the just and the unjust. Nevertheless, even in England, and even so lately as during the War, after lectures compulsorily attended by soldiers, the jest that "It cannot, then, be sinful to have intercourse with virgins and respectable married women" was not uncommon. The silliness of these lectures is realised when it is borne in mind that among the sufferers are millions of infants.

Diseases may be prevented, or they may be cured. Cure is not an hygienic measure of importance. At any rate, the prevalence of no disease has been reduced appreciably by mere cure. Hygiene *is* prevention, which implies some effective form of cleanliness. Thus, diseases of the alimentary tract (*e.g.* cholera, typhoid, and dysentery) are prevented by attention to the food and water supplies. Insect-borne diseases (*e.g.* malaria, typhus, yellow fever, and bubonic plague) are prevented by destroying the insect carriers. Contagious diseases, such as most skin complaints, can be prevented only by personal hygiene.

The venereal diseases are strictly contagious. They have certain peculiarities. In the vast majority of infections, man is the carrier for woman and woman for man; that is, if they be prevented for one sex, they are automatically prevented for the other. As a very general rule, infection occurs only on particular occasions and on particular parts of the body. The microbes are very delicate, and therefore destructible by ordinary disinfectants if the latter be employed soon after the danger has been incurred, while the microbes are yet on the surface of the body. The male is much more easily disinfected than the female—so easily that a child might perform the operation which consists in no more than the swabbing of a few inches of very accessible skin. Lastly, the venereal diseases are the only maladies with which morality is now concerned.

Two methods of prevention are in vogue: exhortations to morality, and the use of chemical disinfectants. No one has objected to the exhortations; but the use of disinfectants has been much opposed. It has been forgotten that cleanliness is next to godliness. Exhortations to sexual morality, though used for many centuries, have not been very effective at any time. A point of psychology is involved. The sexual inclination is an instinct—a mental impulse to action which is awakened by experience, but not created by it. Thus no one *learns* to be hungry, or thirsty, or to suck. All human instincts are the same for all races of men. On the other hand, morals differ with time and place. They are learned. They constitute the rules by which men restrain their instincts and play the game of society. Almost invariably they are acquired at a particular age and in a particular way—during childhood and by imitation. A little child is 'plastic' (*i.e.* imitative), and therefore tends to copy the emotional convictions of its associates.

Consequently, a child can learn with sincere and unquestioning belief the tenets of any religion and its associated system of morals. In later life this power of learning through imitation becomes greatly enfeebled. The adult learns more through evidence; or what he supposes is evidence, for his judgment is often warped by preconceptions acquired during youth. Thus, while the child of ardent Mohammedans or Hindoos may be brought up in any religion and system of morality, it is usually impossible to change the opinions of the parents. In Christendom, and especially among English-speaking peoples, it is remarkable that exhortations to sexual morality are usually delivered by adults only to adults. Consequently, children learn their sentiments from other children among whom a knowledge of sex is traditional. It follows that exhortations to sexual morality delivered to adults are usually very ineffective—as any reader of NATURE may judge from his own feelings. Would any amount of preaching alter his present sentiments?

Prevention by means of chemical disinfectants has been practised for many years, and on a large scale during, and since, the War. During the War, precise statistics, every item of which could be checked from

official records, were available. It was demonstrated that in many instances, under many and diverse conditions, in many parts of the world, high venereal rates had been reduced almost to the vanishing point by means of immediate disinfection practised by the endangered persons themselves. These facts were unpalatable to people whose principal concern was sexual morality. They could not bring themselves to believe, and sought to create unbelief. But the evidence has been examined by several committees of inquiry, and found unassailable—for example, Lord Trevethin's committee. To-day the only people who insist that personal disinfection is valueless are those who, on moral grounds, have refused to advise it, and therefore have no experience of it.

During the proceedings of the Imperial Hygiene Congress there seems to have been general agreement on two points: public sexual immorality had increased, and the prevalence of venereal disease had diminished during recent years. The conclusion to which we are driven is very obvious. Exhortation has had little influence and disinfection much.

The opening address of the Congress was delivered by Mr. Amery, Secretary of State for the Dominions and Colonies, who stated:

"Now we are dealing in this Congress more particularly with a certain aspect of health, and with certain types of diseases. We are dealing here with a problem that is at once one of the most serious and one of the most hopeful to which any body of public workers or reformers can devote themselves. Most serious, because I think it is becoming increasingly realised how wide-spread, how appalling in the misery, suffering, waste of human life, strength and ability they cause, are the consequences, direct and indirect, of venereal diseases. On the other hand, hopeful, because from the medical point of view there can be no doubt that under the conditions of modern science there is no range of diseases which is more obviously and definitely capable of being dealt with, of being cured, and, indeed, if public opinion was strong enough, capable of being extirpated."

In effect, the only reference to chemical disinfection was made by Surgeon-Commander Thomas Shaw, professor of hygiene in the Royal Naval Medical School, Greenwich, who declared:

"As stated by Trotter one hundred years ago, the best means of preventing venereal disease, if promiscuous sexual intercourse is indulged in, is immediate disinfection of the parts. The part played by suitable and immediate prophylaxis is no longer disputed by any responsible person, and as promiscuous sexual intercourse will still continue to be practised by certain people in spite of all efforts to the contrary, our only hope of eventually exterminating venereal disease altogether is by a wider application of this measure. Whilst we all recognise the great importance of social measures in combating venereal diseases, we shall never exterminate them by these means alone."

The remainder of the volume recording the proceedings is occupied with accounts of the prevalence of venereal diseases in the British Empire, with descriptions of measures taken to cure people already infected, and of narrations of attempts to preserve sailors and other plastic types from the sirens of the streets.

The word hygiene does not accurately describe the Congress.

The Biology of the Protozoa.

The Biology of the Protozoa. By Prof. Gary N. Calkins. Pp. 623. (London: Baillière, Tindall and Cox, 1926.) 35s. net.

ALTHOUGH during the last quarter of a century the study of protozoa has been vigorously pursued by many students in many lands, yet the bringing together of the results so obtained, and the critical analysis of often discrepant results, is long overdue. The well-known text-books by Minchin and Doflein to a certain extent fill this need, but one is largely concerned with parasitic forms of protozoa, while the other is not available to those not conversant with the German language.

Moreover, as Prof. Calkins says in his introduction, "protozoology as a branch of the biological sciences has meant little more than the application of biological or zoological methods to a definite but limited group of organisms, the Protozoa." The author has therefore tried to weave the many aspects of protozoological research into a common whole, with the hope of so founding a science of protozoology. The underlying principle of the work is the irritability of protoplasm, combined with protoplasmic organisation. Keeping this fundamental fact in view, the various characteristics of these unicellular animals, namely, metabolic activities, asexual and sexual reproduction, reorganisation and restoration of organisation, etc., are considered.

The word 'unicellular,' as applied to these animals, reminds one of the much-debated point as to whether 'non-cellular' is not a better designation. Prof. Calkins points out that, whereas a single protozoon is to be compared structurally with a single isolated tissue cell of a metazoon, it is a different unit physiologically, and as such should be compared with a complete organism, as was pointed out by Whitman, and later by Gurwitsch, and Dobell.

The book is divided into twelve chapters, covering a wide range of the subject; the first five chapters treat of the general organisation of the protozoan body, nuclei and kinetic elements, structural differentiations, general physiology, and reproduction. This is followed by chapters dealing with each of the big

subphyla of the protozoa: Mastigophora, Sarcodina, Infusoria, and Sporozoa. The classes of each of these groups are described and useful keys to the common genera are given. The concluding three chapters are perhaps the most interesting, for the author discusses such questions as vitality, fertilisation, and the origin of variations.

In a book of only about six hundred pages it is obviously impossible to treat exhaustively this subject matter, and the author has been wise in concentrating more upon free-living protozoa, to the exclusion of the parasitic types, as for example in the chapter on structural differentiations. Here little or no mention is made of the many curious adaptations incident upon the adoption of parasitism; since, however, these have already been well described, the account given by Prof. Calkins of the modifications found in free-living protozoa is particularly welcome.

Under the heading nuclei and kinetic elements, the author has grouped together, in a clear and interesting way, the various organs and cellular elements associated with movements, together with a description of the different configurations grouped together under the term nucleus. To the general biologist the section devoted to kinetic elements will probably appeal most strongly, for it is comparatively few who realise how complex is such a seemingly simple structure as a flagellum or cilium; added to this the reader is introduced to the numerous cytoplasmic granules known as endobasal bodies, centrioles, blepharoplasts, parabasal bodies, etc., all of which appear to play some part in the physiology of movement.

Particular attention may also be directed to the advances recently made towards elucidating the question of co-ordination in protozoa. Sharp, Yocom, McDonald, and others have been able to show that a definite conducting system of fibrils exists in many species of ciliates and that this system emanates from a common mass of protoplasm—the motorium—constituting with the fibrils a 'neuromotor' apparatus. Fig. 57 of Calkins' book illustrates this apparatus in *Euplotes patella* and goes far to substantiate the view that a single protozoon must be regarded as physiologically comparable with a whole metazoon individual.

The chapter on general physiology does not attain the high character of the rest of the book. This is unfortunate, since the title of the volume would suggest that physiology was particularly stressed; and, moreover, there is no modern book dealing with this branch of protozoology which can be recommended to the student. Prof. Calkins' book does help to fill this need, but not completely. In a future edition he would probably be well advised to expand this section to two or three times its present dimensions, even at the expense of some of the other material. The author has evidently been at pains to keep his book within reasonable limits, with the result that sometimes his treatment is a little sketchy; thus little space is given to the questions concerning the response to various stimuli, and little or no mention is made of the reactions brought about by changed environmental conditions or adaptation to new conditions. Again, the important phenomena of encystation and excystation are not adequately discussed. The author has committed himself to the view that external conditions do not play a predominant part in causing the former reaction—a view to which most students of protozoa will subscribe—but the results of the many modern experiments are not given.

A similar criticism may be made against the treatment of nutrition, for, while certain aspects of it are well described, it is a surprise to find such a fascinating subject as choice of food dismissed quite summarily, without even mention being made of the work of such men as Oehler, to give only one example.

Probably the chapters to which all biologists will at once turn are those dealing with vitality; the author means by this term "the sum total of actions, reactions, and interactions between and amongst the substances making up the organisation of protoplasm, and between these and the environment." As is well known, Prof. Calkins, as a result of many years' research, has arrived at conclusions regarding the significance of conjugation and the part it plays in the life cycle of ciliates different from those of other distinguished observers.

The experiments on which these views are founded are well recounted; and to-day Prof. Calkins maintains the following conclusion: "To my mind the phenomena in these forms lead to the conclusion that Protozoa and Metazoa are fundamentally alike in respect to protoplasmic continuity and protoplasmic death, the difference between them is bound up with our definitions of the individual. So far as immortality of Protozoa is concerned, Hertwig's (1914) conclusions appear to sum up the situation: 'However these investigations may turn out, one may say this now, that the doctrine of the immortality of the Protozoa in the form established by Weismann, at a time when we did not know anything of the fertilisation processes of the Protozoa, cannot be retained.'"

The author must be congratulated upon the production of an exceedingly useful and interesting book; and in conclusion the hope may be expressed that at a future date he will furnish us with a more extended account of the general biology and physiology of that group of animals to which he has given thirty years' research.

D. WARD CUTLER.

Our Bookshelf.

Cotton and its Production. By W. H. Johnson. Pp. xxvii + 536 + 16 plates. (London: Macmillan and Co., Ltd., 1926.) 30*s.* net.

THE author has evidently utilised his very extensive experience of cotton-growing in most parts of the world to guide him in compiling this substantial volume from documentary sources. The result is a useful addition to the books about cotton, for besides being well up-to-date it is well balanced and exceptionally free from errors of fact. The author's first-hand knowledge puts his treatment on a higher level than mere compilation, but it is in no sense a critical treatment, and only attempts to present the known or reputed state of affairs. He deals with cotton production throughout the world, taking the information available with discretion.

The general level of the agricultural chapters which deal with the different countries is very fairly maintained in the others. Such subjects as the history and botany of the crop, its manufacture and by-products, its pests and diseases, all receive a chapter each, and these chapters are not likely to mislead the student, but will serve as useful introductions to further study.

Seeing that the scope of the book is such as will serve for reference purposes as well as for general information, it is regrettable that the system of references is very irregular. The "bibliography of cotton" which figures in the table of contents only contains some fifty items, apart from lists of journals and reports; some of these few are merely of casual interest, while others have not been used in the text. Conversely, there is internal evidence for the use of many publications which are not cited, as in the chapter on manufacture. Having regard to the skill with which the author has built up these citations into readable matter, and the great number of sources from which he has drawn them, it is to be hoped that the next edition will be lavishly provided with footnotes. An alternative course would be to issue a thin supplement volume of such references.

The details open to criticism are unimportant, and in most cases are due to the authority cited, for which the author has become responsible; thus the paragraph concerning the reputed depreciation in length of Sakel is very misleading, and the possibilities of rain-grown cotton in the Sudan, as regards quantity, are neglected more than the descriptive treatment warrants.

W. L. B.

Dairy Cattle: Selection, Feeding and Management. By Prof. William Wodin Yapp and Prof. William Barbour Nevens. (Wiley Farm Series.) Pp. xvii + 378. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1926.) 11*s.* net.

THIS book deals with the selection, feeding and management of dairy cattle on the lines which the authors consider suitable for vocational-school students and dairy farmers in the United States. The subject matter of the different chapters is generally well known to the writers and workers in dairy husbandry in Great Britain and does not require special mention, but the method of study recommended in each chapter is novel and characteristic of the organisation and attention to detail which is possible in agricultural educational work when there is a staff sufficiently large to permit of the division of each subject into numerous sections.

The method adopted by the authors is that of stating clearly at the commencement of each chapter the practical operations involved; thus in the chapter on "Improving the Dairy Herd" the operations specified are: (1) Eliminating the low-producing cows; (2) choosing the proper sire; (3) practising rigid selection.

Each operation is then considered and the procedure to be followed is set out concisely in appropriately headed paragraphs. This method appears excellent, and has the merit of at once attracting the attention of the reader to the main points which the writers wish to emphasise. At the end of each chapter is given a list of American text-books and bulletins to which the reader may refer for further information; also a series of questions is set out, and the student is advised to obtain answers for himself by visiting a number of dairy farms. The advice given throughout is excellent, but amid so much attention to detail it is strange that the fundamental dairy farm operation of milking is passed over in a few words, and that in taking composite samples of milk for fat testing no mention is made of the need for the amount of the sample to be proportionate to the quantity of milk from which it is taken.

The book will be interesting and helpful to the lecturer in dairy husbandry in Great Britain who does not already possess an American text-book, but its value to the British student and farmer is limited because the numerous breeds of dairy cattle and kinds of feeding stuffs common in England but little known in the United States are not referred to by the authors.

Les mollusques d'eau douce. Par Prof. E. Chemin. (Encyclopédie pratique du naturaliste, Tome 24.) Pp. viii + 186 + 15 planches. (Paris: Paul Lechevalier, 1926.) 25 francs.

THIS little manual is one of a kind common in France, but only too rare in England, in which a circumscribed portion of some branch of natural history is treated by itself, be it from an elementary or from an advanced point of view. As a matter of fact, this one is more restricted than usual, for while its title would lead one to expect a complete account of the freshwater molluscs, at all events of France, the author announces in his preface that such is far from his intention. He writes, he says, merely for those who are interested in the natural sciences and the marvels of Nature, and his method is to select a common, characteristic form from each genus and describe its salient features, external and anatomical, so far as they can be explored without serious dissection. Comparisons are drawn between these genera, and their relationships to the bigger groups which they represent are outlined.

All this is admirably done, and the explanations are thoroughly clear and as good as any we have seen. On the other hand, in common with many who rest in the biological stage and are incapable of developing into the higher one of zoologists, the author gives vent to his contempt for the systematic side of his subject, and his sole contribution is to append to each generic description brief remarks on, or sometimes only the names of,

the species he includes under it. He has evidently no first-hand knowledge of this branch of the subject, and his statements are antiquated and sometimes erroneous, as for example when the names of *Unio pictorum* and *U. tumidus* are interchanged. Fifteen plates depicting these species are appended to complete the book. Four are in gaudy, unnatural colours, the remainder in bistre half-tone, based principally, it would seem, on photographs, and for the most part devoid of their characteristic surface-markings or sculpturing.

Animal Husbandry. By H. J. Waters and F. G. King. Pp. viii + 546. (Boston, New York and London: Ginn and Co., 1925.) 7s. 6d. net.

No phase of agriculture has made more distinct advance within the last century than that which relates to the care and management of domestic animals. Certainly no other makes quite so attractive an appeal to human nature. This may explain the numerous text-books on this subject which appear from time to time. In one of the latest of these, by means of a judicious interweaving of theoretical principles and sound practical instruction, Messrs. Waters and King have succeeded in promoting that degree of co-ordination which should exist between the science and practice of stock farming.

A well-marked feature of the book is the attention devoted to the improvement in live-stock production, emphasis being laid on the attainment of the breeder's ideal through years of judicious selection and the vigorous culling of the scrub animal. It is pleasing to see that a few chapters are devoted to the encouragement of boys' and girls' clubs. This movement originated in the United States and has now assumed very large dimensions; doubtless it has been a factor of considerable importance in the general advancement in live-stock production. Useful hints are given regarding the formation of such clubs and what should be the ideals of club members.

We are of the opinion that the sections relating to the nutrition of the farm animal might have contained somewhat more detail. However, considering the size of the volume, the authors appear to have covered the ground with remarkable thoroughness.

The whole work is well produced (there are many beautifully reproduced photographs to illustrate the text), and should serve as an introductory or intermediate text-book for rural economy classes in schools and colleges.

Bibliographia Genetica. Onder redactie van Dr. J. P. Lotsy en Dr. H. N. Kooiman. Deel 1. Pp. v + 462. ('s-Gravenhage: Martinus Nijhoff, 1925.) 25 guilders.

DR. LOTSY and Dr. Kooiman have undertaken the task of editing this work, the first volume of which appeared last year. In a series of volumes, contributed to by geneticists from all over the world, it is intended to summarise the whole field of modern genetics. The enormous and rapid development of genetics, which began in 1900 and is still going on at an increasing pace, makes such a series of summaries very valuable to workers in this field and to those who wish to know the present state of the subject without looking up the original papers. Each author covers the field in which his own contributions figure most prominently.

Thus in the present volume of 460 pages we find Fritz von Wettstein summarising—in 38 pages—the genetical work on mosses, including his own important work on polyploidy in these forms. Similarly, Punnett takes up the genetics of the sweet pea, giving a chromosome map of the various linkage groups; Castle deals with rabbits and guinea-pigs, with illustrations of the more important types; Fruwirth sets forth in 48 pages the genetic results on the potato, and Lehmann in 56 pages those with Epilobium.

Of somewhat different character is Haecker's "Aufgaben und Ergebnisse der Phänogenetik," which occupies 222 pages and is divided into eight chapters, dealing with such topics as size and its inheritance, asymmetry, pigmentation, skull shape, etc., in a comparative way.

Each contribution ends with a list of literature and an index which places all the information in the most available form. The volumes are well bound and should find a place in every productive biological library. R. R. G.

A Course of Geometrical Analysis. By Dr. Haridas Bagchi. Pp. xi + 562. (Calcutta: Chuckervertty, Chatterji and Co., Ltd., 1926.) 20 rupees.

IT is evident from this book, which is concerned with differential geometry, that Dr. Bagchi knows a great deal of mathematics and that he is a charming man, but it is equally clear that he would have been well advised not to publish this work in its present form. It consists of a kind of commentary or gloss on Forsyth's "Differential Geometry," to which the author makes handsome acknowledgments—see in particular on p. 228 the disarming way in which he ventures to point out a misprint. He deals at great length with rather elementary and trivial points, referring to Forsyth for the serious algebra and for the explanation of his terms, so that the book is unintelligible by itself. There are long digressions on such matters as homogeneous functions and Jacobians, in which the author has really nothing to say which should not be well known to any one beginning the subject. In fact, the book would be intolerably prolix and quite unreadable were it not for the delightfully quaint turns of speech which are to be found on every other page, but from which, in spite of the temptation, we refrain from quoting. Twenty rupees is a large sum to pay for this kind of amusement; after all, Mr. Anstey has done it quite as well long ago. It is a great pity, because Dr. Bagchi is undoubtedly capable of doing good work in mathematics, if he would not spread himself so much.

Kleines Praktikum der Vegetationskunde. Von Dr. Friedrich Markgraf. (Biologische Studienbücher, 4.) Pp. v + 64. (Berlin: Julius Springer, 1926.) 4·20 gold marks.

DR. MARKGRAF's introduction to the practical study of vegetation is chiefly of interest because of a somewhat detailed consideration of the use of the quadrat method in the field, illustrated especially by reference to bogs and woodlands. This occupies nearly half the volume and, by comparison, the second section dealing with methods of investigating the features of the habitat appears all too brief, even for a beginner.

Letters to the Editor.

The Continuous Spectrum of Mercury.

IN recent papers I have discussed the continuous spectrum of mercury and its association with the resonance line λ 2537. Prof. R. W. Wood showed in 1909 that the green visual fluorescence of mercury vapour with continuous spectrum was destroyed by a red heat. I have recently studied the effect of heat on a stream of mercury vapour, showing the continuous spectrum as it distilled away from the electric discharge in which it originated. The visual glow disappeared, as might be anticipated from Wood's result. I thought it very probable that this was to be explained by the dissociation of mercury molecules which give rise to the (apparently) continuous spectrum. It was of interest to see whether the resonance line due to the atom would survive.

Photographs of the ultra-violet spectrum taken with these ideas in view gave a very surprising result The resonance line *did* survive, but with it was the strong part of the continuous spectrum in the region λ 3300, little if at all affected by the heat This surviving part of the continuous spectrum is separated by an intervening minimum from the visual region which *is* extinguished by the heat.

There is much more to do. I limit myself for the moment to announcing the above, which has been thoroughly confirmed.

The Golgi Origin of Fatty Yolk in the Light of Parat's Work.

DURING the last few years evidence has been steadily accumulating that the Golgi rings or crescents of certain eggs give rise to fatty yolk. As this conclusion has been challenged by certain authors (for example, Harvey, *Quart. Journ. Micr Sci.*, 1925), it seems to me desirable to set forth briefly the evidence in favour of the above view in the light of Parat's work, which lends strong support to it.

To the best of my knowledge, Hirschler (*Zeit. f. Wiss mikr. u tech*, 1915) was the first worker to describe, in the eggs of ascidians, a swelling of the Golgi elements and their fusion with the swollen mitochondria to give rise to compound yolk bodies. This conclusion has been recently supported by Parat and Bhattacharya (*Comptes rendus*, 1926), who have studied the eggs of Ciona by means of Vital dyes. The greater bulk of evidence in support of the Golgi origin of fatty yolk, however, has been furnished by Gatenby and his pupils, and more recently by myself. In the egg of Saccocirrus (Gatenby, *Quart. Journ. Micr. Sci.*, 1922) the juxta-nuclear Golgi apparatus spreads out and proliferates with the growth of the egg, and probably gives rise to granules which are fatty in nature. A similar process has been described by me (*Proc. Camb. Phil. Soc.*, Biol. Sci., 1924) in the eggs of Lithobius, in which the granules that arise from the proliferation of the Golgi apparatus grow to a considerable size and form fatty yolk which comes up in the centrifuged eggs exactly like the fatty yolk of Saccocirrus. In Helix (Brambell, *Brit. Jour. Exp. Biol.*, 1924) some of the Golgi elements are directly metamorphosed into fatty yolk which occupies the upper pole in centrifuged eggs. In Patella, Ludford (*Jour. Roy. Micr. Soc.*, 1921) and Gatenby and Woodger (*Jour. Roy Micr. Soc.*, 1920) give a very circumstantial and convincing account of the origin of fatty yolk from the Golgi elements which has more recently been confirmed by Brambell (*Brit. Jour. Exp. Biol*, 1924), who shows that the fatty yolk occupies the upper pole in centrifuged eggs as is the case in Saccocirrus, Lithobius, and Helix.

During 1924 and 1925 Parat and his collaborators (*Comptes rendus des Séances de l'Académie des Sciences* and *Comptes rendus des Séances de la Société de Biologie*) have published a large number of small papers giving the results of their study of the Golgi apparatus in the genital and somatic cells of both invertebrates and vertebrates. This is not the place for a full discussion of Parat's view. According to Parat, the Golgi elements exist in the form of vacuoles in all vertebrate and invertebrate cells. This he has proved by the use of the Vital stain, neutral red, the crystals of which precipitate in the vacuoles while the mitochondria remain quite colourless. These latter, however, can be stained by the application of Janus green. Vacuole-like or ring-like Golgi elements are of course very common even in fixed preparations of all the cells of invertebrates and the genital cells of vertebrates. The important contribution, however, that Parat has made is that even the network-like Golgi apparatus of the somatic cells of vertebrates really consists of vacuoles. The reticular appearance of the Golgi apparatus is, according to Parat, an artefact produced by the precipitation of metallic silver or osmium in the interior, or at the periphery, or between these vacuoles.

As the somatic cells arise by differentiation from the germ cells, and as undoubtedly the Golgi elements of a particular cell are roughly distributed to the two daughter cells during mitosis, it has been so far difficult to explain how the Golgi crescents or rings of the germ cells could give rise to a network found in the somatic cells of vertebrates. As to the contents of the vacuoles, Parat insists that they are not lipoidal, because osmic acid is the test for fats and not for lipoids The content is mostly a liquid and its reaction is acidic; hence the affinity of vacuoles for the basic neutral red. The absence of coagulum leads us to think that we have to deal in the majority of cases with the solution of crystalloids. But it is a fact that certain colloids not miscible with protoplasm can accumulate in the vacuoles, like aleurone grains in the vegetable cells. Final judgment on the chemical nature of the Golgi apparatus, however, can be delivered only when we are able to analyse it chemically, as has been done in the case of nucleo-proteins, but the view that the Golgi apparatus really consists of vacuoles in all animal cells lends strong support to the view of Guilliermond, Mangenot, Bensley, and others, that the plant cell vacuole is the homologue of the animal Golgi apparatus.

The above view of Parat also lends very strong support to the opinion that fatty yolk may arise from the Golgi elements. In spiders (Nath, unpublished), in Scolopendra (Nath and Hussain, unpublished), and in the firefly Luciola (Nath and Metha, unpublished), the juxta-nuclear Golgi apparatus consists, in Mann-Kopsch preparations, of rings which may also be appropriately described as vacuoles with a sharp chromophilic rim and a central chromophobic area. With the growth of the eggs, the Golgi rings proliferate and swell up and give rise to fatty yolk spheres by the

deposition inside them of free unsaturated fat which is stained black even by the osmic acid in Flemming-without-acetic. The most interesting point, however, is that when these osmicated fatty yolk spheres which appear solid are treated with turpentine, they show a chromophilic rim and a chromophobic central substance, exactly like the Golgi elements. On further decolorisation the yolk spheres appear like clear vacuoles, which give a frothy appearance to the whole egg.

Recently Miss S. D King (*Proc. Roy. Soc.*, June 1926) has given convincing arguments in favour of the Golgi origin of fatty yolk in the eggs of Oniscus exactly as in the eggs of Lithobius. It seems to me that there is no justification for the attacks that have been made on the above view of Gatenby and his pupils. My line of argument is perfectly simple. Golgi rings look like vacuoles, and fat spheres are certainly vacuolar in nature. It seems clear that the vacuole-like Golgi elements give rise to vacuole-like fatty yolk spheres, by a process of deposition in their interior of free fat not miscible with the general cytoplasm.

Anthropology and Administration.

ALL anthropologists will feel grateful to Mr. Ormsby-Gore, as well as to NATURE, for the vigorous pleading on behalf of the Imperial importance of our science by the Under Secretary of State for the Colonies, and for the interesting leading articles in the issues of October 30 and November 6. The passage from the Under Secretary's report quoted in NATURE is of special value for the right appreciation of anthropological methods. Mr. Ormsby-Gore sees clearly that " personal contact " is not enough. A " scientific study of their [the natives'] mental and moral characteristics, of native law and customs, of native history, language, and tradition " is indispensable. As is pointed out in the leading article, " There is now a wealth of accumulated experience and knowledge at our command in our schools of anthropology." I should like to add a few concrete suggestions as to how anthropology should be studied in order to be of direct use to the administrator.

The official in a Crown Colony has to legislate and to administer justice to his subjects ; he has to regulate relations between white settler and native-relations which are predominantly of an economic or judicial nature—and he has to deal in various ways with local custom and belief. Three lines of anthropological approach are therefore of extreme importance to the future Colonial administrator : early economics, the psychology of native races, and, above all, the theory of primitive jurisprudence. Remarkably enough, two of these branches of learning, economics and jurisprudence, have been almost entirely neglected until recently. Text-books of anthropology, and even of social organisation, as well as most records of field-work, ignore them or deal with them inadequately or one-sidedly. Yet both primitive production and consumption of wealth, as well as the principles of justice and its administration, are fruitful subjects of observation in the field, as I have proved from my own experience and have shown in my published work. When trying to co-operate with the Colonial authorities in the utilisation of native labour, and the preservation of native culture, it seems of paramount importance to insist from the onset that our science can and will assist directly the authorities in what they need most.

There is, moreover, no practical difficulty in the way of such teaching in Great Britain, for it has been provided for by two or three universities, including that of London, where anthropology is taught in several of its colleges. At the London School of Economics a chair of ethnology has been in existence since 1913—and afterwards a readership in social anthropology—while later on the teaching of this subject was also established at University College and Bedford College. In the Department of Ethnology of the London School of Economics, under the direction of Prof. Seligman, the study of the early economic systems, the principle of native law and of savage mentality has been carried on for the last fifteen years. With field-workers of the measure of Prof. Seligman and Prof. Westermarck, with sociologists such as Prof. Hobhouse and Prof. Graham Wallas, with jurisprudents specially interested in anthropology such as Prof. Jenks, the teaching of our science has gone hand in hand with that of comparative law, comparative sociology, and economic history.

Recently also chairs of international relations and international history have been set up at the London School of Economics, and are held by Prof. Baker and Prof. Arnold Toynbee respectively. A wide scope is given to the study of the subject, and problems of inter-racial relations ; the mutual influences of western and oriental culture ; and the diffusion of European civilisation among simpler peoples fall within the sphere of these two chairs.

To such studies the background of appropriate anthropological theory is indispensable. The anthropologist is able first to supply the dispassionate attitude of mind so necessary to the discussion of inter-racial problems. His methods, especially if he is trained in field-work, tend to develop that sympathy with each specific culture based on understanding, which is perhaps the best antidote to political bias or false sentimentalism.

At the University of London we have also perhaps the biggest school of comparative linguistics extant, the School of Oriental Studies. I believe that any serious attempt to train future settlers and officials in the anthropological outlook must include linguistic teaching both of a theoretical and practical nature. It is to be hoped that the already existing co-operation between the London School of Economics and University College will soon be extended, also the School of Oriental Studies, and that with the assistance and advice of the Colonial Office, some such scheme of training will be devised as that already in force in the universities of Holland, above all at Leyden. This scheme has proved invaluable to the Dutch Colonial authorities.

There is, then, a definite field for anthropological research which can be made practically useful to the Colonial authorities. By cultivating it more intensively than is done at present, anthropology can also be brought in touch with realities and be able empirically to verify some of its theories.

Nothing is so salutary to a new science as a pragmatic contact with facts. Without in any way swerving from the pursuit of purely theoretical ends, anthropology needs at present to be deflected from the curio-hunting sensation-mongering interest which had been its curse in the past. There is a useful as well as a useless anthropology.

The Recurrence of Magnetic Storms.

A FEW remarks seem expedient on Dr. Deslandres' letter in NATURE of October 30. Various recurrence phenomena, including pulsations with periods of a few seconds or minutes, have attracted the attention of magneticians, but my original letter referred only to the recurrence of magnetic storms, that is, large disturbances of considerable duration experienced simultaneously all over the earth. The various members of a recurring series of storms do not seem to bear any special family resemblance to one another. The methods I have employed have demonstrated recurrence after intervals of 27 days or multiples thereof, but not in shorter intervals. I am uncertain whether Dr. Deslandres agrees that these large prolonged disturbances show only the 27-day interval T, or whether he believes that they also tend to recur to a lesser extent in intervals $iT/6$, where i is integral, and that the failure to show these shorter intervals is the fault either of my data or of my methods. He refers to doubts entertained respecting the international character figures. So far as I am aware, the only criticism passed on these is that any particular character figure, for example, 1·5, is not an absolute measure of disturbance, but may signify different amounts of disturbance in quiet and disturbed years. This criticism is one I have made myself, but the defect does not prejudice the use of the figures for discriminating between disturbance on consecutive days, the only purpose for which the figures have been used in the present connexion.

Dr. Deslandres also seems to suggest that the use of mean data from a number of years may obscure real recurrence intervals prominent in individual years. If, however, mean data from a number of years reduce to insignificance a period prominent in one or two years, it implies a remarkable deficiency of recurrences with this period in the other years, a phenomenon difficult to explain unless the prominence during the one or two years was a matter of pure chance.

As a matter of fact, the results which I gave from the international character figures did not represent an 11-year period, as Dr. Deslandres seems to suppose. Two separate periods, one of six years, 1906 to 1911, and one of five years, 1920 to 1924, were dealt with separately, and neither showed the intervals $iT/6$. The 11-year period 1890 to 1900 which I dealt with preceded the existence of international figures. The results for it were based on Kew data alone, the criterion of disturbance being the absolute daily range of the horizontal force. No trace of a period a submultiple of T appeared in that case either.

As regards the suggestions which Dr. Deslandres has made for the better utilisation of the international character figures, the employment of 14 instead of 5 selected days a month has two rather obvious drawbacks. It entails nearly three times as much arithmetic, and it largely waters down the amplitude of the primary pulse. There is admittedly no special virtue in the number 5; it merely happens to be the number of quiet or disturbed days internationally selected for each month. But long experience has shown that in disturbed months it is difficult to secure more than 5 reasonably quiet days, while in quiet months it is sometimes difficult to get so many as 5 reasonably disturbed days. The suggestion to consider individual cases individually embodies the procedure which I originally followed after Mr. Maunder's investigations directed my attention to the subject. When following this procedure I did not succeed in arriving at any conclusions from which I felt assured that the influence of personal bias had been excluded. For ascertaining definitely the cause of the phenomenon the consideration of individual cases may be essential. It has of course special attractions for astronomers like Dr. Deslandres or the late Rev. A. L. Cortie, S.J., who have corresponding solar data immediately available.

C. CHREE.

75 Church Road, Richmond, Surrey.

THE letter on the above subject by Dr. Deslandres in NATURE of October 30, contains a reference to some preliminary investigations made by me some fourteen years ago.

From Dr. Deslandres' remarks I gather that he regrets that I should have confined myself in these investigations to 10 spots, and I wish to correct this impression, inasmuch as I have subjected all spots which appeared during the years 1912–14, that is, three years, to the identical examination, but the space available permitted only of the publication of one specimen table. The result in all the many other tabulations was the same, but when the material I worked upon gave out, I certainly came to a standstill. However, by an odd coincidence, on the very day I read Dr. Deslandres' communication, I received a letter from Stonyhurst offering to provide me with all the required data on similar lines as those the *Observatory* used to provide so very suitably. Therefore I intend to take the matter up again, and desire at this juncture already to express my thanks to both Dr. Deslandres and the Stonyhurst Observatory officials for their kind encouragement.

I wish to add that I am equally delighted to read that Dr. Deslandres has also found the presence of the D_3 helium-line over merely faculic areas, an observational fact of many years' standing with me, and to which I have often referred in lectures and papers.

Post-Cretaceous Igneous Activity in Western India.

THE discovery of nepheline-syenite and monchiquite in Girnar, Kathiawar, announced by Dr. J. W. Evans in 1901 has, after a lapse of a quarter of a century, been followed by detailed petrographical and field investigations published in recent issues of the *Records of the Geological Survey of India* and the *Journal of Geology* respectively. The central mountain forms a dome of plutonic rocks intruded into the overlying Trap. Further investigations in Gujrat and Kathiawar have revealed a fascinating chapter in the history of post-Cretaceous igneous activity in India which is not dissimilar from the Tertiary igneous activity of Scotland. They acquire a special interest in view of the recent theory of magmatic cycles and its application by Dr. G. W. Tyrrell to the British Isles.

The plateau basalt which was presumably erupted from long fissures is, as a rule, free from evidence of explosive activity and the mode of its extravasation needs no description. This was followed in India by laccolithic intrusions, of which the Girnar and Barda hills are better known than others. A large circular dyke, corresponding to the ring-dykes of the Scottish intrusions, occurs round the central intrusion of Girnar (*Journal of Geology*, Vol. 34, No. 4). The long dykes which follow an approximately elliptical course east of Girnar and are so conspicuous in the Gir Range and near Gondal are, likewise, to be explained as

a result of the stresses set up by a concealed intrusion which denudation has not yet exposed to the surface.

In addition to these, a number of other laccolithic intrusions appear to lie on a line which runs from Baroda *via* Bhavangar and Girnar to the Barda hills. An assumed northerly shift of this line makes it continuous along the intrusions of Cutch, Baluchistan, and Persia. It indicates a zone of weakness which keeps its parallelism to the coast and along which the basaltic magma was still able to intrude itself when the ascensive force was unable to bring it any longer to the surface. Slow crystallisation at some depth in the local magma reservoirs brought about differentiation and resulted in the production of acid types which took a plutonic, hypabyssal, or volcanic phase according to the mechanical strength of the intruded beds and the movement of the magma. The acid igneous rocks of the Deccan Trap, therefore, appear to represent the end product of differentiation in a basaltic magma.

This period of laccolithic and dyke intrusions was followed by the manifestation of local volcanic activity of the explosive type at various centres probably on the top of cooling reservoirs. Detailed investigations have been carried out by us on the Pawagadh hill, near Baroda, the rhyolites of which were first described, after a hurried visit to this locality, by Dr. L. L. Fermor, who had suspected an interbedding of rhyolite with basalt. The results of our examination of the hill show that Pawagadh became a centre of volcanic activity of an explosive type long after the cessation of the eruption of plateau basalt, during which interval valleys had been carved out in the existing lava flows. Doleritic olivine-basalt was extravasated in contrast to the olivine-free compact plateau basalt, followed by andesitic lavas and tuffs. Rhyolite flowed at the end from a central neck at the top of the hill (2811 feet) and from a few other subsidiary vents at a lower level. The Osham hill, where the rhyolite occurs again as the end product, appears to have had a similar history. A number of other volcanic vents are known on the line of laccoliths indicated above. This association confirms the explanation of volcanic activity of the explosive type put forward by Dr. A. L. Day and supported by Prof. A. Holmes (NATURE, vol. 117, p. 66).

The above outline serves to indicate the fact that in Gujrat, Kathiawar and Cutch we have an interesting record of events of an igneous cycle initiated by a fissure eruption. Field and laboratory work is in progress which will throw light on the detailed history of this period.

The State and Industrial Research Associations.

THE arguments adduced by Mr. J. W. Williamson in his paper on "The State and Industrial Research Associations," published in NATURE of Nov. 6, have made out several good reasons for the permanent subvention of such bodies by the State. No doubt his arguments might be met by the counter-argument that each industry should and could take out its own policy of insurance against ignorance.

Between these two alternatives there is a middle course which suggested itself to me in the course of past experience connected with the actual founding of one such association. This course would, I think, meet Mr. Williamson's views, and yet would still leave the responsibility for profitable development to be carried by the industry itself.

The suggestion I would make is cognate with my analysis of research into eight classes, defined by the restriction or freedom of their methods, aims, and subjects respectively (NATURE, Aug. 28, 1926). In the second of these classes the research is restricted to a subject which may be of industrial importance, such as cotton, but it is otherwise free; not bound to any particular technique or science, not constrained to any aim, but working simply to increase the total of scientific knowledge concerning its subject, whether such knowledge be 'useless' or otherwise. Such research is a fit and proper subject for State endowment to a limited extent; indeed, it could probably make out a more forcible claim on social grounds than could pure science, my unrestricted first class.

In the organisation of such a research association as already exists, the endowment would support a nucleus organisation within it, whereto some three members of the staff would be allocated in such a way that even if an industry decided to abandon its association, the nucleus thereof would still continue to exist and function, upon a laboratory footing. Laboratories are not costly if they have not to concern themselves with the application of results; the administrative charges of such a nucleus would be trivial; the staff would, by definition, be picked men who could co-operate as colleagues without other formal direction than that of the accidental senior amongst them. They could be housed in some existing institution until such time as their industry saw fit to re-crystallise its research around this nucleus, in order to make their results usable by further studies made under restrictions of aim or method.

A State endowment of less than 4000*l.* a year would ensure such a nucleus of permanent appointments—not permanent staff—for each industry, and this nucleus would cost the same amount for every industry, large or small. The staff of an existing association would then be assured that, even if their association dissolved, still the roots of their work would continue to grow forward. Issues too big to be profitable could be taken up by this nucleus staff; issues too profitable to be interesting would be willingly met by temporary expansion of the industry's direct contribution, and the subsequent contraction would not involve a risk of disintegrating the whole structure.

A certain insecurity which is inherent in any organisation built entirely on voluntary levies has an unfavourable influence on research, and while I do not quite agree with Mr. Williamson's cogent plea for a permanent State support of research associations as at present constructed, I believe that the insertion therein of such permanent nuclei would sufficiently ensure all the aims he has expressed, and more.

W. LAWRENCE BALLS.

Meldreth, Royston,
Herts., November 10.

Modern Photometry.

ALTHOUGH, as the reviewer of Mr. J. W. T. Walsh's "Photometry" in NATURE of October 23 says "The reader must not object to change" and "This is not the place to discuss fully the vexed question of nomenclature," and that "of course" Mr. Walsh uses the terminology adopted by the International Commission, I join in regretting the exchange of 'candle-power' for the words 'luminous intensity.' The official language of the Commission is French. Of course, 'candle-power' cannot be literally translated into French. I pointed out, at the meeting of the Commission in 1921, that M. Blondel at the Geneva Congress in 1896 had used the expression '*puissance lumineuse*,' but it was objected that the word *puissance*

cannot now be employed in that sense. In English usage, 'candle-power' is strictly a form of power, and might, if we had the data, be defined in ergs per second. In French, an electric current cannot be strictly expressed in amperes, but the *intensité* of a current can be so stated. In English, the notion of *intensité* is here redundant, and, as the reviewer observes, "In scientific English the word 'intensity' always connotes something analogous to 'energy per unit area.'"

A good deal might be said about the proper use of the term 'flux,' when 'luminous flux' is to be substituted for 'light.' Flux is generally employed in English to connote a flow, not a rate. 'Luminous radiation' is all that is wanted, without introducing the conception of a rate. Need we stop to consider, or wait to know what light is before using the word in scientific English? Heat is not easy to define, temperature is less easy, but no new terms are wanted here.

A. P. TROTTER.

Teffont, Salisbury,
October 30.

I AM very glad to find Mr. Trotter in agreement with me regarding some points in photometric nomenclature, but in reply to his concluding remarks I have only to suggest that the scientific use of the term 'light' should be at least as exact and simple as its ordinary use in English. Terms like 'ultra-violet light' are simply ridiculous. That is why I suggested a greater care in the use of the word. Why manufacture new terms because a very small proportion of the population misuses the good old words?

L. C. M.

Broadcasting Birth-control.

SIR JAMES MARCHANT, in a letter published in the *Times* of November 17, refers to my "extreme and one-sided views" on the subject of birth-control. As there appears to be much misconception in regard to what I actually did say on this subject during the broadcast debate on "Is Science Bad for the World?" on November 16, I should like to have the opportunity of putting my words on record. They were as follows:

"Birth-control is capable of great harm, if it is not regulated; but its absence would lead to greater harm. It therefore must be regulated and supervised by the State" (or, I would now add, by the medical profession), "and the nation should allow no interference on the part of prudery or of religious intolerance. . . ." Here I was interrupted.

I claim that this statement was neither extreme nor one-sided. Whether subjects like 'birth-control' should ever be mentioned on the wireless is another issue altogether. To me personally, letters such as that of Sir James Marchant appear to add point to the fear which has been expressed that State control of broadcasting might well tend to dulness and sterility through a banning of all controversial matters. Had broadcasting been possible in 1859, doubtless no expression of opinion would have been allowed over the wireless on the shocking question of whether man had not been specially created, but had evolved from animals.

However, I am here only concerned to defend myself from the imputation of having abused my privileged position at the microphone. I should also add that a year ago I was invited to give a series of wireless talks on biology and human life, and that no objection was then raised by the B.B.C. to the brief references to birth-control which I there made. I therefore conclude (and earnestly hope that I am correct) that though the policy of the B.B.C. may be against the raising of the question in a controversial way in debate, this does not preclude the topic from ever being mentioned over the wireless.

JULIAN S. HUXLEY.

Strand, London, W C 2.

Spectrographic Junction between the X-ray Region and the Extreme Ultra-violet.

IN a letter published in NATURE of October 16, p. 551, Dr. A. Dauvillier has announced some preliminary results of attempts to get spectroscopic evidence of the unknown region between the X-rays and the extreme ultra-violet. He has followed the same general methods and technique as have been used by me in measuring the K- and L-series of the formerly unknown domain of wave-lengths 12 Å.U.-25 Å.U. (*Phil. Mag.*, February 1926).

My experience from this work is that a thorough critical scrutiny of the obtained spectrograms is necessary to exclude erroneous interpretations. To show that the lines found were not ordinary short wave-lengths reflected in higher orders or in other atomic planes than those supposed, Dr. Dauvillier has used goldbeater's foil. Our experience is that such foils, even of the thinnest obtainable sort, absorb completely all wave-lengths greater than 13 Å.U.-15 Å.U., and therefore it is scarcely possible by this means to identify the longer wave-lengths.

It is also surprising that a foil of magnesium thick enough to prevent the photographic plate from fogging by the rather intense ordinary light would transmit this very soft radiation in any considerable amount, especially when the relatively small intensity of the N- and O-series, as also theoretically suggested by Kramers, is taken into account.

It will, however, be of great interest to get a detailed report of these experiments, which, if they prove to be correctly interpreted, are of high scientific value.

ROBERT THORÆUS.

Physical Laboratory of the University,
Upsala, Sweden, October 29.

Quantum Theory and Intensity Distribution in Continuous Spectra.

THE undulatory mechanics makes it possible to give a quantum theory of aperiodic phenomena, and, in particular, to compute the intensity distribution for continuous spectra. The theory has recently been applied to the hyperbolic orbits of the hydrogen atom (*Proc. Camb. Phil. Soc.*, Oct. 1926). The results are too complicated to be given here in detail; but they yield an estimate of the intensity distribution in the continuous X-ray absorption spectra. This is, I believe, the first experimental verification of this part of the theory.

According to the theory, absorption sets in discontinuously at the series limit with a finite value, which, for a given n_k electron, is proportional to the wave-length of the limit. For very short waves the absorption coefficient is of the form $f(n,k)Z^{2k+2}\lambda^{2+k}$, where Z is the effective nuclear charge and λ the wave-length of the radiation, and where $k = \frac{1}{2}, \frac{3}{2}$ . . . . The values of $f(n, k)$ give atomic absorption coefficients $Z^{\alpha}\lambda^{\beta}$, where α ranges from 3 to 4·5, and where β, for the shortest waves, is 2·5, and for the customary range varies between 2·5 and 3. This is in agreement with the empirical formulæ.

University Laboratories and Research.[1]

By Sir J. J. THOMSON, O.M., F.R.S.

PHYSICAL laboratories at the present day are very different from those existing when I began to study physics now, alas, more than fifty years ago. In those days they could be counted on the fingers of one hand. They were not palatial buildings, but for the most part consisted of a few odd rooms, wrung from a reluctant governing body by the importunity of the professor. The physical laboratory of Owens College, now the University of Manchester, where I began my study of physics, was a few rooms which nobody else wanted in Cobden's house in Quay Street, and I believe that one of the rooms in Lord Kelvin's laboratory at Glasgow was an old coal-cellar. The whole equipment of apparatus could in many cases not have cost more than a few hundred pounds. Now almost every university and technical school has a separate building equipped with expensive apparatus.

The provision of these laboratories, and the funds required for their maintenance, has become a very serious question for those responsible for the finances of our universities. I am afraid that physical laboratories are especially expensive. I am afraid, too, that the sums required for their equipment and maintenance are much more likely to increase than to diminish. They have indeed increased very rapidly of late years. Let me give an example of my own experience. At the beginning of this century there were about thirty persons doing original work at the Cavendish Laboratory. Their researches cost the laboratory between 300*l.* and 400*l.* a year. The cost now would be at least six times that amount. As science progresses the instruments required become more and more elaborate and expensive. The old endowments of the universities and the fees from students are quite inadequate to meet the expenses on the new scale. New studies require new endowments; there is still need, nay, there is increasing need, for the 'pious founder.'

It would be ungrateful, however, not to acknowledge the liberal help which is now given to physical science by the Government of the country, partly by grants to the universities, partly by grants for research administered by the Royal Society, and partly by the formation of the Advisory Council for Scientific and Industrial Research, which, among other things, finances the National Physical Laboratory. The Government, indeed, is now giving to physical science far more than any Government gave before. To the liberality of some of the city companies we owe some fine laboratories, and there are many private benefactors to whom our gratitude is due, but there is still room, nay, need, for many more.

It is not necessary for me to dwell on the educational value of the study of science in our universities and schools. Indeed, there are those who maintain that it is the literary studies that are in danger of neglect. I believe, however, that the vast majority of scientific men recognise the great, nay, the vital importance of literary subjects in education, and would view with horror a system from which they were absent. Both are necessary, but in my opinion science without literature would be worse than the old system of literature without science.

The educational value of the training in science depends to a great extent upon work in the laboratory. What are the educational values of science? Are they not that science arouses and does something to satisfy the wonder and curiosity we feel about the marvellous processes going on in the world around us; that it cultivates and develops the powers of observation; that, and this is a most important point, it teaches us to reason about facts that come under our own notice? It gives the student confidence in the powers of reason. I think every teacher of science knows that when a student calculates from the principles he has been taught what will happen, say, when light passes through a system of lenses, and on proceeding to try the experiment finds that the result agrees with his predictions, it comes to him as a great surprise. It comes almost as a shock that human reason can lead to accurate results. Nothing helps a student to use his reason more than the belief that it can be trusted. But to get these educational values from science the laboratory is essential; it is there that the facts on which he has to exert his reason are to be found, where the contact between the facts and the intellectual effort takes place. Again, by his experiments the properties of light, electricity, and so on are impressed upon his mind with a vividness possible in no other way. It is in the laboratory that we realise that close touch with Nature which is essential to the progress of science.

It is the duty of the universities to enlarge the bounds of knowledge, as well as to instruct the community in the knowledge already won. Such research is of great value to the community The discoveries made in the universities by people working simply to increase human knowledge, without any idea whatever of any industrial application, are the very discoveries which create new industries and revolutionise the old. Take the case of the electrical industry. How did that come into existence? It was not because somebody set to work to develop a method for the transmission of power. It arose because Faraday wanted to try, in the laboratory at the Royal Institution in London, what would happen if he moved a magnet about near a coil of wire. That industry would never have been created if he had simply worked with the idea of discovering something to transmit power. I want to emphasise this point because there are many who say that the only legitimate object of research to which public funds should be applied is research with definite industrial intention. I am the last to decry *ad hoc* research, but it is not enough.

When bows and arrows were the most formidable weapons, it would have been a very good thing to establish a Bow-and-Arrow Research Association to make sure that one had got the best bow and arrow possible. But some man, working to get knowledge for its own sake, discovered gunpowder, and made the best bow and arrow obsolete. The truth is that Nature is so full of wonderful things that there is probably a much better solution of any problem than any we possess. We shall not find it by working directly on the problem, but if we work away, faithfully recording

[1] From an address delivered at the opening of the new science laboratories at the University College of North Wales, Bangor, on November 2.

what we see in our experiments, we shall probably get a hint and arrive at results which may be of importance. It is difficult to say that any discovery which is made is devoid of commercial value. Our experience in the War showed us that the most recondite phenomena, known only to a few, could be applied for the service of the country.

I have heard the fear expressed that the multiplication of laboratories may lead to something like over-production—that there may not be enough discoveries to go round. Such a fear seems ludicrous to a physicist who knows that a discovery is not a terminus but an avenue opening up new and wider fields for work. We are surrounded on all sides by physical and chemical phenomena of which our knowledge is not even in its infancy, scarcely in embryo. Consider for example the chemical and physical properties of living matter. A tiny seed is put into the ground and becomes with nothing but the soil, water, air, and light a workshop weaving for leaf, flower, and fruit fabrics of exquisite texture, moulding these with unerring accuracy into shapes of the greatest variety and complexity, dyeing them all the colours of rainbow, often spreading the colours in patterns full of minute and elaborate detail, laying up stores of substances, most of which are beyond the power of the chemist to produce, and finally producing other seeds able to produce the same effects. Compared with results like this our workshops, our looms, our dye-works seem clumsy and inefficient. What is the mechanism by which these wonderful results are produced? We have no idea.

To find out the mechanism of this tiny seed we shall have to develop methods of investigating the changes that go on, almost molecule by molecule. Of late years methods have been devised which are continually diminishing the distance between us and the solution of these problems, and in the not too indefinite future we may hope to get to know something of the way in which those marvels are accomplished. This requires the co-operation of many sciences, and it seems to me that the new buildings at Bangor are admirably fitted to take part in this great work.

Richard of Wallingford and his Rectangulus.

By Dr. R. T. GUNTHER.

THE celebration of the sixth centenary of the elevation of Richard of Wallingford to the Abbacy of St. Albans in 1326 is an occasion of far more than local interest, for it is also the celebration of the sixth centenary of the beginning of trigonometry in England.

Richard's father was a blacksmith in the village of Wallingford, who died when the son was only ten years of age, but Richard was fortunate enough to be adopted by the Prior of Wallingford, who sent him to Oxford at the age of seventeen. Six years later he was admitted to the monastery of St. Albans, perhaps, as Sir Edgar Wigram has suggested, because he instinctively recognised that in those days a monastery was the only refuge where a man of science could find license and leisure to prosecute his studies undisturbed. But after three years training, Abbot Hugh sent him back to Oxford as one of the students whom every Benedictine house was bound by statute to maintain at the University, in order to ensure that its learning should be kept up to standard. Apparently to the deep concern of the chronicler, Richard then proceeded to spend valuable time on mathematics and astronomy, which he was expected to devote to theology. But in 1326 he had his reward by being elected Abbot of St. Albans, and, as after events proved, turned his scientific training to good purpose by reducing the debt and by rebuilding the Cloister of his Abbey.

We have two miniature portraits of Richard of Wallingford in the illuminated chronicle of Matthew Paris. In the first he is engaged at his bench making or measuring a circular instrument with a pair of compasses. His simple tools are lying by his side and his Abbot's mitre is on the floor. In the second portrait he is pointing to the famous clock which he made for the Abbey. A point of singular interest is the fact that in both portraits he is represented with a spotty face, indicating the ravages of the incurable disease of leprosy which he had contracted at Avignon. Indeed, of this we have confirmatory evidence in a prayer composed by him in later life after his promotion as Abbot. The words are worth quoting, if only as an example of the devotions of an English man of science of the fourteenth century.

> Though I be a man of lowly state, and smitten by Thy providence with an evil plague, so that I am not worthy to walk among men, but should by law be cast without the camp; yet Thou, O Lord my God, by what secret judgement I know not, dost yet hold me in honour, such honour as I have known none of my parents or kindred to attain to, in all health of body; and as I oft-times remember with wonder at Thy great bounty, dost so incline the hearts of the great towards me, that ever when present, they d not abhor my speech and the deformity of my face and hands, but rejoice to converse with me. . . .

We may, therefore, claim that the miniatures are truthful representations of "The Father of Trigonometry" in England.

Wallingford's trigonometrical methods are indicated in two works, *De sinubus demonstratis* and *De sinubus et arcubus in circulo inveniendis*, and their practical application is further described in his treatise on the Art of working with a Rectangulus.

Two scientific treatises on the 'Albion' and the Rectangulus are dated about the time of his election as Abbot. Fortunately, illustrated copies of the manuscript are still extant and they include many working drawings which reveal the construction of the instruments so clearly that a reconstruction is possible.

The 'Albion' has often been stated to have been the Abbey clock for which he is famous; but the evidence of the original manuscript points to its having been an elaborate Aequatorium or Volvelle composed of a number of circular dials for showing the position of the planets: the name 'Albion,' or all-by-one, having reference to the various operations which could be performed by the one instrument. There is no mention of cogwheels, pulleys, and weights, or of any driving

or regulating apparatus in [illegible] xion with the Albion. Doubtless it was intended to [illegible] used with his other invention, the Rectangulus, with which the relative positions of stars could be measured.

In the prefatory sentences to his treatise on this instrument, Richard tells us that he invented the Rectangulus in order to obviate the laborious and difficult use of the Armillary Sphere in determining the course and place of fixed stars and planets, and for other problems which were usually solved by the astrolabe and the torquetum. The fundamental principle of the instrument is based on the theorem of Euclid on the equality of the angles and lengths of equidistant lines between parallels.

The instrument consists of three superposed limbs or rules connected by hinges in such a manner that each limb may not only be opened out at varying angles like the blade of a pocket knife, but may also be rotated round a peg-pivot below its hinge. Above all is an alidade, or rule with perforated sight-vanes, which is so hinged to the third limb that it can be either elevated above it or be moved parallel with it. The hinges may all be clamped more or less tightly by wedges driven through slots in the pegs, like those used in astrolabes.

To complete the instrument six scales of bronze were prepared and graduated. Three of these are fixed to the sides of the three limbs; the other three are movable, being pivoted on the pegs under the limbs. The lowest scale was divided along the edges into 60 equal divisions called degrees or parts of chords, *gradus seu partes cordarum*, each of which might, in the case of a large instrument, be further subdivided into 60 parts, while the middle or intervening band was divided by a table of right and versed chords, *corde recte et verse*. This middle divided band is omitted in the five other scales. The division of the upper scale of chords, which are called right chords, are numbered from the peg to the end of the scale; the lower scale, called versed chord, is numbered from the end of the rule to the peg. The ends of the alidade and upper limbs are provided with plumb-lines.

In his second treatise on the use of the Rectangulus, Wallingford explains in ten chapters how various observations and calculations are to be made. In the first place the whole instrument must be adjusted for level by a plumb-line fixed near the surface of the base pillar. The instrument is then ready for the first exercise, "To find the right and versed chord of a given arc less than a quarter of a ci[illegible] to find any arc from a given chord." The [illegible] in his ov[illegible] words, as translated by Sir John Fin[illegible] is to

let the perpendicular of the second limb hang over the first limb at the given arc, the length between the peg and the string reckoned from the peg to the end of the limb is the right chord of the arc. The distance beyond the string, reckoning from the point of the limb, gives the versed chord of the same arc. The reverse process enables an arc to be found from its chord. Note that the plumb-line hangs at right angles when it falls on equal divisions of the scales on both sides of the limb, and this is chiefly why the scales of chords are double on all the scales. The right and versed sine of an arc greater than a quarter of a circle may be easily found from what has been said, for the right sine of an arc less than a quarter of a circle is the right sine of the arc of the rest of the circle. Further, the versed sine of an arc greater than the quarter of a circle but less than a semicircle is greater than the semidiameter by the amount of the right chord of the angle by which the given arc is greater than a quarter of a circle, as is shown elsewhere.

Then follow chapters upon how "To find the meridian," "To find the altitude of a star above the horizon and its azimuth," "To find the latitude of a place by a star which does not set," "To find the latitude and longitude of a star from the equinoctial circle," "The declination of a star and its latitude in the ecliptic," "To find the true place of the sun from its aspect," "To find the true place of the moon in longitude and latitude," "The true place of fixed stars in latitude and longitude."

The treatise concludes with the sentence, "The Rectangulus was invented for the purposes which have been explained, and therefore, because what has been explained is sufficient for an apt pupil, the way is clear to everything that can be done by other instruments. Here I finish."

Wallingford died in 1335 at the age of forty-three. It is reported that the Abbot's house where he was sleeping was struck by lightning, and, weakened as he was by his disease, he did not survive the shock. His tomb is in the Abbey Sanctuary just east of the altar rails.

A Remarkable Suborder of Fishes.

DURING the Danish *Dana* Expeditions of 1920–1922 in the North Atlantic and the Gulf of Panama, under the leadership of Prof. Johs. Schmidt, a magnificent collection of ceratioid fishes was made, which forms the subject of a monograph by Mr. C. Tate Regan,[1] Keeper of Zoology in the British Museum (Natural History), from which the accompanying illustrations have been reproduced. Prior to the *Dana* Expeditions, and excluding the *Michael Sars* collection, as yet undescribed, only about sixty examples of this amazing suborder of fishes were known, so that the *Dana* addition of 220 specimens representing 39 species, many of which were new to science, was of great biological value.

The Ceratioidea form part of the order Pediculata, that group of highly specialised fishes in which the first ray (illicium) of the spinous dorsal fin is placed on the head and modified into a 'line and bait.' Their characteristic features are evidently related to their conditions of life. They are inhabitants of the deeper parts of the ocean, the majority living in mid-water, probably from 500 to 1500 metres below the surface, where there is little or no light. Related to the absence of light is the structure of the 'bait,' or terminal expansion of the illicium, which is a luminous bulb; the outer skin of the bulb is generally transparent, and within is a glandular sac that opens to the exterior by a pore and has a luminous secretion; the lower, or

[1] "The Pediculate Fishes of the Suborder Ceratioidea." By C. Tate Regan. The Danish *Dana* Expeditions 1920–1922 in the North Atlantic and the Gulf of Panama. Oceanographical Reports edited by the *Dana* Committee, No. 2 (Copenhagen, Gyldendalske Boghandel; London: Wheldon and Wesley, Ltd., 1926.) 15s.

sometimes the posterior part of the sac is pigmented, and this pigmented area, according to Brauer, is covered inside by a layer of cells which acts as a reflector. Externally the bulb may be furnished with papillæ, flaps or tentacle-like filaments. There are great differences in the length of the 'line' or first dorsal ray; from fishes in which the luminous bulb is sessile on the head, to those in which it is borne on a line several times as long as the fish itself. The line is articulated to the anterior end of a movable basal bone which as a rule lies in a trough on the upper side of the head. Those more highly specialised forms, in which the basal bone is slender and flexible and completely exserted, may be considered true anglers, for they have both rod and line, and Lasiognathus (Fig. 1), which is in addition provided with hooks, may well be termed a complete angler.

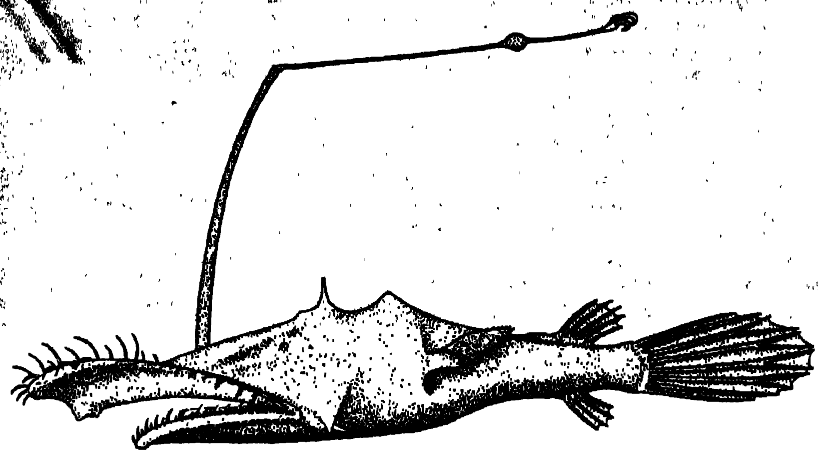

FIG. 1.—Lateral view of *Lasiognathus saccostoma*, Regan. Length 75 mm.

The majority of the ceratioids appear to be piscivorous, and have a large mouth and jaws furnished with slender acute teeth which are generally arranged in about three series. The teeth are depressible inwards, an arrangement which would make it very difficult for a ceratioid to release a fish it had seized, even if it wanted to. Neoceratias (Fig. 2), with teeth on top of the head that recall the spines of an echinoid, is perhaps the strangest of all. In some genera the stomach is extraordinarily distensible; thus a Melanocetus has been known to swallow a Lampanyctus three times its own length and many times its weight. Equally remarkable are the pincer-like jaws of Rhynchoceratias, and the forwardly directed telescopic eyes of Aceratias, indicating that the fishes of this genus have binocular vision.

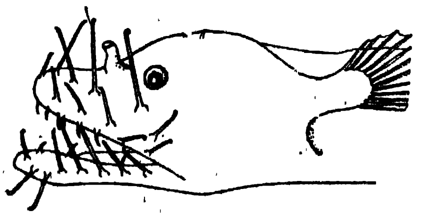

FIG. 2.—Head of *Neoceratias spinifer*, Pappenheim. Length to base of caudal fin, 25 mm. After Pappenheim, 1914.

Probably the chief interest in the ceratioids lies in the fact that they are unique among vertebrates in having the males dwarfed and parasitic on the females. The species in which males are known are *Photocorynus spiniceps* (male 10 mm. long attached to a female of 62 mm.), *Edriolychnus schmidti* (male 14 mm. long attached to a female of 62 mm.), and *Ceratias holboelli* (males of 80 and 85 mm. on a female of 1030 mm., and a male of 105 mm. on a female of 1000 mm.) (Fig. 3).

The males resemble the females in general form, but differ from them in the development of structures for attachment, in the absence of the illicium, the reduction or absence of spines on the head, the absence of teeth, and the vestigial condition of the gut; the only organ of importance in the abdominal cavity is the large testis. The method of attachment to the female is of especial interest. In Photocorynus and Ceratias, upper and lower outgrowths of the anterior end of the head of the male unite in front of the mouth and fuse with a papilla-like projection from the skin of the female.

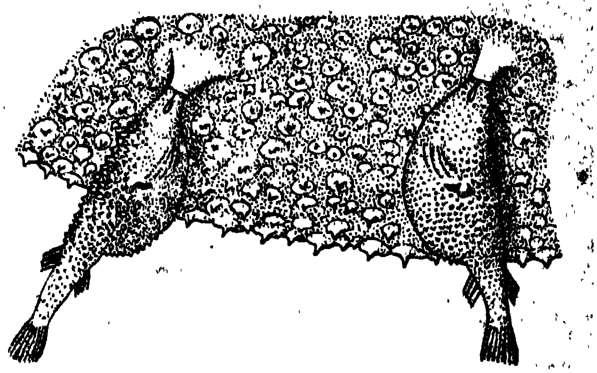

FIG. 3.—Two males of *Ceratias holboelli*. Half natural size. After Sæmundsson.

From his microscopic examination of sections of a strip of the tissue connecting the male and female Ceratias, Mr. Tate Regan is of the opinion that the male and female are completely blended, the highly vascular fibrous tissue of the outgrowths of the male being continuous with that of the papilla of the female, and he regards it as almost certain that the blood-systems of the two fishes are continuous. He does not favour the view that the attachment may be of the nature of a placenta, which implies that the two animals separate later on, but suggests that the males, soon after they are hatched, attach themselves to the females, if they are fortunate enough to meet them, and remain attached throughout life. In all probability the males are incapable of free development, and it is likely that the majority fail to find a female and perish, although another possibility has been suggested, namely, that the post-larval fishes that find and become attached to females develop into males, and those that do not, into females.

The Reform of the Calendar.

SINCE the War a number of ingenious schemes have been put forward for the reform of the calendar. Such an important step should not be taken unadvisedly, lightly, or wantonly, but the advantages claimed should be considered, the extent of the demand for it assessed, and the possibility of finding a scheme which would meet general approval carefully weighed. The League of Nations, being in a position to consult the various bodies which could give authoritative expression to opinion on the subject and the aid of which would be required in carrying out any changes proposed, undertook a full inquiry. It appointed a committee, with Prof. van Eysinga of Leyden as chairman, and with representatives of the Holy See, the Orthodox Church, the Church of England, the International Chamber of Commerce, and the International Astronomical Union upon it. This committee has recently issued a short and valuable report.[1]

The principal defect in the Gregorian Calendar arises from the unequal lengths of months, quarters, and half-years, which introduce a certain amount of irregularity in statistics, accounts, commercial and transport figures. This is increased somewhat because different days of the week are of unequal value as regards volume of trade, and thus one year or one quarter is not strictly comparable with another.

Minor defects are that special tables are required by banks in their calculations of interest, and that dates of periodical events, for example, the opening of Parliament, cannot be fixed without reference to a calendar. As many as 185 schemes of reform were received by the committee, including 33 from France, 27 from the United States, 24 from Germany, and 5 from Great Britain. The minimum change proposed was to take a day from August and give it to February. A second suggestion made the months of three of the quarters of the year consist of 30, 30, and 31 days respectively, and the last quarter of 30, 31, and 31 days. The question may well be asked whether the advantages are sufficient to justify the change.

A more radical reform is obtained by the use of one day without name in ordinary years and two such days in leap-years. The remaining days of the year may then be divided into 52 weeks, which may be arranged as four quarters of thirteen weeks, the months consisting of 30, 30, and 31 days, or as 13 months of 4 weeks each. The advantages and disadvantages of these two schemes are compared, and preference on the whole given to the former. The committee is satisfied, and most people will agree with it, that there is no general demand for these changes, which would be strongly opposed by many religious bodies. Without general assent, confusion would result, and it may be remembered that the Gregorian Calendar was introduced in 1582, adopted in Scotland in 1600, but not in England until 1751, and in eastern Europe only six years ago.

The committee next considers the question of fixing or 'stabilising' Easter. At present Easter Sunday varies between March 22 and April 25. This wide range makes difficulties in the arrangement of school and university terms and of public holidays. Many commercial transactions and transport services are prejudiced, in particular, business dealing with textiles, articles of fashion, and the hotel-keeping industry. There appears to be a consensus of opinion in these circles that the second Sunday in April would be the most convenient date. The committee favours a slightly different date, namely, the day following the second Saturday, in order to avoid the contingency of the festival of the Annunciation and Passion Sunday both falling on the same date.

The committee has made general inquiries of the attitude of the heads of different Christian Churches on the stabilisation of Easter. It is agreed that there is no dogmatic reason against a fixed date. It appears that the Church of England and the Greek Church are ready to accept the change if the Church of Rome also accepts it. The Holy See does not consider that there is sufficient reason for changing a date handed down by immemorial tradition and sanctioned by councils from early times, and would not be prepared to consider the question except on the advice of an Œcumenical Council. The Protestant Churches of Europe and America and the Jewish Community raise no objections to the proposal.

The report of the committee of the League of Nations shows that there is a general belief, certainly in England, that the stabilisation of Easter would bring substantial advantages and a wish to see the change made. As there are no difficulties of dogma involved, it may be hoped that ecclesiastical concurrence is not impossible. Incidentally, uniformity in keeping Easter will be secured between the different Churches. At the present time the Greek Church uses the position of the moon to determine Easter, while the tables of Clavius are still retained by the Roman and Anglican Churches. Sometimes the two methods give the same date; frequently they differ a week, and occasionally a month.

Obituary.

PROF. J. D. F. GILCHRIST.

PROF. J. D. F. GILCHRIST, who died recently in Capetown at the age of sixty years, had been in South Africa for thirty-one years. Gilchrist's early university days were spent at St. Andrews and Edinburgh. At one time he had thought of entering the Presbyterian ministry, but after coming under the influence of inspiring leaders in natural science at St. Andrews and Edinburgh, he definitely resolved to pursue a biological career. After a period at Münich and Zurich, and at biological stations, more especially that of St. Andrews, he was appointed, on the recommendation of the late Sir John Murray, of the *Challenger*, and of Prof. M'Intosh, St. Andrews, to the position of Government Marine Biologist at the Cape of Good Hope.

Gilchrist was probably the first to hold the title of Government Biologist in any country, and in his later days he was wont to tell his friends about the weary,

uphill task he had during his first year, in a government office in Parliament Street, Cape Town, without either laboratory or practical equipment of any kind. He was, however, able to persuade the Ministry of Agriculture that a vessel for dredging and trawling, a museum for storing the specimens, and a marine laboratory and aquarium were necessary.

Gilchrist was particularly fortunate in securing as the first captain of the government trawler, Alexander Turbyne, a keen fisherman naturalist, who had been trained under the late Sir John Murray. An important practical result of the preliminary surveys of the S.S. *Pieter Faure* was the discovery in 1898 of a rich fish-ground on the Agulhas Bank, within easy reach of the markets of Cape Town. This discovery appealed alike to the public and to the Government, and led to greater financial support.

While recognising the necessity of developing the economic aspect of marine biology, Gilchrist always kept the more purely scientific point of view in his mind. The Cape waters had only been explored in a cursory manner by such expeditions as the *Challenger* and the *Gazelle*, and thus there was open ground for more thorough investigations. The dredging and trawling expeditions of the *Pieter Faure* resulted in the capture of more than twenty thousand specimens, the majority of which, with the exception of the fishes, were despatched home to be studied by specialists. From the papers published by these workers, and from his own contributions, Gilchrist edited the volumes "Marine Investigations in South Africa" (1902–1907). In 1907, however, during a period of severe financial depression in the colony, the office of Government Biologist was abolished, but the publications were revived in 1913, under a new board, as "Marine Biological Reports of the Cape Province."

From 1905 to 1917, Gilchrist was professor of zoology in the South African College, and when, in 1918, the latter developed into the University of Cape Town, he held the chair of zoology until in 1925 ill-health compelled his retirement. After his resignation he still carried on some work at his favourite haunt, the St. James Marine Station, on the shores of Kalk Bay.

Gilchrist was the author of numerous papers, dealing more especially with the description of new or rare species of fish, and of their larval development; but he also contributed publications of more general interest, such as those on the early stages of *Cephalodiscus gilchristi*, on the enteropneust, *Xenopleura vivipara*, on the remarkable crawling medusa (*Cnidonema capensis*, g. et sp. n.), and on the temperature and currents of South African seas.

Sometimes Gilchrist may have conveyed the impression of a man who lived in a little world of his own, wrapped up in thoughts of his fishes and other denizens of the sea, but that he could free himself from these deliberations is proved by his work for science in the colony, as president of the Philosophical and later of the Royal Society of South Africa, and as one of the main organisers of the South African Association for the Advancement of Science.

Gilchrist married Elfreda Ruth, daughter of S. H. Raubenheimer, of George, C.C., and is survived by his widow, a son, and a daughter.

News and Views.

ONE of the problems to which the Imperial Conference has been devoting attention is the present position of forestry within the British Empire. A sub-committee was set up, which dealt with this matter on broad lines. It is a hopeful augury for the future that the question of a forest policy common to the Empire as a whole, with especial reference to the world's timber supplies, should have been examined in some detail. It is an accepted fact that the available virgin supplies of the soft woods (pines and firs) are giving out, Canada and north Russia and Siberia containing the chief remaining stocks. About eighty per cent. of the wood used for industrial purposes consists of the soft woods. As regards the hard woods, the available supplies of these from temperate climates are not regarded as satisfactory, and their replacement by tropical hard woods offers difficulties which are very far from solution. Apart from the question of the availability of the existing supplies to meet demands, there exist social and economic problems which make it necessary that each country, and perhaps more especially the British Empire, should formulate a policy which shall maintain a sufficient forest area under a conservative forest management. At the present day a large proportion of the Empire forests have little that can be termed a scientific conservative management in being; the Imperial Conference will have made a long step forward if, as a result of the deliberations and recommendations of the sub-committee, a consistent forest policy is formulated and adhered to. Other matters given consideration were Empire settlement and its connexion with forestry, the meeting of the Empire Forestry Conference in Australia and New Zealand in 1928, forest products research work, and the proposed inauguration of an Imperial Forestry Bureau.

THE silver medal of the Zoological Society of London has been awarded to Capt. H. C. Brocklehurst, the Game Warden of the Sudan, in recognition of his services to the Society, and for the active part which he has taken in the preservation of the wild fauna of that part of Africa. The medal, which was designed by Landseer, has been awarded on forty-eight previous occasions, the first recipient being Sir Roderick Murchison, in 1847, "for assisting in the introduction of the Aurochs." Capt. Brocklehurst has been instrumental in obtaining several valuable collections of animals for the London Zoo. The last of these included two giraffes, two Sudanese oryx, and three shoebills, or whaleheaded storks, now one of the rarest birds in the world. The white rhinoceros, which a little time ago was threatened with extinction, comes directly under Capt. Brocklehurst's care, and it is reassuring to hear from him that, owing to the proper administration of suitable game laws, this wonderful

animal, which sometimes exceeds 6 ft. at the shoulder, not only is out of danger of becoming extinct, but is even increasing so rapidly that a certain number are now allowed to be shot each year, and he has every hope of obtaining a young one for the Society's collection. From other parts of Africa the reports on game preservation are equally reassuring, especially from the Transvaal, where, after twenty-six years of political struggle, the Great Sabi Game Reserve has been established on a permanent basis, and has been given the name of the Kruger National Park. In relation to this it is highly satisfactory to note that Col. J. Stevenson Hamilton, who was chiefly responsible for getting this measure approved by the Union Government, has accepted the post of secretary to the Society for the Preservation of the Fauna of the Empire.

THE Nobel prize for medicine has been awarded to Dr. Johannes Fibiger, professor of pathological anatomy in the University of Copenhagen, who has spent many years in the study of cancer and is best known for his work on the nematode *Gongylonema neoplasticum*. This worm lives in cochroaches, and, when these are eaten by rats, passes into their stomachs, where by the irritation it produces it initiates the growth of malignant tumours. Prof. Fibiger has worked out the whole process in great detail, and thus made notable additions to our knowledge of the relationship of irritation to cancer. Other examples where the irritant is a worm are the cancers of the bladder in man in Egypt caused by Schistosomum and the sarcoma of the liver in rats often associated with the hydatid phase of *Taenia crassicollis*.

CANON J. M. WILSON, who at Rugby and Clifton did much to introduce practical science teaching into schools, and is now in his ninety-first year, must be known to a wide public as having been a consistent champion of evolutionary ideas in religion long before such ideas had become at all popular in theological circles. The earnestness, moderation, and candour of his writings commended evolution to many minds which otherwise would have continued to regard it with dislike and misgiving. A recent pamphlet by Canon Wilson, "Christianity in the Light of the Idea of Evolution" (London: *Guardian* Office), shows that the powers of this veteran apologist have not declined. Indeed, with remarkable acumen, he lays his finger on what certainly are the critical points to-day. The principle of evolution has now been extended beyond the biological sphere to anthropology and psychology, and it is these applications which are causing trouble to many thoughtful people. Religious beliefs are no longer refuted, but explained, as one writer has put it. Yet, as Canon Wilson sees it, the idea of a gradual evolution of belief is a very valuable one, even from the specifically religious point of view. "The evolution of theology," he writes, "may be welcomed; or it may be ignored and hushed up; or it may be disliked and denounced. But it cannot be denied. It is a fact, and a fact of the greatest significance." This evolution of ideas may be [illegible] from another point of [illegible] This conception is [illegible] in [illegible] the Old Testament, which is "the s[illegible] of man's progressive discovery in theology."

IN England this would nowadays be accepted by even conservative scholars; but it is not always realised, as it is by Canon Wilson, that the same principle applies to the New Testament and to the development of the Creeds. In the New Testament there are several quite distinct strata of theological development, and the need for 'restatement' was felt so early as the first century. It is only by disregarding history that the idea of a fixed and final theology becomes possible. The problem now is, as Canon Wilson points out, "to enshrine in a transformed and more elastic framework the old and deep religious experiences expressed in the Bible and the Creeds and other formularies." This is scarcely the place to expand these ideas, but it is gratifying and encouraging for students of science when they see an eminent theologian taking up an attitude of this kind; for even men of science have their religious instincts, which they would be better able to satisfy if the spirit animating Canon Wilson were more widespread. His position is that "religious faith is henceforth to be based on experience and observation; it has become scientific." From this point of view theology must always be secondary, being the interpretation of an experience. In science there are no such things as final interpretations or unchangeable hypotheses; and if the same principle were recognised in religion, religion would share some of the vitality of natural science, and be a great deal more useful to humanity.

WE have received the abstract of a lecture entitled "Life and Mind" which was delivered by Dr. Bernard Hollander before the Ethological Society on October 25. Dr. Hollander is to be congratulated on his courage, for life and mind may be said to be the two ultimate problems of the universe, since only through the senses and minds of living beings do we know anything at all about the universe. He asserts that life and mind are 'forms' of energy—a statement which we think erroneous. Dr. Hollander, indeed, is not comfortable about it himself, for he goes on to say: "If the brain were purely a mechanical apparatus producing mind, we could not be at the same time spectators. Those who think so always look at others. No one considers his own self a piece of mechanism, a part of the universal clockwork." We think that the confusion arises from overlooking the fact that life and mind are presuppositions of all knowledge. What we call 'mind' is a name for our own personality and its activities through which we learn about everything else, energy included. All else is a series of presentations to our mind, presentations which are coloured by its activities. We can no more get outside ourselves and view ourselves from outside than we could lift ourselves out of a marsh by our own waistbands. The first and soundest conclusion which we come to about phenomena, a conclusion arrived at before we reach the mature age of one year, is that many of these

phenomena are the result of the activities of personalities like our own. Other phenomena we gradually perceive are the expression of simpler activities, and our conceptions of matter and energy are all in the last resort pale abstractions from our primary conception of 'selves' For the sake of convenience in classifying phenomena, we neglect this consideration, and affect to regard animals and plants as mere collections of matter and their activities as 'a kind of energy' Life, as Tyndall pointed out long ago, is not energy at all but the control of energy, the constant composition and moulding of energy If in attempting to solve an algebraic problem we should designedly leave out one factor in order to arrive at a simpler solution, we should fully realise that this solution could only be partially true When mechanistic biologists ignore the subjective element in knowledge, their solutions must necessarily be profoundly untrue

IN a lecture to the Royal Geographical Society on November 15, Mr J A Steers discussed some of the changes that are taking place in the coastline between Hunstanton and the Orwell-Stour estuary This is a submerged low coast modified by marine erosion and the action of longshore currents which have dammed several of the streams and elsewhere have led to the growth of spits Mr Steers mentioned an effect of tides which is sometimes overlooked The direction of tidal drift is known to change with ebb and flow, but owing to the difference in level of the water the material worked on at high water is distinct from that worked on at low water so that there often are two opposed movements of beach material on the same foreshore This is noticeable at Blakeney, where the shingle has pushed westward, and the sand, at a lower level eastward Among other interesting points raised in the lecture was the origin of the shingle on the north coast of Norfolk Analysis shows 99 per cent of it to be flint and the remainder to be igneous rock of Scottish and to a less extent Scandinavian origin, with a few fragments of sedimentary rock The prevalence of flint points to an origin not far distant but the exact source is not yet known Mr Steers discussed at some length the origin of Blakeney Point, Lowestoft Ness, Orford Ness, and other recent growths of the coast

To hold an exhibition of coal products during the present stressful period in the coal industry might be considered somewhat hazardous, for exhibitions involve considerable expenditure on the part of exhibitors, but publicity, and especially co-operative publicity, has been found to pay, and nothing seems to daunt the spirits of our industrial firms in good times or in bad The National Coal Products, Chemical, and Engineering Exhibition, which is being held on November 16–27 in Manchester, is a co-operative venture sponsored by the Manchester Section of the Society of Chemical Industry and organised by Provincial Exhibitions, Ltd When planned last May, it was hoped that the coal strike would be ended long before November, but as events proved contrary, the original scheme of confining the exhibition to tar and tar-products was abandoned, and the subject of methods of utilising coal was substituted. As the strike still continued, it was decided also to display many exhibits relating to the value of research upon coal and its products. The list of exhibitors in the City Hall contains the names of the principal organisations that are investigating coal, those of a few chemical firms and a large number of plant manufacturers. Everything possible has been done to attract and instruct the public, and if we are not sure that (as the official catalogue states) all the visitors will feel that in Manchester they are in the actual workshop of the country, and not merely looking into the Empire's shop-window as in London, we are certain that the promoters of the exhibition deserve the thanks of the scientific community for their initiative and enterprise In connexion with the exhibition, a conference on tar is being held on November 26, at which important papers are being read by members of the Society of Chemical Industry, the Institution of Gas Engineers, and the Coke Oven Managers Association

THE Lloyd Roberts Memorial Lecture was delivered at the Manchester Royal Infirmary on November by Dr W E Gye, who chose as his subject "The Cancer Problem" He reviewed his former work and described further experiments, all of which tend to confirm the conclusions he then reached His work has been largely prosecuted with the Rous chicken sarcoma, which, unlike most malignant tumours possesses a 'filterable' virus If a Rous tumour b triturated and filtered through a porcelain filter, th filtrate injected into a fowl induces tumour-formation the causative agent is therefore a filterable or ultra microscopic one If the filtrate be heated to 55° C for 15 minutes, or treated with an antiseptic such a acriflavine before injection, it loses its potency, th causative agent becoming inactivated But if portion of heated filtrate be mixed with a portion filtrate treated with acriflavine and the mixtu injected into a fowl, tumour formation results D Gye concludes, therefore, that the causative agent the Rous tumour consists of two parts, one of whic may be destroyed by heat, the other by an antisept such as acriflavine, and that both are necessary fo tumour formation To the former heat-labile sul stance the name of 'specific factor' is given, th other factor is regarded as being a living virus micro-organism A tumour of one species of anim cannot be transplanted into another, but a mixture inactive Rous tumour extract (inactivated by acr flavine) with extract of human cancer produces in th fowl a tumour microscopically like the Rous tumou Many substitution experiments of this kind have bee performed with similar results, with one or tw curious and inexplicable exceptions only Dr G believes that the specificity or essential characters a malignant tumour are carried by the heat-labi agent called the 'specific factor,' and that the oth factor is a living virus (or viruses) which becom operative only when the specific factor is present well. The fact that cultures in serum broth

tumours (up to the seventh remove) may be substituted for direct extracts in these experiments supports this view. At the same time, other possible, though unlikely, hypothesis are being explored.

THE Factories and Workshops Report for 1925, which was recently issued by H.M. Stationery Office, is instructive and interesting. The work done by the inspectors is very thorough, and the recommendations they have made in previous years have been of great value to the many industries concerned. It seems fairly certain that explosions in works employing benzene and other inflammable products are sometimes caused by electrostatic sparks. This can be prevented in some cases by the use of suitable brush collectors to discharge the electricity on driving-belts. The total number of accidents directly attributable to electricity is 414, and includes 24 fatal cases. This is less than last year; and considering the great increase in the work done in the electrical industry last year it is satisfactory. Twelve of the fatal cases were due to shocks from pressures not exceeding 250 volts. In all these cases alternating current was employed. In one case when a man was inspecting the machinery of a motor car, using a lamp connected with the supply, the lamp broke and the metal car, being insulated from earth by the tyres, became 'alive,' owing to touching a terminal. Although the man was able to call out for the switch to be turned off he was unable to let go and was killed. Another fatal accident was due to a practical joke, the bell handle being connected with one of the supply mains. The worst accidents are caused by a hand to foot shock; the hand, for example, touching the cover of a defective switch, the cover of which has become alive, and the foot making a good contact with the earth through a damp boot. If a person is well insulated from earth he only gets a trifling shock when a spark takes place between him and a high-tension terminal. The present regulations seem quite satisfactory, but they need to be enforced. The senior electric inspector, Mr. G. S. Ram, urges that contractors and others should take special precautions when installing an alternating current supply.

THE increasing facilities rendered available in recent years for the publication of geophysical papers have amply justified themselves, and appear to have greatly stimulated interest and investigation in the subject. In Great Britain the only distinctively geophysical periodical is the *Geophysical Supplement to the Monthly Notices of the Royal Astronomical Society*, and the Society has rendered great service by giving the subject of geophysics this valuable support. The supplement is paged separately from the *Monthly Notices* proper, and forms a distinct journal; it is now nearing the end of its first volume, and No. 7, recently issued, deals in its eight papers with an interesting variety of subjects: seismic waves, the elastic yielding of the earth, the rigidity of its central core, magnetic storms, tidal motion, and the relation between barometric pressure and gas pressure in mines. All these papers have been presented to the Society in the early part of this year. Another thriving journal, also published mainly in English which deals largely but not entirely with geophysics, is the *Japanese Journal of Astronomy and Geophysics*, published by the National Research Council for Japan; beside published papers in full, it gives short abstracts of other cognate papers published in Japan. The recently issued part, vol. 3, No. 3, contains an article on the possibility of gravitational waves in soil, together with no less than 86 abstracts (occupying 33 pages of small print) of other astronomical and geophysical papers.

AN Egyptian wing has been added to the Museum of the University of Pennsylvania, Philadelphia, in memory of the late Mr. Eckley Brinton Coxe, junior. Mr. Coxe was president of the Museum from 1910 until 1916, and was not only a generous benefactor during his lifetime, but also left a sum of half a million dollars at his death for the promotion of Egyptian studies. It will be remembered that extensive investigations at Memphis, including the excavation of the Palace of Merenptah, were carried out by the Eckley B. Coxe Expedition, and many of the objects now installed in the wing and shown for the first time were obtained by this expedition or others on this foundation. A description of the new wing, which was opened in May last, and of some of the principal exhibits, appears in the *Museum Journal* (Philadelphia) for June. It contains twelve rooms appropriate in design and harmonising in colour and proportion with the exhibits. Eight rooms are devoted to Egypt, while Ur, Beisan, Persian art, and Arabic art each have a room, those of Ur and Beisan being used for exhibition of the objects obtained by the expeditions of the Museum now in progress.

THE Sterling fellowships were established by a gift of one million dollars from the trustees of the estate of the late John W. Sterling to stimulate scholarship and advanced research in all fields of knowledge. They are open to graduates who desire to carry on studies under the direction of the Graduate Faculty of Yale University. The fellowships are divided into two general classes: Research or Senior Fellowships for candidates of the standing of the Ph.D. degree, of the annual value of 200*l*.-500*l*.; and Junior Fellowships for candidates who are well advanced in their work towards the Ph.D. degree, of the annual value of 200*l*.-300*l*. All fellows are appointed for a single year in the first instance and are required to submit reports on their work, either at stated intervals or at the expiration of their fellowships. Application forms, to be returned by March 1, can be obtained from the Dean of the Graduate School of Yale University, New Haven, Connecticut.

THE British Museum (Natural History) has issued four additional natural history booklets in the attractive series commenced last year. The new subjects include the pine marten, the harvest mouse, the fallow deer and the barn owl (Price 6*d*. each). As before, each booklet contains a short account of the history and habits of the animal, and is accompanied by a charming coloured illustration. Among

the latest sets of postcards to be published by the Museum is the second series of portraits of famous naturalists (Price 1*s*.). This set includes Sloane, Banks, Leeuwenhoek, Mendel, Seba and Shaw, among others, and a pamphlet enclosed with the set gives concise details of their lives, with special reference to their contributions to natural history. The series of British Museum postcards now covers a wide range of subject and interest, and there can be little doubt that their publication has contributed considerably to the popularity of the institution and to public interest in its collections.

MR. F. G. LLOYD, 1 Sinclair Road, Kensington, W. 14, writes to ask if it is very uncommon now to find the Camberwell Beauty butterfly near London, as a patient had given him a perfect specimen caught near Honor Oak Park Station in the summer of 1911 or 1912. Dr. James Waterston, of the Natural History Museum, South Kensington, has been good enough to send us the following answer to this inquiry: "The Camberwell Beauty is, in Great Britain, a somewhat rare visitor, occurring not in the late spring or early summer (as is commonly the case with other immigrants), but more frequently in August or later. While the species has been proved to hibernate occasionally in Britain, no authentic occurrence of the larva or pupa is on record. 1911 appears to have been a Camberwell Beauty year, and, according to information supplied by my friend Capt. N. D. Riley, the species was then recorded (August) from, amongst other places, Berkhampstead; Bradwell-on-Sea, Essex; Brading, Isle of Wight; Chelsfield, Kent. With all this, the occurrence of the Honor Oak Park Station specimen falls into line. The interest of Mr Lloyd's record is rather a sentimental one, the species on this occasion having been taken, after a long interval, in the locality from which it received its popular name."

THE *Scientific American* for October contains a very discursive but interesting article on "Hunting Fossil Insects," written in the well-known free-lance style of that entomological genius Prof. T. D. A. Cockerell. The insects dealt with are two collections of Tertiary fossils, one from some new beds on the banks of the Kudia river in the Amagu region of Siberia, opposite the southern shores of Sachalin, the other from the Santa Barbara district, Province of Jujuy, Northern Argentina. In each case, Prof. and Mrs. Cockerell underwent an adventurous journey to obtain the specimens, and the chief interest of the article lies perhaps in the illuminating remarks about the conditions of the countries through which they passed. Prof Cockerell has, we believe, dealt with both collections scientifically elsewhere. We think it important to point out that he is in error in assuming that his Argentine Tertiary insects were the first fossil insects to be discovered in the whole of South America. Prof Wieland, of Yale University, discovered two very fine Rhaetic specimens near Mendoza a good many years ago; one of these was a Homopteron and the other a caddis-fly. It was a pity that Prof. Cockerell did not know of this bed, as he might have found further specimens. From the article before us we learn some interesting points about the sect of the "Old Believers," whom, it appears, the Bolsheviks have left somewhat severely alone, so that they still keep their old religion and customs. "Our guide explained that even the Old Believers had had their revolution"; but apparently it was a mild one, as they are still allowed to drink whisky, though tea and coffee are taboo!

SIR ARTHUR KEITH and Mr. C. R. Peers have been elected honorary members of the Yorkshire Philosophical Society.

REPLYING to a question in the House of Commons on November 21, Mr. Amery, Secretary of State for the Colonies, said that the appointment of director of the Amani Institute has been accepted by Mr. W. Nowell, Director of Science and Agriculture, British Guiana. On his arrival in England from British Guiana the new director will be invited to submit recommendations as to the staffing of the Institute.

A PORTRAIT of Michael Faraday, and a reproduction of the portrait of Lord Kelvin painted by Herkomer for the Institution of Civil Engineers, both by Mr. George Harcourt, R.A., will be shown in the lecture theatre of the Institution of Electrical Engineers in the positions allotted to them at the ordinary meeting on December 2. After introductory remarks by the president, Mr. Harcourt's portrait of Faraday will be presented to the Institution by Mr. Sydney Evershed.

AT the annual general meeting of the London Mathematical Society, held on November 11, the following officers were elected: *President*, Prof. G. H. Hardy; *Vice-Presidents*, Prof. S. Chapman, Prof. A. L. Dixon, Mr. J. E. Littlewood; *Treasurer*, Dr. A. E. Western; *Librarian*, Prof. H. Hilton; *Secretaries*, Prof. G. N. Watson, Mr. F. P. White; *New Members of Council*, Prof. H. F. Baker, Prof. A. S. Eddington, Prof. E. H. Neville.

IT is announced in *Science* that the Perkin medal for 1927 has been awarded to Dr. John Teeple, treasurer of the American Chemical Society, for "significant scientific, technical, and administrative achievements, particularly the economic development of an American potassium industry at Searles Lake, Calif." The committee of award consists of representatives of the American Section of the Society of Chemical Industry, the American Chemical Society, the American Electrochemical Society, the American Institute of Chemical Engineers, and the American Section of the Société de Chimie Industrielle.

AT the annual general meeting of the Philosophical Society of the University of Durham, the following officers were elected: *President*, The Earl of Durham (Chancellor of the University of Durham); *Secretary*, Dr. Grace Leitch; *Treasurer*, Mr. J. W. Bullerwell; *Editor*, Dr. Todd; *Librarian*, Dr. Bradshaw; *Assistant Librarian*, Mr. E. Patterson; Sectional Officers, the chairman and secretary of each section being given in brackets: Chemical and Physical (Dr. P. L. Robinson and Mr. O. Darbyshire), Geo-

logical and Biological (Dr. Kathleen Blackburn and Dr. Allan), Mathematical (Mr. Colborne and Mr. Miles), Applied Science (Dr. Morrow and Dr. Baker), Philosophy (Dr. A. Robinson and Mrs. Alderson), Archæological and Historical (Dr. J. Wight Duff).

WE are informed by Messrs. Ernest Benn, Ltd., that Lady Bell is editing the letters of Gertrude Bell, which will be published, probably in two volumes, during the course of 1927.

THE latest catalogue (No. 146) of Messrs. Dulau and Co., Ltd., 34 Margaret Street, W.1, gives particulars of nearly 1300 volumes on zoology, botany and gardening, agriculture, geology, palæontology and mineralogy. Copies can be had free from the publishers.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant in the Engineering School, Trinity College, Dublin—The Registrar (November 29). An assistant master, with qualifications in mathematics, at the Government High School, Nassau, Bahamas—C.A. (T.), Board of Education, Whitehall, S.W.1. For Scottish candidates (T.), Scottish Education Department, Whitehall, S.W.1 (December 6). An officer for research work and a professor of pathology at the Punjab Veterinary College, Lahore—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (December 10). Chief designer, designer, chief testing engineer, and first assistant testing engineer at Admiralty Engineering Laboratory, West Drayton—Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1 (December 13). An instructress in fruit and vegetable preservation, and housemistress of one of the hostels of the Swanley Horticultural College for Women—The Principal of the College, Swanley, Kent (December 15). A bacteriologist in the Department of Agriculture of the Irish Free State—The Secretary, Civil Service Commission, 33 St. Stephen's Green, Dublin (December 16). A principal of the University College of Wales, Aberystwyth, in succession to the late Principal J. H. Davies—The President of the College (D. Davies, Esq., M.P.), Plas Dinam, Llandinam, or The General Secretary, University College, Aberystwyth (January 31). A pathologist at the Cancer Hospital to conduct investigations in the effects of radiation on malignant and normal tissues and body fluids—The Secretary, Cancer Hospital, Fulham Road, S.W.3. A government analyst for the Public Health Department, Southern Rhodesia—The Secretary, High Commissioner for Southern Rhodesia, Crown House, Aldwych, W.C.2. A keeper of the laboratories of the Royal Horticultural Society at Wisley—The Secretary, Royal Horticultural Society, Vincent Square, S.W.1. A temporary assistant in the Research Department, Woolwich, under the Directorate of Explosives Research—The Chief Superintendent, Research Department, Woolwich, S.E.18. An agricultural chemist at the Kirton Agricultural Institute—The Principal, Kirton Agricultural Institute, near Boston, Lincs.

Our Astronomical Column.

COMET COMAS SOLA.—It appears fairly certain from the first ten days' observations of this comet that it is a periodic one, of Jupiter's family. The following orbits are by Mr. G. Merton and Dr. A. C. D. Crommelin respectively:

T	1927, March 2·316 U.T.	1927, March 24·940 U.T.
ω	24° 58′ 20″	37° 0′ 18″
Ω	68 8 14	65 24 50
i	11 50 54	14 0 4
e	0·41065	0·53380
$\log q$	0·20526	0·26290
Period	5^y·525	7^y·789
Equinox	1920·0	1926·0

The elements bear some resemblance to those of Spitaler's Comet, 1890, VII.: ω for that comet was 13° 20′; Ω 45° 6′; i 12° 51′; $\log q$ 0·2596; period 6·4 years. It has not been seen since that apparition. Observations of the present comet are expected to continue for several months, which should decide the question of identity.

BRITISH TELESCOPES.—We have pleasure in directing attention to a recent publication entitled "Astronomical and Optical Instruments" which has been issued by Sir Howard Grubb, Parsons and Company, largely for the purpose of describing and illustrating the resources and equipment of the Company's new optical works at Newcastle-on-Tyne. The contents of the publication consist of a series of four short articles on (1) the development of optical instruments for astronomy and astrophysics; (2) the British optical industry; (3) the history of Sir Howard Grubb, Parsons and Company; (4) the new optical works of the Company at Walker Gate, Newcastle-on-Tyne. The articles are very attractively written, and are well illustrated with a number of clear reproductions. Of special interest are the plans of sectional elevation of the 45-ft. dome and the 41-inch refractor, and two photographs showing the framework of the dome and its rising floor now under construction at the works. Reference to this large telescope and to the optical works in general was made in NATURE of September 4, p. 340. The list on pages 44-45 of some of the principal large astronomical instruments made by the firm since it was founded by Thomas Grubb is eloquent testimony to the debt which astronomy, in particular, owes to these noted makers of telescope objectives and instruments.

EARLY ARABIAN ASTROPHYSICS.—More than 90 pages of volume 56/57 of the *Sitzungsberichte der Phys.-Med. Soz. Erlangen* are devoted to a presentation of the contents of an early Arabic treatise on the Light of the Moon by Al Hazen, with comments by the translator, Dr. Karl Kohl, of the University of Erlangen. Al Hazen, or al Hasen Ibn al Haitham, was born at Basra but spent most of his life in Egypt. He incurred the displeasure of the Calif al Hakim by the failure of his scheme for preventing the flooding of the Nile and had to conceal himself until the death of the Calif in 1020. He then returned to Cairo, where he died in 1038. His book begins with a short account of contemporaneous knowledge as to the light of the moon; he then shows that phases and eclipses necessitate a spherical moon, goes on to describe his own apparatus and observations, shows that neither transmission nor reflection (according to the laws of ordinary reflection) can explain the light, and concludes, therefore, that the moon is self-luminous, the sun imparting by means of its rays the power of self-luminosity. The original treatise appears to be in the India Office, but we have been unable to find any statement as to how it became available for translation.

Research Items.

Promiscuity and Primitive Marriage.—A discussion on promiscuity and group marriage by Lieut.-Col. E. F. Gordon Tucker and Mr. Leslie H. Gilbert appears in the *Sociological Review*, vol. 18, No. 4. Col. Tucker holds that the investigation of marriage must start with the physiological facts of the intensity of the sexual inclination. He argues that while no very helpful lesson can be derived from the varied conduct of the Quadrumana as to the sexual relations of human precursors among savage men, we get on one hand a widespread 'incest horror,' and, on the other, compulsory marriage among close relatives, but not the closest. Yet among Polynesians brother and sister marriage is a source of honour. Postulating a primitive group, the extent of continuity in gregariousness would be dependent on food supply. If the group were constant and sedentary, promiscuity would arise owing to the strength of the sex instinct and the hypothetical absence of the restraining forces of education, law, and religion. It is a question whether sexual jealousy would be strong enough to overcome these forces. Where the group was not constant owing to scarcity of food supply, either permanent or seasonal, individual men going off to find food would each take a woman to perform woman's work—root and beetle grubbing—and this custom would tend to give rise to individual marriage. In these conditions it is unnecessary to postulate promiscuity as a precedent condition of the classificatory system of relationships as Morgan did. The position of the mother's brother follows as a natural result. In his reply Mr. Gilbert argues from the universality of the individual marriage, while the terms of the classificatory system might be deduced from the Levirate and Sororate, which functions actively to-day, and further, that in the marriage groups, eligibility for marriage does not necessarily connote actual sexual relation. The so-called vestigial customs are magico-religious, though no one explanation can account for the diverse sexual orgies. The promiscuity theory demands the abrogation of the parental instinct, both of woman and man, which are essential to the survival of society in view of the conditions of human birth and infancy.

Physical Anthropology of the Pamirs and Amu-Daria Basin.—Physical measurements collected by Sir M. Aurel Stein on his third archæological expedition to Central Asia in 1915, are analysed by Mr. T. A. Joyce in the *Journal of the Royal Anthropological Institute*, Vol. 56, Pt. 1. The measurements are of fourteen different groups covering Mongolo-Turki, Tajik, and Iranian and Persian stock, for the most part nomad pastorals, but including primitive hunters and fishers from the Helmand River and military levies from Baluchistan. The examination of these measurements points to a double grouping into (1) those of the north and north-west—the Yazghulami, Vanji, Darwazi, and Karateghin, relatively dolichocephalic, narrow-nosed, eurypro-sopic and short-statured; and (2) those of the south and south-east—the Shignani, Ishkashmi, and Wakhi, relatively brachycephalic, long-nosed, lepto-prosopic, and tall-statured. Intermediate to these groups are the Roshani, dwellers in a secluded valley, who may be taken as the main element of the bulk of these peoples in its purest form, the pure *Homo Alpinus* type. North and east this type has been modified in various degrees by contact with a broad-nosed Mongolo-Turki type. A Karateghin-Vanji group has been modified by contact with a narrow-nosed branch of Mongoloid peoples, while a Seistani-Sayad group are basically Indo-Persian or Indo-Afghan, but contain a leaven of the old Pamir strain.

Inheritance of Fleece Characters.—Fraser Roberts (*Jour. of Genetics*, 17 1, 1926) has an interesting paper dealing with the genetics of the piebald sheep, described variously as Spanish, or Barbary, or Jacob's sheep. He is of opinion that the characterisation of these sheep in Great Britain has not altered since 1760, and in his experience they invariably breed true, whole black or self-white lambs never appearing. In crosses with English breeds, the F_1 offspring were uniformly self-blacks, and it is concluded from further experimentation that the piebald sheep possesses a dominant black factor and also a recessive factor which restricts the black to certain

Haddock Biology.—Mr. Harold Thompson has recently published the third of an important series of studies on haddock biology (*Fisheries, Scotland, Sci. Invest.* 1926, No. 2. Edinburgh and London: H.M.S.O. 2*s*. 6*d*. net.) In preceding papers it was shown that the acceptance of the "scale theory" for haddock is substantially vindicated by the test of experience, and that few, if any, unsurmountable difficulties occur in its general application to the study of the stock in the sea from year to year. The present paper deals with the growth of sea-born baby haddock reared under artificial conditions in aquaria. Two or three weeks were necessary before the fish accommodated themselves to the new conditions, and this check in growth was marked by an apparent ('false') winter mark on the scale in all cases in which transference of the fish from the sea was carried out during the season of greatest growth, namely, from May to October. Abundant proof was obtained of the unfailing formation of normal winter markings on each occasion that a fish passed through one or two winters in captivity. The experiments also demonstrated the important fact that, for the first three years at least, the size of the haddock scale increases on the average in proportion to that of the fish. The growth under artificial conditions was surprising, for all the captive fish showed an increase of nearly 100 per cent in their growth-rate as compared with controls at sea—a result probably due in large measure to the fact that the food-supply was continuous and plentiful.

Sex Differentiation in Bonellia.—Prof. R. Goldschmidt (*Biol. Zentralbl.*, Bd. 46, Heft 8, 1926) holds that the male Bonellia cannot be regarded simply as a case of neoteny and of suppressed development. Regarded from the point of view of the morphogenesis of the female, the male is by comparison suppressed in development, but from the point of view of sex differentiation the male is an early ripening larva; it is not neotenic like axolotl, but precocious like the larva of Miastor. Prof. Goldschmidt regards the quickening of the sexual differentiation of the male as evidence of the activating function of the secretion on the proboscis of the female, while Baltzer, who places the retardation of metamorphosis in the foreground, takes the opposite view of the action of the proboscis secretion Prof. Goldschmidt, reviewing Baltzer's results, concludes that in Bonellia sex is genetic; those larvæ with the female determinant develop always into females; those with the male determinant which develop as parasites become as a rule males, but after only short parasitism become intersexes; and those developing without parasitism pass through transitory intersexuality into females.

He also examines Baltzer's work from the point of view of developmental physiology and concludes that, before this and the genetical side of the problem can be elucidated, more observations are required.

HOST-PARASITE SPECIFICITY.—Prof. R. W. Hegner (*Science Progress*, Oct. 1926) discusses host-parasite specificity—the association of a particular species of host with a particular species of parasite—with special reference to human protozoa. In many cases a parasitic species appears to be rigidly adjusted to one species of host and unable to live in any other species, *e.g.* the organism of human malaria must often be transferred to horses, cattle, and pigs, but infections do not result. The habits of the host often determine the transmission of human protozoa, *e.g.* insanitary conditions determine largely the spread of intestinal protozoa. The factors within a host which enable natural parasites to bring about an infection but prevent 'foreign' parasites from doing so are briefly considered. Prof. Hegner points out that the conditions within the bodies of anopheline and culicine mosquitoes, and especially of closely allied anophelines, must be very similar, and that therefore the adjustments of the malarial parasites to their insect hosts must be very delicate. The actual factors responsible for the minute differences are unknown but are open to experimental study. In discussing the conditions responsible for differences in susceptibility between young and old, he suggests that some type of resistance develops with age, but the mechanism of this resistance is not known. The termination of an infection with protozoa also probably depends largely on the building up of resistance by the host; failure of the food supply appears to play a minor part. A more extensive account of the biology of host-parasite relationships, with special reference to the protozoa living in man, is given by Prof. Hegner in *Quart. Review of Biol.*, 1, 3, 1926.

PROBLEMS OF VEGETATIVE PROPAGATION.—Dr. R. C. Knight makes an interesting contribution to our knowledge of conditions under which hard-wood cuttings can be successfully propagated as a result of his experiments, mainly with plum stocks, reported in the *Journal of Pomology*, vol. 5, pp. 248-266, October 1926. He concludes that the amount of callus formation is not necessarily indicative of the amount of root production, these two processes bearing no consequential relation to one another. They are not similarly affected by external conditions: thus callus formation is favoured by a high water content in the soil, while root production, on the other hand, may be better with a lower water content, because the lower water content permits more efficient aeration. Treatment of the tissue of the cuttings with various reagents was attempted, but on the whole the results of such treatments were irregular and never so favourable as to give a hint of a method of practical importance.

THE FALL OF FLORAL ORGANS.—Isawo Namikawa has investigated fully the details of the abscission or exfoliation of floral organs, and publishes many details of interest in the *Journal of the College of Agriculture*, Hokkaido Imperial University, 27, pp. 63-131, July 1926. Catkins particularly have formed the subject of study, and in every case a more or less differentiated separation zone is present. Except in the fertilised female cone of Alnus, abscission takes place in all catkins examined. By abscission is understood a separation brought about by living tissue; exfoliation is the term given to the falling of floral organs as the result of drying and death, with separation following mechanical rupture. In Narcissus, Lycoris, Menyanthes, and Ribes, the floral organs are thus exfoliated as the result of ligno-suberisation of a more or less differentiated cell-layer at the base of the floral organ. The female cone of Alnus falls with a part of the vegetative shoot when this is cut off by abscission.

EARTHQUAKES IN FRANCE.—The earthquakes of France, studied in past times by Perrey (1872) and Montessus de Ballore (1892), have lately attracted closer attention. For a valuable summary of recent investigations we are indebted to M. Edmond Rothé, director of the French Seismological Bureau (*Matériaux pour l'étude des calamités*, No. 9, 1926, pp. 3-47). During the seven years 1919–25, the number of earthquakes felt in the whole of France was 79, the yearly average being thus about the same as in Great Britain. Of the six seismic regions which M. Rothé defines, the more prominent are those of the Alpes Maritimes and the valley of the Rhône, and of the Pyrenees, in the former of which were felt the Riviera earthquake of 1887 (of Italian origin) and the Provence earthquake of 1909, an earthquake of special interest, as the ground in the central region seems to have been elevated by about $1\frac{1}{2}$ inches.

OIL AND COAL RESOURCES OF THE OREGON BASIN, WYOMING.—The area covered by this geological survey (the work of D. F. Hewett, *U.S. Geol. Sur. Prof. Paper* 145) lies along the west side of the well-known Big Horn Basin in north-western Wyoming. Stratigraphically, the Carboniferous, Jurassic, Cretaceous, and Tertiary systems are represented; coal deposits, mainly of a lenticular character, occur in the Montana members of the Upper Cretaceous, also in the Fort Union formation of middle Tertiary age; petroleum is mainly derived from the Frontier member of the Upper Cretaceous, and is exploited particularly at the Grass Creek field. Apart from detailed studies of these natural resources, this monograph is of interest for the attention which is given therein to the analysis of the sediments involved. In particular 'bentonite,' a peculiar clay with some unusual properties and of widespread occurrence in the Rocky Mountain region, receives discussion; from mineralogical and mechanical analyses the author concludes that this substance is the alteration product of a volcanic glass, or at least partially derived from some mineral which was crystallised in the glass. It would seem that the alteration ensued soon after explosive phases of vulcanicity had taken place, vapours being condensed and gathering particles into drops, thus producing mud-showers, ultimately forming the clay; the volcanoes responsible for the mother-substance of bentonite were probably situated in the region west of Wyoming, possibly in central Idaho. The mineralogical analyses of other sediments are clearly not exhaustive, most of the 'heavy' mineral constituents being disregarded, except biotite, apatite, and zircon, where these species occur; it is quite certain that further investigation of such accessories would have served the author's purpose still better, "in the hope that . . . additional light on the character, source, and manner of deposition of the sediments" would be forthcoming. This monograph is rich in diagrams, photographs, and maps, but the mass of detail, the absence of any introductory abstract of essential geology and economics, and the omission of any summary make it difficult reading.

SPECTRA OF HEAVY METALS.—Vol. 2, No. 6, of the *Proceedings of the Imperial Academy of Japan* contains preliminary notes of some spectroscopic investigations. The fine structure of several bismuth lines has been examined by Nagaoka and Mishima by means of crossed Lummer-Gehrcke plates, and tables

of wave-length intervals are given. By exciting the spectra of thallium and gold by means of high tension and heavy current (20 kv. and 1 ka.) Nagaoka and Futagami find that new lines are produced in almost coincident positions for the two metals. They give also a considerable list of almost coincident lines for these substances taken from existing measures, and point out that gold and thallium respectively could be produced from mercury if a proton could be expelled from or introduced into the mercury nucleus. The same experimenters record also the spectra of mercury produced by two different types of explosion.

IMPROVED SPECTROGRAPHS AND SPECTROMETERS.—Messrs. Hilger's supplementary catalogue describes a considerable number of improvements to existing forms of instrument and includes also particulars of apparatus of new type. Among the latter is a new range of spectrograph with interchangeable optical systems containing plane or concave grating, or prism (glass or quartz). Each model is made in three sizes, for focal lengths of 100, 150, and 300 cm. respectively. A large aperture glass spectrograph, giving small dispersion, for use with faint sources, should commend itself to many investigators. A special spectroscope is made also for the rapid detection of foreign metals in steel, and is in use in important steel works in Great Britain and America. Visual observation of ultra-violet radiation can be made by an instrument similar in form to the well-known Hilger small quartz spectrograph, but provided with a fluorescent screen above which is fixed a wave-length scale. The instrument is in constant adjustment. Numerous improvements in the constant deviation wave-length spectrometer have been embodied in the "1926 Model." The older form of the instrument ("Standard Model") is, however, still available at a slightly lower price.

ELECTRONIC STRUCTURE OF THE ATOM.—The lecture recently delivered by Prof. A. Sommerfeld at Manchester has been reprinted, under the title of "Electronic Structure of the Atom and the Quantum Theory," from vol. 70 of the *Memoirs and Proceedings of the Manchester Literary and Philosophical Society*. After outlining the main features of the present view of electronic orbits in the atom, Prof. Sommerfeld goes on to consider the relation of atomic structure, as revealed by spectroscopy, to chemistry. He attaches great importance to the work of Main Smith and Stoner in dividing the energy levels characterised by given principal and azimuthal quantum numbers (n_k) into sub-groups distinguished by the value of the inner quantum number, j. Chemical combination is considered to be determined by the tendency of an atom to complete its outermost shell of electrons, and there is considerable evidence that the tendency to complete a sub-group, n_{kj}, is effective in this respect, as well as the tendency to complete a group, n_k. From such considerations, many of the observed chemical combinations which otherwise appear to be inexplicable receive a natural interpretation (see also NATURE, June 5, p. 793).

THE INERTIA OF THE ELECTRIC CARRIER IN COPPER.—In the October number of the *Physical Review*, R. C. Tolman and M. Mott-Smith describe a comprehensive series of experiments designed to study the inertia of the electric carrier in copper. They used an apparatus similar to that used in the experiments of Tolman, Karrer, and Guernsey, in which a copper cylinder was oscillated about its axis, and the current due to the lag of the electrons in the cylinder was detected by means of a coil of many turns of fine wire connected through an amplifier to a tuned vibration galvanometer. In order to determine the phase of the effect, the alternating electromotive force in the coil was balanced against an alternating electromotive force produced in an earth inductor which rotated in synchronism with the oscillation of the cylinder, so that adjustments of the amplitude and phase of the balancing electromotive force were possible. An exhaustive investigation of the effect of the earth's field on the magnitude and phase of the effect was also made. It was found that the actual magnitude of the electromotive force observed was 19 per cent. less than that expected on the simple theory in which the effective mass of the carrier was assumed to be that of an electron in free space. The average phase of the observed electromotive force lagged 10° behind the acceleration, whereas on the simple theory it should be in unison.

OPTICAL PROPERTIES OF SUGARS.—The *Journal of the Washington Academy of Sciences* for October 4 contains a short paper on the optical properties of *l*-arabinose, fructose, *d*-glucose hydrate, α-lactose hydrate, lyxose, *d*-mannose, *d*-melibiose, raffinose, rhamnose monohydrate, *d*-ribose, sucrose, trehalose and *d*-xylose, giving the refractive indices determined by the immersion method in mixtures of mineral oil and monochloronaphthalene, in yellow light. The behaviour in polarised light between crossed nicols is also listed, as well as the appearance of the crystals. The work is due to G. T. Keenan, of the Bureau of Chemistry.

TECHNIQUE IN ENZYME INVESTIGATION.—In *Die Naturwissenschaften* for October 15, appears an interesting résumé by R. Willstätter of the methods and results of the work upon enzymes proceeding under his direction at Munich. Willstätter emphasises the point that though the enzyme system is colloidal it is also a complex organic substance the chemical composition of which is of first importance in understanding its behaviour. Thus, as a catalyst, an enzyme is frequently very specific in its action, and undoubtedly chemical structure must be accountable for such specific action on saccharose as R. Kuhn is reported to have found. Unpublished experiments suggest that there are glucosaccharases and fructosaccharases that can be isolated from fungi which, as their name suggests, attack the biose by linkage on to different constituent hexose molecules. Willstätter discusses the problem of isolation of enzymes and describes methods by which, within one day, invertase preparations can be obtained 300–500 times purer than previously. The invertase content in yeast can be increased 15–20 times by allowing it to ferment at the lowest possible sugar concentration for a day. This result raises a doubt whether conclusions can be drawn from the natural presence of an enzyme as to its significance to the organism. An account is also given of the method of purification by adsorption and regeneration of the enzyme from the adsorbent which has been developed with so much success at Munich. In this connexion, Willstätter points out that the suspended hydrates of alumina are by no means simple inorganic complexes; a whole series of compounds is possible, different in their amount of chemically combined water and in their general properties, including their behaviour as adsorbents. Thus "alumina γ" adsorbs lipase, leaving trypsin and anylase in solution; "β alumina," on the other hand, also adsorbs the trypsin. Many other interesting examples are given and the difficulties are discussed that lie in the way of attempts to estimate enzyme quantities in view of the many factors modifying the kinetics of an enzyme catalysed reaction.
